Dedicated at the feet of
Sreema, the Divine Mother
and
Sri Aurobindo, the Divine Master

All Nature dumbly calls to her alone
To heal with her feet the aching throb of life
And break the seals on the dim soul of man
And kindle her fire in the closed heart of things.
All here shall be one day her sweetness’ home,
    All contraries prepare her harmony;
Towards her our knowledge climbs, our passion gropes;
    In her miraculous rapture we shall dwell,
    Her clasp shall turn to ecstasy our pain.
Our self shall be one self with all through her.
In her confirmed because transformed in her,
    Our life shall find in its fulfilled response
Above, the boundless hushed beatitudes,
Below, the wonder of the embrace divine.

Sri Aurobindo (in ‘SAVITRI’)
Physiology is the key subject in medicine. Starting from the knowledge of body functions, physiology provides the concept of dysfunctions, the basis of understanding the disease processes and the insight into disease management and prevention. Physiology is the core of medical wisdom. Due to its enormous contribution to the growth of medical knowledge, the Nobel Prize in health sector has been designated as Nobel Prize in Physiology and Medicine. Physiology as a subject in medical science has changed over the years from its nonclinical to preclinical and then to the current proclinical format with the incorporation of Applied and Clinical Physiology as the essential components in its core curriculum. Physiology is the foundation of medical practice. Many clinical investigations related to neurological disorders, autonomic dysfunctions, cardiovascular and respiratory diseases, endocrinal, renal, reproductive and metabolic problems are carried out in the well-equipped laboratories of physiology departments. Further, many research investigations are conducted in physiology laboratories. Sooner, the superspecialty course in Clinical Physiology will be a reality.

In India, Physiology as a subject in medical curriculum has changed immensely over decades. With the introduction of the new Medical Council of India (MCI) guidelines in 1997, the duration of first MBBS course was reduced from its original one-and-half years to one year. With subsequent modifications by MCI, directing physiology to become a more clinically oriented subject, a need aroused in reshaping the subject, integrating it with subjects of paraclinical and clinical medicine and orienting physiology knowledge for application-based learning. Therefore, in the present textbook, we have made all our sincere efforts without diluting the core concepts of physiology that includes regulation and integration of body functions, to amalgamate the knowledge in physiology with other subjects for its application in medicine.

After the publication of our Textbook and Practical Book of Physiology, the students and teachers in Physiology across the globe have been requesting to write a comprehensive book in Physiology that can offer a holistic concept of functions, integration, dysfunctions of body systems, and physiological basis of management and prevention of diseases. With all their wishes and blessings, finally this book has been made available to them. We hope this book will fulfill the aspiration of the readers in acquiring and applying the knowledge of physiology in clinics. Nevertheless, this is a project in evolution, and needs inputs, support and encouragement from our readers for its endless progression.

Gopal Krushna Pal
Pravati Pal
Nivedita Nanda

Oh India, land of light and spiritual knowledge!
Wake up to your true mission in the world,
Show the way to union and harmony.

The Mother (of Sri Aurobindo Ashram, Puducherry, India)
Acknowledgments

Let us work as we pray. For indeed work is the body’s best prayer to the Divine.

The Mother (of Sri Aurobindo Ashram, Puducherry, India)

With pride and privilege, we acknowledge the contribution of all our past teachers, especially the professors of VSS Medical College, Burla, Odisha for educating us acquire the principle and practice of clinical medicine. We also gratefully acknowledge our past physiology teachers at Jawaharlal Institute of Postgraduate Medical Education and Research (JIPMER), Puducherry, India for having guided us learn the essentials of physiology, and notable among them are Dr DP Thombre, Dr V Srinivasan, and Dr (Late) DB Koner.

We sincerely acknowledge the contribution of Shri Jitendar P Vij, Group Chairman, Jaypee Brothers Medical Publishers Pvt Ltd, New Delhi for personally coming to Puducherry, and motivating and inspiring us to take up this special responsibility of writing such a wonderful book. For preparing the manuscript of the present book, we are especially thankful to Ms Chetna Malhotra Vohra (Associate Director - Content Strategy) and Ms Angima Shree (Senior Development Editor) for their constant support and timely help. The contribution of Ms Angima Shree is immense and praiseworthy. We also thank the other editors and designers of the Jaypee group who helped in the preparation of this book. We acknowledge Mr Narendra Singh Shekhawat (Delhi, India), Mr Venugopal (Bengaluru, Karnataka, India), and Mr Muralidharan (Puducherry, India) of the Jaypee group for their support. We are also thankful to Jaypee Brothers Medical Publishers for providing us many of the pictures and materials of their medical publications.

We are thankful to all our colleagues and students across the globe for reading our book and providing us their inputs for its further improvement. We thank all our colleagues and residents of JIPMER for their constant inspiration and support.

Auroprajna and Auroprakash, the divine children gifted to us, have been the constant support to us in all our endeavors. We shall fail in our duty if we do not appreciate the contribution of our sister Sabita Nanda, who has been constantly taking care of all our family requirements. We always keep in high esteem our parents Dr (Late) Artatran Nanda, Smt Anupama Nanda, Sri Mrutyunjay Pal and Srimati Malatimani Pal for showering on us their love and blessings and providing us everything to come to the greater heights in our life. We take this opportunity to express our heartfelt obeisance to Ms Kumud Ben of Sri Aurobindo Ashram, who is no more physically on this earth but lives in our hearts forever.
**Special Features of the Book/How to use it Best**

All sincere prayers are granted, every call is answered. With my Blessings.

The Mother (of Sri Aurobindo Ashram, Puducherry, India)

This *Comprehensive Textbook of Medical Physiology* has the following special features. These tips are meant for the readers to best use the book.

**Learning Objectives:** The topics start with ‘Learning Objectives’. By reading the learning objectives, a student will know the gross content of the topic, and how much he should acquire from it after reading the topic. The objectives have been divided into ‘Must Know’ criteria that a student should minimum acquire, and ‘May Know’ criteria that a student is desirable to acquire. These ‘Must Know’ and ‘May Know’ criteria will help a teacher prepare the content of his lecture class and to focus more on the major criteria.

**Scientists Contributed:** Invariably, important topics start with the contributions of great scientists in the concerned field, especially those who have received the Nobel Prize and/or are popular for their contributions in that field. Often, examiners ask to name the scientists who have invented/discovered the concepts or profoundly contributed to the development of the subject. This will not only give the information of the history of medicine, but will also inspire students and teachers to take up research in physiology and medicine. This part the readers should not miss!

**Application Box:** The concepts of Physiology have lot of applications in daily life and medical practice. Therefore, a major component of physiology is ‘Applied Physiology’. These important concepts and applied aspects of the topic are depicted in the ‘Application Box’ and highlighted by green-colored boxes. If a student will miss to read these boxes, he/she will miss the core concepts in physiology.

**Clinical Physiology:** Presently, the learning in physiology is oriented to understand the etiology of the disease, and the physiological basis of management. Therefore, the major part of physiology is devoted for ‘Clinical Physiology’. The Clinical Physiology has been depicted in this book in the following formats:

- At the end of each topic, a description has been given for the common dysfunctions and disorders or diseases. A note has been given to explain the pathophysiology of the disease process and the physiological basis of the management. This is primarily to sensitize the 1st MBBS student for learning medicine, and to highlight the importance of physiology in learning medicine.

- Constructed pictures or original photos of the common diseases have been shown at the end of the topics. This is to create interest in the mind of the 1st MBBS student for clinical medicine. It also helps to understand and memorize Clinical Physiology.

- The core concepts related to diseases and patient management have been highlighted in ‘Clinical Box’. This provides the core concepts of understanding clinical medicine. The clinical boxes are highlighted with pink-colored bars.

The Clinical Physiology part is the uniqueness of this book, which is not given in any other textbook in this structured format. A student should never miss to read these clinical components in physiology.

**Important Note:** Some important and useful facts that are not covered in application or clinical boxes, are depicted as ‘Important Note’. These are useful information that may be asked in examinations, especially in viva voce.

**Structured Presentation:** Every chapter is divided into various parts by different headings and subheadings with different fonts and colors. Further, all important and complex mechanisms are structured and presented in a *point-wise description*. This structured presentation will help the student easily grasp the topic and memorize it. Further, this will ensure that a student does not miss any of the relevant points.
Flowcharts: All major concepts are simplified and summarized in ‘Flowcharts’. Not only it helps to memorize and recap the topic, but also, presenting the text along with flowcharts in examination helps the examiner easily assess the knowledge of the student. Usually, presentation with flowcharts in examination is more marks-fetching. The presentation of many flowcharts is a special feature of this book. A student must read and remember these flowcharts.

Schematic Diagrams and Graphs: All the relevant and significant mechanisms, theories and concepts are described in this book with the help of schematic diagrams and graphs. If a student is able to draw a labeled schematic diagram, it is always considered that a student has understood the topic. Especially in an examination, due to shortage of time, if a student draws a good schematic diagram and gives a brief answer with the help of flowcharts, even if he fails to give a descriptive answer, he gets good marks invariably. Therefore, the student should never miss to understand the diagrams and figures.

Tables: All important data, special concepts and lengthy information that a student needs to remember have been presented in structured tabular format. Reading the tables helps to revise and remember these facts quickly.

Histological Pictures: All mechanisms and manifestations of a disorder that require structural knowledge of a tissue or organ to comprehend the concept of the disease have been identified with appropriate histological pictures. For example, when a student sees the blood cells of an anemia in a blood smear, he understands and remembers better. A student must see these histological pictures.

Chapter Summary: All topics end with a ‘Chapter Summary’ that has been divided into two parts:
1. The first part is the ‘Key Concepts’, that depicts the central theme or the major take-home message of the topic. This is not the chapter summary, rather the summary of the main concepts.
2. The second part is the ‘Important to Know (Must Read)’ that provides all the probable long questions and short questions that usually come in theory examinations. Also, the questions that are usually asked in oral (viva) examination, are listed in this section. Students will definitely find it very useful. This will also help teachers to frame questions for the examination. A student should never miss this part.

Thus, this book is a comprehensive textbook that has incorporated all the requirements of a medical student for imparting the knowledge and skill of the subject, for acquiring all the ingredients needed to appear in the examination, and to complete the course with the best results.

# Table of Contents

## Section–4: Autonomic Nervous System

- 30. Functional Organization of Autonomic Nervous System 287
- 31. Sympathetic System 295
- 32. Parasympathetic System 301
- 33. Control of Autonomic Functions and Applied Aspects 306
- 34. Autonomic Function Tests 312
- 35. Heart Rate Variability 317

## Section–5: Gastrointestinal System

### Part A: Introduction to GI System
- 36. Functional Organization of GI System and Principles of GI Regulations 327
- 37. Gastrointestinal Hormones 335

### Part B: GI Secretions
- 38. Principles of GI Secretion and Secretion of Saliva 341
- 39. Gastric Secretion 348
- 40. Pancreatic Secretion 362
- 41. Physiology of Liver, Liver Function Tests and Pathophysiology of Jaundice 370
- 42. Biliary Secretion 378
- 43. Intestinal Secretion 384
- 44. Secretion of Large Intestine 389

### Part C: GI Motility
- 45. Introduction to GI Motility 393
- 46. Chewing and Deglutition 398
- 47. Esophageal Motility 401
- 48. Gastric Motility 404
- 49. Small Intestinal Motility 412
- 50. Motility of Large Intestine 416

### Part D: Digestion and Absorption
- 51. Principles of Digestion and Absorption 421

## Section–6: Endocrine Physiology

- 52. Introduction to Endocrinology 431
- 53. Mechanisms of Hormone Action 441
- 54. Hypothalamus and Hypothalamo-pituitary Axis 453
- 55. Pituitary Gland: The Anterior Pituitary 459
- 56. Posterior Pituitary 475
- 57. Thyroid Gland 481
- 59. Adrenal Cortex 506
- 60. Endocrine Pancreas 527
- 61. Calcium and Phosphate Metabolism and Physiology of Bone 547
- 62. Parathyroid Gland, Calcitonin and Vitamin D 556
- 63. Pineal Gland 566
- 64. Local Hormones 569
# Section 7: Reproductive System  

## Part A: General Reproductive Physiology  
65. Sex Differentiation and Development, Puberty and Menopause  
66. Physiology of Puberty and Menopause  

## Part B: Male Reproductive Physiology  
67. Male Reproductive System  

## Part C: Female Reproductive Physiology  
68. Female Reproductive System: Functional Anatomy, Oogenesis and Follicular Development  
69. Menstrual Cycle and Ovulation  
70. Ovarian Hormones and Control of Ovarian Functions  

## Part D: Physiology of Conception, Pregnancy, Lactation and Contraception  
71. Physiology of Copulation  
72. Pregnancy and Parturition  
73. Physiology of Breast Development and Lactation  
74. Physiology of Contraception  

# Section 8: Renal System  

## Section 8: Renal System  
75. General Introduction and Functional Anatomy of Kidney  
76. Renal Blood Flow  
77. Glomerular Filtration  
78. Tubular Functions  
79. Mechanisms of Urine Concentration and Dilution  
80. Water Excretion, Diuresis, and Diuretics  
81. Acidification of Urine  
82. Kidney Function Tests and Pathophysiology of Renal Failure  
83. Physiology of Micturition and Bladder Dysfunctions  

# Volume 2  

# Section 9: Cardiovascular System  

## Part A: General Introduction  
84. Functional Organization of Cardiovascular System  

## Part B: Heart  
85. Functional Anatomy of Heart, Cardiac Muscle, Conducting System, and Cardiac Innervation  
86. Properties of Cardiac Muscle  
87. Electrophysiology of the Heart  
88. Electrocardiogram  
89. Cardiac Cycle  
90. Cardiac Output  
91. Heart Rate and Arterial Pulse  

## Part C: Circulation  
92. Principles of Hemodynamics  
93. Arterial System
### Part C: The Motor System

125. Introduction to and Organization of Motor System  
126. Segmental Organization of Motor System  
127. Muscle Spindle and Golgi Tendon Organ  
128. Spinal Reflexes  
129. Descending Pathways  
130. Regulation of Posture and Movement

General Physiology

1. Defining the Role of Physiology in Modern Medicine
2. Functional Organization of Human Body
3. Principles of Homeostasis
4. Cellular Organization and Intercellular Connections
5. Physiology of Genetics and Apoptosis
6. Transport Across the Cell Membrane
7. Membrane Potential
8. Body Fluids
“All the world possibilities in man
Are waiting as the tree waits in its seed:
His past lives in him; it drives his future’s pace;
His present’s acts fashion his coming fate.
The unborn gods hide in his house of Life.”

Sri Aurobindo (in ‘SAVITRI’)
Homoeostasis is the state of internal harmony among the body systems. A disease is an expression of functional disharmony of the systems that usually occurs due to prolonged disturbances of any kind. Understanding the nature of disturbance is critical to comprehend the pathophysiology of a disease and the physiological basis of management of the disease. Therefore, to learn any branch of medicine, it is essential to acquire the basic knowledge of systemic physiology related to the specialty. The concept in physiology helps understand, diagnose and treat the disease. For example, for management of a case of acute myocardial infarction (AMI), the physician should know the physiology of coronary blood flow, electrophysiology of cardiac myocytes, homeostasis of myocardial perfusion, principle of regulation of coronary circulation, and the factors that disturb coronary hemodynamics to produce myocardial ischemia. All these physiology concepts help the physician to understand the mechanism of genesis and spread of pain of AMI, to appreciate the nature of radiation of myocardial ischemic pain to left upper arm, to interpret ECG abnormalities to diagnose AMI, and to prescribe appropriate drugs that improve coronary blood flow, re-establish myocardial perfusion and prevent progression of infarction. For many diseases, knowledge in physiology facilitates proper diagnosis and effective treatment. Therefore, the great Physiologist EH Starling had said “Physiology of Today is the Medicine for Tomorrow”.

Physiology is the study of body functions, their mechanisms and regulations in all living organisms. Human physiology is the study of functions of various cells, organs and organ systems of human body. It encompasses the integration and control of organ systems that help in smooth functioning of body systems as a single unit. Medical physiology is the application of knowledge of human physiology in the management of dysfunctions and diseases in human beings.

In essence, human physiology is similar to the physiology of other mammals and vertebrates. However, as human being is the highest creation in the hierarchy of nature’s evolution, the physiological processes that govern human life are more refined and developed. Nevertheless, the intricacies of human mind and vital and their profound influence on body functions have made human physiology more complex. Therefore, treatment of human diseases not only requires knowledge in physiology and medicine, but also the understanding of human behavior.

**Physiology for Learning Medicine**

Physiology provides the essential knowledge to understand the process of homeostasis, which is defined as the constancy of the internal environment of the body. Homeostasis is the state of internal harmony among the body systems. A disease is an expression of functional disharmony of the systems that usually occurs due to prolonged disturbances of any kind. Understanding the nature of disturbance is critical to comprehend the pathophysiology of a disease and the physiological basis of management of the disease. Therefore, to learn any branch of medicine, it is essential to acquire the basic knowledge of systemic physiology related to the specialty. The concept in physiology helps understand, diagnose and treat the disease. For example, for management of a case of acute myocardial infarction (AMI), the physician should know the physiology of coronary blood flow, electrophysiology of cardiac myocytes, homeostasis of myocardial perfusion, principle of regulation of coronary circulation, and the factors that disturb coronary hemodynamics to produce myocardial ischemia. All these physiology concepts help the physician to understand the mechanism of genesis and spread of pain of AMI, to appreciate the nature of radiation of myocardial ischemic pain to left upper arm, to interpret ECG abnormalities to diagnose AMI, and to prescribe appropriate drugs that improve coronary blood flow, re-establish myocardial perfusion and prevent progression of infarction. For many diseases, knowledge in physiology facilitates proper diagnosis and effective treatment. Therefore, the great Physiologist EH Starling had said “Physiology of Today is the Medicine for Tomorrow”.

**Learning Objectives**

On completion of study of this chapter, the student **must** be able to:
1. Understand the importance of physiology in learning various aspects and branches of medicine.
2. Appreciate the role of physiology in understanding the principles of medical practice.
3. Realize the value of physiology knowledge for conducting medical research.

The student **may** also be able to:
1. Learn the role of physiology in health promotion and disease prevention.
2. Comprehend that physiology knowledge facilitates integral progress of human being.
For Learning Medical Subjects

A medical student with ample knowledge in physiology can easily learn pharmacology and pathology. In principle, pharmacology is extension of physiology. For example, while learning pharmacotherapy for bronchial asthma, the student learns the use of catecholaminergic agents, especially β-receptor agonists that cause bronchodilation and provide immediate relief. It is easy for the student to understand pharmacotherapeutics of asthma as he has studied in physiology that sympathetic stimulation causes relaxation of bronchial smooth muscle by releasing norepinephrine, acting through β-receptors. Similarly, action of all of drugs has physiological basis; and therefore, a fundamental knowledge in physiology is essential for learning pharmacology.

Physiology is useful in learning pathology. For example, in physiology the student learns neutrophil as the first line of defence against acute infections and monocyte as the defence for chronic infections. Therefore, in histology slide when he finds abundant neutrophils in the microscopic field, he comprehends the infection or inflammation is of acute nature, and presence of abundant monocytes or macrophages makes him realize the infection or inflammation is of chronic nature. Similarly, understanding pathological basis of diseases requires the basic knowledge in physiology. In fact, all the diseases have a pathophysiological basis.

Likewise, the student utilizes his knowledge in physiology for learning all branches of medicine. Etiopathogenesis, clinical manifestation, diagnosis and management of all diseases have the physiological basis. Without basic concepts in physiology, a student will not be able to understand the principle of medicine. Hence, all the chapters in medicine textbooks start with an introduction to relevant clinical physiology.

In surgery textbooks, there are portions for surgical physiology. In all branches of medicine, such as gynecology, ophthalmology, otorhinolaryngology, pediatric medicine, endocrinology, oncology, gastroenterology, pulmonology, neurology, cardiology and so on, a considerable portion is devoted to clinical physiology of the topic that helps reader comprehend the physiological basis of the management.

The knowledge in physiology guides a physician to understand the principles of medical practice and the rationality of disease management. The present-day physician often tends to provide prompt symptomatic relief by prescribing a list of medicines starting from analgesics to antibiotics. This is because the modern man is in a hurry and wants immediate relief from the sufferings. There is no time, interest and knowledge for an assisted-natural remission of the disease. The physician wants to earn his money and reputation of being a good physician by providing a quick relief. But, this type of treatment does not help the person in the long run, as often medicine suppresses immunity. Although, few diseases require prompt and aggressive treatment by modern therapeutics such as antibiotics, many diseases are cured by assisted-natural remission with minimum medicines. For example, for management of hypertension in the early stage, a good physician can advise reduction in salt intake and stress level, practice of mental relaxation, regular physical exercises and adaptation to a healthy diet and lifestyle. Usually, these nonpharmacological practices are known to decrease blood pressure. Therefore, the physician should motivate his patient to practice natural measures, and should not prescribe a list of blood pressure reducing drugs that have known side effects. Medicines should be prescribed only when these natural means fail to show desirable results.

Physiology educates physicians that effective treatment of many diseases requires improvement of immunity of the subject as enhancement of immunity halts the spread of diseases and slowly discards the disease from the body. For, example, fever due to acute inflammation is a natural manifestation of the disease and part of the defense mechanisms of the body. Therefore, instead of immediately prescribing antibiotics, physician can reassure the patient that the body heals itself or at best he can prescribe mild antipyretic-analgesic. Administration of higher antibiotics and analgesics suppresses the immunity of the patient that exposes him to various infections. The doctor should explain to the patient that fever is a natural defence mechanism against infection, as rise in body
temperature kills the organisms. Moreover, prescribing antibiotics in the early part, the course and usual manifestation of the disease is missed, and therefore the diagnosis of the disease is overlooked. Another example, a simple boil (cellulitis), which heals by itself, does not warrant prescription of antibiotics. A doctor should assure the patient about the natural course of the boil and may advise him for warm fomentation on the part that improves blood flow to the region and facilitates the process of healing. Treatment by antibiotic from the beginning may halt the healing process of the boil and in some cases may produce antibioma (tumor due to antibiotics). A doctor should know that frequent use of antibiotics suppresses immune system of the body and predisposes the body to other infections. A physician with ample knowledge in physiology helps patient in facilitating the natural remission and recovery without prescribing higher medicines. Hence, a good physician is a physiologist.

For Disease Prevention and Health Promotion

Pathophysiology elucidates the physiological basis of pathology. A physician with physiology knowledge understands the measures that prevent occurrence of diseases. Presently, India is the epicenter of metabolic disorders and cardiovascular risks. A physician knows that regular physical exercises with a good eating habit retard the process of atherosclerosis and oxidative stress that prevents occurrence of cardiovascular and cerebrovascular accidents, many metabolic diseases, and retards degeneration and decay. A physiologist not only practices healthy lifestyle himself for his personal health but also encourages others to adapt to such a life. This promotes the community health. Therefore, a good physiologist is a physician.

We give emphasis on preventive and promotive aspects of health, which will be more promulgated by physiologists and will be established as preventive and promotive physiology.

Physiology is the core subject of medical research. The inventions and discoveries in medical science and advances in medicine are mainly due to research contributions from physiology. Therefore, from its inception in 1901, the Nobel Prize in the field of medical sciences has been designated as ‘Nobel Prize in Physiology’ or ‘Physiology and Medicine’. Many Nobel Prize winners in medicine starting from Emil Adolph Von Behring (1901), Sir Ronal Ross (1902), Prof. Finsen NR (1903), Prof. Ivan Petrovich Pavlov (1904) to Dr. Robert G. Edward (2010), John O’Keefe (2014) are physiologists or physicians who have worked in medical physiology or medical fields linked to physiology. Etiopathogenesis of the diseases and physiological basis of management are elucidated through research discoveries in physiology.

**Physiology for Medical Research**

Research in basic and clinical physiology has contributed to enormous growth of clinical medicine. Basic research reveals the mechanism and pathophysiology of diseases, whereas clinical research unravels the management and prevention of diseases. Usually clinicians will not have enough interest and time for research. The collaborative research between physiology and clinical departments creates avenues for clinical research, ignites research interest in clinicians, improves research outlook, attracts extramural financial support from various funding agencies and yields more productive results. The ultimate objective of a medical research should be to reduce suffering, facilitate healing, cure the ailment, prevent the occurrence of disease and promote health. Physiologists
should make efforts for larger participation of physician in research and ensure research to be more applied and clinical.

**PHYSIOLOGY FOR INTEGRAL PROGRESS**

**Physiology for Ethics**

Physiology teaches the ethics and values of life. Appropriate judgment and application of knowledge for healing the human suffering is true physiology. Ethics of medical practice was devised by Hippocrates, an ancient Greek physician. Hippocrates was a teacher at the School in the Health Temple at Cos, Greece. Writings of the group are distinguished by a high ethical tone, keen observation, logical application of existing ideas and cautious judgment. Hippocrates established the popular ethics of medical practice for physicians, which is commonly known as ‘Hippocratic Oath’ that all physicians solemnly pledge at the time of obtaining their degrees to start medical practice [Reference: Jones WHS and Withington ET. The works of Hippocrates. 4 volumes. London, Heinemann: 1923].

**Physiology for Integral Knowledge**

Physiology provides the foundation for medical practice. Understanding physiology is central to obtain and maintain perfect health. Physiology is the key subject in Medicine. Knowledge in physiology is fundamental in understanding all other subjects in medicine. Physiology is the core of medical research. Learning physiology is crucial to the integral progress.

**CHAPTER SUMMARY**

Physiology is the key subject in Medicine. Knowledge in physiology is fundamental in understanding all other subjects in medicine. Physiology provides the foundation for medical practice. Understanding physiology is central to obtain and maintain perfect health. Physiology is the basis for prevention of diseases and promotion of health. Physiology is the core of medical research. Learning physiology is crucial to the integral progress.
CHAPTER 2

Functional Organization of Human Body

LEARNING OBJECTIVES

On completion of study of this chapter, the student WILL be able to:
1. Understand the physiological organization of different systems of the body.
2. Say the general functions of each system.
3. Conceptualize the general integration of body systems.

NATURE OF ORGANIZATION

The organization of human body was studied first time systematically by Leonardo da Vinci, the great artist-philosopher-scientist of all the times.

Scientist contributed

Leonardo da Vinci
(1452–1519)

This picture of Leonardo has a very close resemblance with Sri Aurobindo and once he had commented on him as one of his past incarnation.

Leonardo left extraordinary drawings of physiological interest on body functions, muscle actions, and on heart valves, papillary muscles of ventricle and hydraulic operations in the cardiovascular systems. He had adequate knowledge on functioning of the human body. He had many paintings that are widely acknowledged and appreciated. Among them, commonly known are the paintings of Mona Lisa, The Last Supper and The Great Lady Anatomy. The painting of ‘great lady anatomy’ depicting the internal anatomical structures with details of some of the internal organs in a female (given below), is the first kind of scientific picture on the human anatomy and physiology.

Unicellular vs Multicellular Organisms

Unicellular Organisms

In unicellular organisms such as ameba, the processes that sustain life are carried out by a single cell interacting with the environment around it. Therefore, unicellular organisms have simpler organization:
1. As they are surrounded by fresh water, the O₂ and soluble nutrients enter the cell by simple diffusion, and macromolecules of nutrients are ingested by phagocytosis.
2. Metabolic waste products, including CO\(_2\) diffuse out of the cell into water, and undigested materials are removed by exocytosis.
3. The presence of contractile proteins in the cell enables it to move by pseudopodia away from noxious stimuli or towards food, and facilitates the movements in phagocytosis and exocytosis.
4. Reproduction is achieved by simple cell division, and no meeting of sexes is involved.

**Multicellular Organisms**

In multicellular organisms such as animal and man, the cells are organized into tissues (nerves, muscles, connective tissue, lymphoid tissue, epithelial tissue, blood etc.); and the tissues are organized into larger units known as organs (e.g. kidney, liver etc.). The tissues and organs are further organized into functional systems meant for performing various body functions.

**Major Physiological Systems**

The body systems can be broadly divided into:
1. The **system for supplying nutrition to the body**, which is achieved by the gastrointestinal (GI) system.
2. The **systems to support the body for locomotion and external works**. The movements are performed by the muscles and bones (the musculoskeletal system), and the nerves supplying the skeletal muscles.
3. The **systems for internal communication, integration and regulation**: The communication between the cells and organs and control of organ systems is achieved by the circulating blood, gaseous exchange at tissue level through respiration, the hormones secreted from endocrine glands, and the neurons innervating the tissues.
4. The **systems for reproduction**: Reproduction is accomplished by the reproductive organs.
5. The **systems for excretion**: Though kidney is the major organ of excretion, lower parts of GI tract (colon, rectum, and anal canal) and skin also contribute to excretion of wastes from the body.

Thus, the major body systems are:
- **Musculoskeletal system**: This system enables the body to adopt posture against gravity, and move about in the environment. This is mainly for execution of works.
- **Gastrointestinal system**: The GI system serves to ingest, digest, and absorb nutrients, water and electrolytes, and excrete undigested or unabsorbed waste matter.
- **Respiratory system**: The respiration is responsible for delivering atmospheric oxygen to the blood, and excreting CO\(_2\) produced by the cells of the body.
- **Blood**: The blood serves as transport medium for conveying nutrients and oxygen to all the cells, and for delivering waste products from tissues to the organs that excrete them (the lungs and kidneys). Blood contains cells that take part in body defence mechanisms.
- **Cardiovascular system**: The heart is the central pump that generates pressure for flow of blood in the blood vessels that serve as vehicular system for blood to flow.
- **Urinary system**: The urinary system consisting mainly of kidneys, ureter and urinary bladder excretes waste products such as urea, uric acid and creatinine, and plays a major role in maintaining the constancy of the internal milieu.
- **Endocrine system**: Hormones secreted by various endocrine glands serve mainly regulatory functions. They control metabolism, growth, development and reproductive functions.
- **Reproductive system**: Reproductive organs and genital structures ensure maintenance of progeny and the species.
- **Nervous system**: The nervous system is mainly for coordination, communication and regulation of body functions.

**CHAPTER SUMMARY**

The human body consists of various systems that are organized to perform their respective functions independently and interdependently. The major objectives of this systemic organization are to provide nutrition and energy for carrying out external works, provide support to the body for locomotion, execution and protection from environment, to control body activities, and to reproduce the offspring for continuation of the species.
Chapter 3

Principles of Homeostasis

Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:

1. Define homeostasis.
2. Name the scientist who gave the concept of *milieu intérieur*, and the scientist who coined the term homeostasis.
3. Explain the feedback mechanisms of homeostatic regulation.
4. Give the examples of homeostatic regulations.
5. Understand that dysfunctions are mainly due to failure of homeostatic regulations.

The student **MAY** also be able to:

1. Describe the details of negative and positive feedback mechanisms.
2. Give a note on intracellular homeostasis.

Concept of Homeostasis

Homeostasis is **defined** as the maintenance of constancy of the internal environment of the body. In the nineteenth century, **Claude Bernard**, a French physiologist, was first to introduce the concept of *milieu intérieur*, which means the internal environment of the body. He had the following remarkable observations:

1. The volume and composition of the fluid are maintained constant, independent of the changes in the environment in which the animal lives.
2. He designated the fluid (ECF) in the body as the internal environment, to differentiate it from the external environment of the body.
3. He suggested that the ability to regulate internal environment is the major reason for humans and animals to live a normal life in spite of changes and challenges imposed on them by the external environment.
4. He noted the difference between intracellular and extracellular fluid and had proposed that the extracellular fluid is the internal environment of the body.

Extracellular Fluid as the Internal Environment

About 60% of the total body weight is water, which means a man weighing 70 kg has a total water content of about 42 liters, of which 28 liters is present inside the cells and 14 liters is present outside the cell. The electrolyte composition of the extracellular fluid roughly resembles that of seawater, which is rich in sodium and chloride, and poor in potassium. The intracellular fluid contains more potassium and less sodium-chloride.

Scientist contributed

**Claude Bernard**, a student of François Magendie (1783–1855) was a genius and great French physiologist of all time. He was the first scientist to introduce the concept of *milieu intérieur*, preservation of the internal stability despite changes in the external environment. This concept was later utilized to understand the mechanism of 'homeostasis'. He emphasized the concept of integrated interrelation between the parts of a living being. He demonstrated the glycogenic function of the liver, manifold digestive action of pancreatic juice, vasomotor mechanism (sympathetic control) for regulation of blood flow. Many important practical concepts have been derived from his studies on CO poisoning, asphyxia and anesthesia. He was the first to provide satisfactory explanation for the mechanism of action of any drug.

In 1929, an American physiologist **Walter Cannon** coined the term 'homeostasis' (*homoios* means 'like')
Section 1: General Physiology

Flowchart 3.1: Feedback mechanism of homeostatic regulation. Note, failure of feedback control leads to the dysfunctions or diseases.

Feedback Mechanisms of Homeostatic Regulations

Homeostatic regulation is mainly achieved through the feedback mechanisms that operate to safeguard a set point already set for the physiological variable. The stimulus for feedback control is a change in the level of the variable, which is detected by the sensor (the receptors) that activate the feedback system which in turn triggers a response to bring the variable back to the normal range of the set point and restores homeostasis (Flowchart 3.1). There are two types of feedback regulations: The negative feedback and the positive feedback.

Negative Feedback

The negative feedback mechanism is the usual mechanism of homeostatic regulation. When the variable is raised above the set point, the negative feedback mechanism triggers processes that inhibit the formation of the variable (Flowchart 3.2) and when the variable is lowered below the set point, negative feedback system withdraws the inhibition to allow production of the variable. Thus, the negative feedback system provides the physiological basis for homeostatic regulation (detailed description is given below).

Positive Feedback System

In a positive feedback system, increase in the variable triggers processes that further increase the variable. Therefore, this control mechanism does not operate to provide homeostasis. Rather, positive feedback mechanism is a vicious cycle that terminates only when the stimulus applied to trigger is withdrawn or the process itself is self-terminated. Examples of positive feedback regulation are:

1. The parturition reflex initiated by oxytocin: Towards term, when the head of the matured fetus presses on the uterine cervix, the cervical distension sends signal to posterior pituitary to release oxytocin.

Flowchart 3.2: Components of negative feedback regulation system.

HOMEOSTATIC MECHANISMS

Homeostasis is the stability of the internal environment. It is not only the equilibrium of the internal environment as a whole, but also the balance of the composition and components of the environment and the physiological variables that influence the environment. Homeostasis of the composition of internal environment, especially of the body fluids, and various other body parameters that influence the environment, is the minimum requirement for smooth functioning of the body. Abnormal deviation from these homeostatic processes leads to bodily dysfunctions. Therefore, it is fundamental to know how the homeostasis of different physiological variables is achieved and how the abnormalities in these homeostatic regulations lead to various dysfunctions.
increases the excitability of myometrium and causes uterine contraction. Contraction of uterus further pushes the fetus onto the cervix, and cervical distension further increases oxytocin release that promotes uterine contraction, and the vicious cycle continues till the baby is delivered.

2. **LH surge**: This is increased luteinizing hormone (LH) secretion that leads to ovulation. Normally, estrogen inhibits LH secretion. But, before ovulation, estrogen provides positive feedback to LH secretion, which results in LH surge.

3. **The Hodgkin’s cycle**: Sodium influx that causes upstroke (depolarization) of nerve or muscle action potential (Flowchart 3.3). Opening of few set of sodium channel provides positive feedback for opening of other sodium channels that results in massive sodium influx causing depolarization.

4. **Activation of digestive enzymes**: The activation of digestive enzymes pepsinogen and trypsinogen by pepsin and trypsin respectively.

5. **Enzyme cascade hypothesis of coagulation**: Activation of one clotting factor, which acts as an enzyme to activate the next clotting factor in the coagulation cascade.

**Negative Feedback System**

Negative feedback control system requires a sensor that detects the change in variable, a control center that receives input from the sensor and initiates command signal, and an effector that brings in responses according to the command signal directed from the control center (see Flowchart 3.2). Physiological variables sometimes require more than one homeostatic mechanism for their regulation. For example, control of arterial pressure involves pressure monitoring system, volume monitoring system, hormonal mechanisms, reflex regulation, autonomic control, etc.

The **sensor**: The sensor contains receptors that monitor the change of the variable and provide sensory signals to the control center of the changes detected. The examples are carotid sinus and aortic arch that contain baroreceptors in their wall and detect change in pressure in their lumen. They send signals to the control centers located in the medullary cardiovascular centers.

The **control center**: Usually, control centers are located in the central nervous system, especially in the brain. For example, centers for blood pressure regulation are located in medulla and the hypothalamus.

The **effector**: The effector is the target organ that carries out the command of the control center to achieve an effective response. For example, blood vessels and heart are the effector organs for blood pressure regulation. Depending on the rate of sympathetic and vagal discharges, the effector organs change their activities to achieve the target effect. When the deviation is the increase in the variable above the set point, the effector will be inhibited and inhibition continues until the variable is reduced to the normal set point. Reverse process is initiated when the variable is reduced below the set point (Application Box 3.1).

**Application Box 3.1**

**Priorities in homeostatic controls**: Life-saving regulatory mechanisms normally take precedence over those that are activated routinely. For example, regulation of body temperature on exposure to extreme weather gets priority over the control of water content of the body in natural conditions. Similarly, activation of withdrawal reflex in response to a noxious stimulus, which protects the body from injury, takes precedence over other somatic reflex and visceral reflexes.

**Kidney Plays a Vital Role**

The kidneys are important organ for the homeostasis of many physiological variables such as regulation of blood volume and blood pressure, pH balance, electrolyte composition of body fluids, and osmolarity of fluid compartments.

**Examples of Homeostatic Regulations**

Important examples of homeostatic regulations are control of pH, osmolarity, and water and electrolyte composition of the body fluids, regulation of solutes in the blood like blood sugar, balance of body weight, etc. Another example is the myotatic or stretch reflex that seeks to maintain muscle length. Details of few examples are given below:

Body temperature regulation: The temperature of the body is maintained within a narrow range of 96°F to 98.4°F. Increased temperature above normal is called as fever and below is called as hypothermia. When temperature is above normal, the body activates controlling mechanisms to increase heat loss through cutaneous vasodilation.
and sweating. When hypothermia develops, the body responds by decreasing heat loss through vasoconstriction and by increasing heat production through shivering.

**Blood pressure regulation:** The normal systolic pressure in adult is kept constant between 100 and 140 mm Hg and diastolic pressure between 60 and 85 mm Hg. Sustained rise in pressure is called hypertension, and fall in pressure is called hypotension that initiates many neural and humoral mechanisms to restore blood pressure (for details refer “Regulation of blood pressure”).

**Regulation of hormone secretion:** Secretion of many hormones such as thyroxine, cortisol, etc. is regulated mainly by negative feedback mechanisms. Increase in hormone concentration in plasma inhibits their production and decrease in concentration facilitates their production mainly by altering the secretion of their regulating trophic hormones. This forms the basis of diagnosis of these hormonal disorders.

---

**CHAPTER SUMMARY**

Homeostasis is **defined** as the maintenance of the constancy of the internal environment of the body. Homeostatic regulation is achieved by two feedback mechanisms: The negative feedback and the positive feedback.

**Negative Feedback**

The negative feedback mechanism is the general mechanism of regulations in which if the variable is raised above the set point, the feedback mechanism triggers processes that inhibit the formation of the variable and if the variable is lowered below the set point, the feedback system withdraws the inhibition to allow production of the variable. Regulation of hormone secretion is the common examples.

**Positive Feedback**

In a positive feedback system, increase in the variable triggers the processes that further increase the variable. This process triggers a vicious cycle that terminates only when the stimulus applied to trigger is withdrawn or the process itself is self-terminated. Important examples of positive feedback regulation are parturition reflex initiated by oxytocin, LH surge during ovulation, The Hodgkin's cycle of sodium influx during depolarization of action potential, and enzyme activation in coagulation cascade.

**Important to Know (Must Read)**

1. Usually no Long Questions are asked from this chapter.
2. Homeostasis, Feedback mechanisms, Negative feedback system, may be the Short Questions.
3. In Viva, examiner may ask… Define homeostasis, Give examples of homeostasis, and What are the feedback mechanisms and give their examples.

---

**INTRACELLULAR HOMEOSTASIS**

Though, traditionally homeostasis (constancy of internal environment) refers to the stability of extracellular fluid volume and composition, it is also applicable to intracellular fluid and intracellular conditions. Rather, the primary objective of homeostasis is to maintain intracellular homeostasis that promotes cell or tissue (organ) functions. Homeostasis is greatly affected by intracellular activities. For example, pH homeostasis, temperature homeostasis, Na⁺ homeostasis, K⁺ homeostasis, etc. depend mainly on intracellular enzyme activities and cell metabolism. Similarly, intracellular milieu is largely influenced by changes in the ECF volume and composition. Hence, homeostasis is mostly achieved by the coordinated and balanced interaction between intracellular and extracellular environments of the body.
CHAPTER 4

Cellular Organization and Intercellular Connections

Learning Objectives

On completion of study of this chapter, the student MUST be able to:

1. Give the structure and list the functions of cell membrane, organelles and nucleus.
2. Name various cytoskeletons and molecular motors of cell and give their functions.
3. Classify intercellular junctions and give their functions.
4. Describe the importance of gap junction in health and disease.
5. Classify cell adhesion molecules and give their functions.

The student MAY also be able to:

1. Give the details of composition of cell membrane and function of each constituent.
2. Describe the details of the structure, functions and dysfunctions of each organelle of the cell.
3. Explain the detailed structure, functions and dysfunctions of microfilaments, cellular motors and cell adhesion molecules.
4. Give the structure, functions and dysfunctions of intercellular junctions.

Cellular Organization

The cell is the structural and functional unit of tissues. A cell consists of three fundamental structures: cell membrane, cytoplasm and nucleus (Fig. 4.1).

1. The cell membrane or the plasma membrane is the boundary in all animal cells that surrounds the cytoplasm, the fluid medium containing a variety of organelles.

2. In cytoplasm, organelles are bound by membranes similar to the structure of cell membrane. The organelles usually present in animal cells are mitochondria, ribosome, peroxisome, lysosomes, centrioles, endoplasmic reticulum and Golgi apparatus. Cytoplasm also contains filamentous cytoskeletal structures such as microfilaments, intermediate filaments and microtubules.

3. The nucleus is present at the center of the cell. In addition, there are many other proteins in the cells like actin and myosin that provide strength and mobility to the cell and also the mechanisms for adhesion to other cells.

Structure of Cell Membrane

The cell membrane is basically a double layer of lipid molecules having thickness of 7–10 nm, into which are inserted...
or attached various protein molecules (Fig. 4.2). Lipids constitute about 45% of the dry weight of the membrane and protein constitutes about 50% and carbohydrate constitutes 5%.

**Fluid-Mosaic Model of the Membrane**

Though, many models for cell membrane have been described in the past, the widely accepted one is *Fluid-Mosaic Model* described by Singer and Nicolson in 1972.

**Special features** of this model are:

2. The model is called fluid mosaic model as the membrane lipids are present in the fluid form that allows the flexibility of the membrane without disturbing the structural integrity.
3. The membrane proteins are loosely attached and float in the fluid phospholipid bilayer. Rapid and random redistribution of integral proteins occurs in the membrane.
4. Also, phospholipids undergo rapid redistribution in the plane of the membrane.
5. This type of diffusion within the plane of the membrane is called **translational diffusion**. This occurs rapidly for phospholipids, which can move several micrometers per second.
6. The fluidity of the membrane is mainly dependent on the lipid composition of the membrane.

**Effect of temperature**: In a lipid bilayer, the hydrophobic chains of fatty acids are highly aligned or arranged orderly to provide a rather stiff structure. When temperature increases, the hydrophobic side chains undergo a transition from its ordered gel or crystalline state to a more disordered liquid state. The temperature at which this disorder or melting occurs is called **transition temperature** (Tm). When the fatty acid chains are longer and more saturated, they interact more strongly with each other and cause higher values of Tm. As a result, higher temperature is required to increase the fluidity of the lipid bilayer having long chain and saturated fatty acids. Thus, **degree of unsaturation** determines the fluidity of the membrane.

**Lipid Bilayer**

The major lipids in the cell membrane are phospholipids, glycolipids and cholesterol.

1. The **phospholipids** are phosphatidylcholine, sphingomyelin, phosphatidyserine and phosphatidyl ethanolamine.
2. **Glycolipids** are generally found in the outer layer.

Lipids are **amphipathic** ("amphi" means both) molecules as their head or polar region is hydrophilic and tail or nonpolar region is hydrophobic (Fig. 4.3). The globular or the head end contains phosphate or hydroxyl moieties that are positively charged and soluble in water. The tail end contains two chains of fatty acids that are insoluble in water. The arrangement is such that the hydrophobic tail ends are directed toward the center and the hydrophilic head is located to periphery of the membrane (as depicted in Figure 4.2). Thus, hydrophilic head of lipid molecules faces the aqueous phase from both inside and outside the cell. A similar bilayer arrangement is found in bile salts where they form spherical micelles.

3. **Cholesterol** is incorporated into the hydrophobic regions of the membrane, and serves to reinforce the lipid permeability barrier.

**Application Box 4.1**

**Determinant of the fluidity of membrane**: The fluidity of a membrane depends on the composition of lipids and the degree of unsaturation. The major determinant is its **cholesterol-phospholipid ratio**. In eukaryotes, the ratio is about 1:1. Higher cholesterol content reduces the fluidity of the membrane.
Chapter 4: Cellular Organization and Intercellular Connections

The individual phospholipid molecules can move freely within the specific layer (but not from one layer to another). Hence, the cell membrane is said to be fluid in nature (Application Box 4.1).

**Functions of the Lipid Bilayer**

The main function of the lipid bilayer of a cell membrane is to create a permeability barrier between the interstitial fluid and the cytoplasm. The permeability of a substance depends on whether it is lipid-soluble or water-soluble. Lipid soluble substances like oxygen and alcohol can pass easily through the cell membrane, whereas water soluble substances like urea and glucose cannot pass easily. Thus, lipid bilayer makes the membrane semipermeable.

**Membrane Proteins**

The protein content of biological membrane depends on the function of the membrane. For example, in the Schwann cell, the cell membrane is concerned with insulating the nerve axon, which is mainly the function of lipids. Therefore, protein constitutes less than 25 percent of the membrane. In membrane of mitochondria, which is involved in cell metabolism, 75 percent of the membrane is protein. However, average protein content of membrane is 50–60% of the membrane mass.

Membrane proteins are of two types: Integral proteins and peripheral proteins (Fig. 4.4).

**Integral Proteins**

Some membrane proteins that span the entire thickness of the membrane are known as integral proteins. They are also called transmembrane proteins. Some integral proteins penetrate only a portion of the membrane (Fig. 4.4), so that they are exposed either to the external environment of the cell (interstitial fluid) or to the cytoplasmic surface of the membrane (intracellular fluid). Some membrane proteins also move laterally within the membrane (e.g. membrane receptors can move to sites of endocytosis).

The **functions of integral membrane proteins** are as follows:

1. **Serve as channel proteins**: Channels or pores are integral proteins through which water-soluble substances can diffuse across the cell membrane.
2. **Act as carriers**: Carrier proteins transport substances across the cell membrane by facilitated diffusion; for example, transport of glucose through glucose transporter.
3. **Serve as ion pumps**: Membrane proteins serve as pumps for active transport of ions across the membrane; for example, Na⁺–K⁺ ATPase that pumps K⁺ into the cell and Na⁺ out of the cell against their concentration gradient.
4. **Serve as receptor and enzyme proteins**: Integral proteins that are present toward the outer half of the membrane usually serve as receptors and usually those on the inner half serve as enzymes. Membrane G proteins belong to this category of proteins.
5. **Antigenic functions**: Complex membrane proteins such as glycoproteins act as antigens on the surface of the cell; for example, blood group antigens in the membrane of red cells.

**Peripheral Proteins**

Some protein molecules are inserted lightly in the outer or inner border of the membrane or are just bound to the surface of the membrane. Such proteins are called peripheral proteins.

They are of two types: Intrinsic and extrinsic proteins. **Intrinsic proteins**: They are present on the inner surface of the membrane. They usually serve as enzymes or anchor proteins for cytoskeleton and other microfilaments that maintain cell shape.

**Extrinsic proteins**: They are present on the outer surface of the membrane. They serve as cell adhesion molecules for anchoring cells with basal lamina and with neighboring cells. They can be removed without disrupting the membrane.

**Membrane Carbohydrates**

The external surface of the cell membrane is loosely covered by a carbohydrate layer known as the cell coat or glyocalyx. These carbohydrates are usually oligosaccharides that are covalently linked to membrane proteins forming glycoproteins or lipids forming glycolipids. Some are also polysaccharide chains of proteoglycans, the integral membrane protein. Thus, the outer surface of the lipid bilayer is covered by a layer of glycoproteins and glycolipids.

**Functions of the Glyocalyx**

1. Glyocalyx serves as a protective coat. Carbohydrate is negatively charged and therefore prevents negative particles like protein molecules to interact between cells.
Section 1: General Physiology

2. Some of the transmembrane glycoproteins like selectins recognize and bind with specific oligosaccharides on other cell membranes, and therefore, permit temporary cell-to-cell adhesion. Such temporary adhesion occurs between neutrophils and endothelial cells at the site of inflammation. Stronger adhesion between cells is formed by integral membrane proteins such as integrins.

3. Some carbohydrate molecules serve as receptors.

Functions of Cell Membrane

1. Cell membrane maintains a constant and distinctive intracellular environment, which is essential for functioning of the organelles. For example, the intracellular fluid has lower concentration of sodium and chloride, low pH, but higher concentration of potassium, organic phosphates and magnesium.

2. Cell membrane maintains cell volume by actively transferring ions across it, especially by pumping sodium ions out of the cell.

3. In neurons and muscle cells, it maintains a potential difference between intracellular and extracellular surfaces, which enables cells to respond to various stimuli.

4. Cell membrane helps in recognizing foreign cells or antigens so that they can be destroyed by phagocytes.

Special Features of RBC Membrane

The red cell membrane is most extensively studied membrane. In addition to the general features of membrane described above, red cell membrane contains some special proteins such as integral and peripheral proteins.

Integral Proteins

Two special types of integral proteins are found in red cell membrane (Fig. 4.5). These are glycophorins and band-3 proteins.

Glycophorins: Glycophorins are glycoproteins that contain 60% carbohydrate and 40% protein. The carbohydrate component is oligosaccharide and the polypeptide component contains 131 amino acids. Oligosaccharides of glycophorins serve as antigen for MN blood group.

Band-3 proteins: Band-3 protein is a dimeric protein with molecular weight 93,000 that traverses membrane about 12 times. It acts as “pore” or transport protein that exchanges bicarbonate ions in the capillaries of lungs.

Peripheral Proteins

The inner surface of red cell membrane contains two special proteins that are linked to the cytoskeleton and are essential for stabilization of membrane and biconcave shape of the cell. These are spectrin and ankyrin.

Spectrin: Spectrin is a fibrous protein that contains an α-chain with molecular weight of 240,000 and a β-chain with molecular weight of 220,000. Along with ankyrin it is attached to cytoskeletal protein that maintains membrane integrity and cell shape.

Ankyrin: The cytoskeletal proteins are attached to spectrin through ankyrin. Ankyrin has molecular weight of 200,000. It has two domains: one bind with spectrin and other with N-terminal region of band-3 protein that extends into cytoskeleton (Application Box 4.2).

Application Box 4.2

Diseases due to membrane protein defects: Disorders of red cells such as hereditary spherocytosis and elliptocytosis occur due to defects in the membrane proteins (for details, refer “Red Blood Cell”).

Cell Organelles

The usually occurring organelles in animal cells are mitochondria, endoplasmic reticulum, Golgi apparatus, ribosome, peroxisome, lysosome and centriole. The red blood cell is the only living cell, which loses nucleus and most of its organelles such as mitochondria, ribosome and lysosome during maturation.

Mitochondria

Mitochondria are the “power house” of the cell. They are cigar-shaped organelles whose shape, size and number vary in different tissues of the body. They are most abundant in cells that have high rate of metabolism, as in liver, cardiac muscle, etc.

Structure

Mitochondria consist of two important components: Membranes and cristae.

Mitochondrial Membranes

Electron microscopy shows that each mitochondrion has two layers of membranes: the outer and inner membranes.

Outer Mitochondrial Membrane: This forms a continuous envelop of the organelle. Outer membrane consists mostly of phospholipids and cholesterol, and contains a specific membrane protein that forms “porin”. Porins are channels that permit substances with molecular weight of less than 10,000 to diffuse freely across the outer membrane.
**Inner Mitochondrial Membrane:** It is rich in proteins, and the ratio of lipid to protein is 0.27 to 1. Hence, it is virtually impermeable to polar and ionic substances. The inner membrane is folded into multiple incomplete septa like structures called **cristae** (Fig. 4.6), which is rich in many enzymes like cytochromes b, C, a and a3, NADH dehydrogenase, succinate dehydrogenase, electron transferring flavoproteins, carnitine-palmitoyl transferase, etc.

**Mitochondrial Matrix**

The region enclosed by the inner membrane is called **matrix**. An amorphous material fills the matrix, which contains enzymes involved in the Kreb’s citric acid cycle and fatty acid oxidation (Table 4.1). Matrix also contains several strands of DNA, ribosomes and enzymes for synthesis of proteins coded in the mitochondrial genome.

**Functions**

The inner membrane contains the cytochromes of the electron transport system and the associated enzymes for oxidative phosphorylation. The TCA cycle takes place in the matrix. The initial breakdown of proteins, carbohydrates and fats occurs in the cytoplasm of the cell, and the final end product that enters the mitochondria as acetyl-CoA combines with oxaloacetate to form citric acid. The end products of the citric acid cycle (Kreb’s cycle) are CO₂, H₂O and ATP.

Like most components of the cell, mitochondria have a short lifespan and are constantly renewed. As they have strands of DNA they are capable of self-replication as well as protein synthesis (Clinical Box 4.1).

**Clinical Box 4.1**

**Mitochondrial diseases:** The disease that affects mitochondrial energy transduction is called **Leuf’t’s disease.** The abnormality of mitochondrial DNA leads to cellular dysfunction called as **mitochondrial cytopathy syndrome,** which manifests with muscle weakness, degenerative lesions of the brain and high levels of lactic acid in blood. Mitochondria are also damaged by free radicals and affected in age-related degenerations.

**Endoplasmic Reticulum**

The endoplasmic reticulum (ER) consists of a network of anastomosing membranous **tubules, vesicles,** and flattened **cisternae.** The membranes of ER are continuous with the outer membrane of nucleus and are also connected with Golgi apparatus (Fig. 4.7). ER is the site of the synthesis of proteins and lipids for the membrane of the cell and organelles, and secretory vesicles of the cytoplasm. They are of two types: rough ER and the smooth ER.

**Rough Endoplasmic Reticulum**

When surface of ER is studded with ribosome, the organelle is called rough ER (RER) or **granular ER** as it gives a “rough” or “granular” appearance to it. In some cells such as red blood cells, the ribosomes lie free in the cytoplasm. RER are present in more number in cells that are actively involved in protein synthesis like acinar cells of pancreas and neurons. In neurons, the **Nissel granules** are modified RER.

**Functions of RER**

1. It is concerned with **protein synthesis.** Therefore, it is abundant in cells of endocrine glands and cells secreting digestive enzymes.
Section 1: General Physiology

2. It also plays some role in the conjugation of carbohydrates with proteins to form glycoproteins, a function which it shares with the Golgi apparatus.

Smooth Endoplasmic Reticulum

When ribosomes are not attached to the surface of ER, the organelle is called smooth ER (SER) or agranular ER as its surface has “smooth” or “agranular” appearance.

Functions of SER

1. It is concerned with the synthesis of lipids. Hence it is abundant in cells that synthesize cholesterol, steroid hormones and phospholipids.
2. In muscles, it is called sarcoplasmic reticulum, which is specialized for the storage of calcium ions that is released during excitation-contraction coupling.
3. SER is part of intracellular transport system as it is continuous with the RER and Golgi apparatus.
4. It is also the site for the detoxification or neutralization of hormones and toxic substances.

Golgi Apparatus

The Golgi apparatus (GA) is also known as Golgi complex or dictyosome. It is present in all cells and generally is located close to the nucleus. It appears as flat discs that are dilated peripherally and stacked together in a bunch as stack of cisternae (Fig. 4.8). Anatomically and functionally it is closely associated with endoplasmic reticulum. Functionally GA two main regions: cis and trans.

The region nearer to the nucleus is the cis face (cis Golgi) and the region close to the membrane is the trans face (trans Golgi) (Fig. 4.7).

Major Functions of GA

1. It is the site for the packaging of secretory products into the secretory granules. Materials produced in rough ER travel through the lumen of smooth ER. Vesicles budding off from smooth ER transport material to cis-face of Golgi complex. Some proteins are phosphorylated here, and then pass to the trans-face, where they are packaged into the secretory vesicles (Fig. 4.7).
2. It is the site for the incorporation of carbohydrates into the newly synthesized proteins to form glycoproteins.
3. Lysosomal enzymes are formed in GA.
4. Transports material to other organelles and cell surface.

Lysosomes

Lysosomes are membrane-bound spherical organelles that contain a variety of hydrolytic enzymes meant for intracytoplasmic digestion. More than 40 different lysosomal enzymes (lysozymes) have been isolated. Some important lysozymes are listed in Table 4.2. Lysosomes are found in almost all animal cells except erythrocytes. They are particularly abundant in cells having high phagocytic activity such as neutrophils and monocytes.

Important Note

Absence of lysosomes: Lysosomes are present in all cells except RBC. They are prominently present in neutrophils.

In granulocytes, the lysosomes appear as cytoplasmic granules. Lysosomal activity of a cell tissue can be determined (Application Box 4.3).

Application Box 4.3

Marker for lysosomal activity: Acid phosphatase is used as a marker for lysosomal activity.

Fig. 4.7: Structure of endoplasmic reticulum (ER). Note that the inner part of ER is in continuity with the nuclear membrane and the outer part interacts with Golgi complex. Rough ER has numerous ribosomes on the membrane, and smooth ER has no ribosome on the surface.

Fig. 4.8: Structure of Golgi complex. Note the structure mainly consisting of stack of cisternae.
During the process of phagocytosis, the **phagosome** that is formed by the cytoplasmic pseudopodia containing foreign body such as bacteria, viruses, etc. fuse with the lysosomes to form **phagolysosome** (Fig. 4.9) and lysosomal enzymes later digest these foreign organism. Therefore, lysosomes are known as **autophagosomes**.

The interior of lysosome is acidic (pH is about 5) compared to its cytosolic exterior (pH of cytoplasm is about 7.2). Acidic interior of this organelle is due to the action of proton pump, the H⁺-ATPase, present on the lysosomal membrane that pumps protons (H⁺) from cytosol into the lysosomal interior against its electrochemical gradient. The lysosomal enzymes are **acid hydrolases** as they function best in acidic pH.

**Types of Lysosomes**

There are three forms of lysosomes: Primary lysosomes, secondary lysosomes (endolysosome) and tertiary lysosomes (phagolysosome) (Flowchart 4.1).

Primary lysosomes: They are formed with hydrolytic enzymes synthesized by rough endoplasmic reticulum and packaged in the Golgi apparatus. They are generally referred to as **storage vacuoles**.

Secondary lysosomes: These are lysosomes fused with endosomes. Hence they are called **endolysosome**.

Tertiary lysosomes: These are **autophagic vacuoles** or **autophagosomes**. They are formed by fusion of phagocytic vacuoles with primary lysosomes. Hence they are called **phagolysosome**.

**Functions of Lysosome**

1. Lysosomes contain many enzymes essential for **intra-cellular digestions**. Absence of these enzymes leads to various storage diseases (Clinical Box 4.2), as listed in Table 4.3.
2. Lysosomes kill and remove infective organisms and foreign bodies.
3. Acrosome, located on the head of spermatozoa is a specialized lysosome that contains many hydrolytic enzymes. Acrosome plays an important role in penetration of ovum by sperm.
4. **Autolysis**: When a cell is damaged or ruptured, the enzymes liberated within the cytoplasm digest the cytoplasmic contents, a process known as **autolysis**. The autolytic enzymes are mainly lysosomal enzymes.
5. Lysosomes remove intracellular products of metabolism from the cell.
Cutaneous angiokeratomas and hypohydrosis.

Mental retardation, coarse facies, CVS involvement.

Unique features

Hepatosplenomegaly, and skeletal dysplasia.

Mental retardation, macrocephaly and hypercusis in infants.

Proliferation of peroxisome is caused by many syntheses. Peroxisomes are small spherical organelles having diameter of about 0.5 µ, and therefore denoted as microbodies. Specialties of peroxisomes:

1. They are formed by budding from or by division of smooth endoplasmic reticulum. They are referred to as subcellular respiratory organelles. But, they do not have energy-coupled electron transport system.

2. They contain oxidases that promote oxidation of lipids (especially β-oxidation of long chain fatty acids) forming acetyl-CoA and hydrogen peroxide (H₂O₂), and catalases that liberate oxygen from H₂O₂. They protect the tissue from oxidative stress (Application Box 4.4)

3. With the help of peroxins, the protein chaperons, various proteins with specific signal sequence are directed to peroxisome. The membrane of peroxisome contains a number of specific proteins that transport substances between peroxisome matrix and cytosol.

4. Peroxisome matrix contains more than 50 enzymes that are involved in many metabolic reactions of lipids (long chain fatty acids, plasmalogens, cholesterol, bile acids) purines, amino acids and H₂O₂. Deficiency of enzymes leads to many diseases (Clinical Box 4.3)

5. Proliferation of peroxisome is caused by many synthetic products that act on receptors in the nuclei of cells, known as peroxisome proliferation activated receptors (PPARs). PPARs are members of nuclear receptor superfamily those on activation bind to DNA and produce changes in mRNA production. PPARs have extensive physiologic effects and affect many tissues and organs.

Lysosomal storage diseases: Congenital absence of lysosomal enzymes leads to accumulation of materials in the lysosome that are degraded by lysosomes, causing lysosomal storage diseases. Especially, elimination of certain substances from the cells of the body, e.g. glycogen, cerebrosides, gangliosides and sphingomyelin mainly depend on the activity of lysosomal enzymes. Therefore, in the absence of active lysosomes, intracellular accumulation of these substances interferes with normal cell function and produces diseases. Accumulation of partly digested cellular material is called inclusion bodies.

Ribosomes

Though ribosomes are usually present on the surface of endoplasmic reticulum, they are also present as free organelles in the cytoplasm. They contain about 85% of RNA of the cell. They are the major site of protein synthesis. RNA is also present in nucleus, mitochondria and cytoplasm, and consequently protein synthesis occurs in these structures too. They may be present singly (monoribosome) or in groups (polyribosomes)

Peroxisomes

Peroxisomes are small spherical organelles having diameter of about 0.5 µ, and therefore denoted as microbodies. Specialties of peroxisomes:

1. They are formed by budding from or by division of smooth endoplasmic reticulum. They are referred to as subcellular respiratory organelles. But, they do not have energy-coupled electron transport system.

2. They contain oxidases that promote oxidation of lipids (especially β-oxidation of long chain fatty acids) forming acetyl-CoA and hydrogen peroxide (H₂O₂), and catalases that liberate oxygen from H₂O₂. They protect the tissue from oxidative stress (Application Box 4.4)

3. With the help of peroxins, the protein chaperons, various proteins with specific signal sequence are directed to peroxisome. The membrane of peroxisome contains a number of specific proteins that transport substances between peroxisome matrix and cytosol.

4. Peroxisome matrix contains more than 50 enzymes that are involved in many metabolic reactions of lipids (long chain fatty acids, plasmalogens, cholesterol, bile acids) purines, amino acids and H₂O₂. Deficiency of enzymes leads to many diseases (Clinical Box 4.3)

5. Proliferation of peroxisome is caused by many synthetic products that act on receptors in the nuclei of cells, known as peroxisome proliferation activated receptors (PPARs). PPARs are members of nuclear receptor superfamily those on activation bind to DNA and produce changes in mRNA production. PPARs have extensive physiologic effects and affect many tissues and organs.

Application Box 4.4

Peroxisomes protect from oxidative stress (OS): H₂O₂, a potent oxidant produced during metabolic reactions is one of the agents for oxidative stress. H₂O₂ is destroyed by catalase, a peroxisomal enzyme, which is designated as an antioxidant for combating OS. Thus, peroxisomes protect cells from the toxic effects H₂O₂. Hence, increased catalase activity is one of the markers of OS.

Clinical Box 4.3

Diseases of peroxisomes: Peroxisomes may be abnormal or absent in inherited disorders

1. Zellweger syndrome, which occurs due to mutations in the gene encoding certain proteins such as peroxins or peroxisomal enzymes. This syndrome is characterized by profound neurologic impairment, accumulation of very-long chain fatty acids, abnormalities in synthesis of bile acids and marked reduction of plasmalogens. The child usually dies within a year in this disorder.

2. Another similar genetic disorder is infantile Refsum disease, which is less severe and only few proteins are affected.

3. Brown-Schilder’s disease (Adenoleukodystrophy) occurs due to insufficient oxidation of very long chain fatty acids by peroxisomes. This is an autosomal recessive disease manifests with progressive degeneration of liver, kidney and brain.

4. Primary hyperoxaluria occurs due to defective peroxisomal metabolism of glycosylate derived from glycine.

Centrosomes

Centrosome is located close to the nucleus in eukaryotic animal cells. It is formed by two centrioles placed at right angle to each other that are present within the amorphous pericentriolar material. Centrioles are short cylindrical structures made up of microtubules placed in group of three (triplets) that run longitudinally in the wall of centrioles. There are nine sets of triplets arranged at regular intervals in the wall of each centriole (Fig. 4.10). The subunits of microtubules in centrosome are γ-tubulins. Centrosomes are microtubule-organizing center (MTOCs).

Functions

Centrosomes regulate chromosome movement during cell division. They duplicate themselves and move apart...
from each other to the poles of mitotic spindle to monitor the process of cell division.

**Cytoskeleton**

Cytoskeleton is an intracellular system of fibers that not only maintains the structural integrity of the cell, but also allows appropriate change in cell shape for cell mobility and participation of cell in various physiological activities. It consists of microfilaments, microtubules and intermediate filaments. These cytoskeletal elements are made up of different cell proteins (Table 4.4).

**Microfilaments**

All eukaryotic cells contain microfilaments that contribute to the maintenance of and change in cell shape and regulation of cell functions. These are long solid filaments (Fig. 4.11A) having diameter of about 7 nm. They are made up of actin. Actin is the most common cell protein that accounts for about 15% of total protein in the cells.

Actin in the globular form is called \( G \text{actin} \), which is the unpolymerized actin subunit. \( G \text{actin} \) subunits polymerize to form the filamentous actin, referred to as \( F \text{actin} \). In vivo, actin filaments polymerize and depolymerize. Also, polymerization occurs at one end of actin filament and depolymerization occurs at the other end.

**Special characteristics:**
1. Though microfilaments are well developed in muscle cells, they are present in almost all cells and better organized in cells that secrete granular content by exocytosis. For example, the developed contractile system in platelets consists of microtubules and extensive network of microfilaments.
2. Microfilaments help platelets to change shape and move granules from interior of cytoplasm to canaliculi for release of chemicals (release reaction of platelet).
3. In cells with microvilli on their epithelial surface, microfilaments extend into the microvilli.

**Functions**

1. Microfilaments are the major contractile fibers of the cell that help in change in cell shape and cell movement.
2. As microfilaments exhibit contractile phenomena within the cytoplasm, they help in phagocytosis, transport and secretion of cellular materials, cell contraction, cell discharge, movement of secretory granules, etc.

**Fig. 4.10:** Transverse section across a centriole. Note nine groups of tubules, each group having three microtubules.

**Figs. 4.11A to C:** Structure of microfilaments (A), intermediate filaments (B) and microtubules (C).
3. Filamentous actin helps in movement of chromosome and cell division.
4. Through anchoring proteins, F actin fibers attach to various cytoskeletal structures and interact with membrane bound proteins.
5. Microfilaments project into the microvilli present on the epithelial surface such as on the intestinal mucosa, and extend up to the tip of microvilli. They help in microvilli movement.
6. Microfilaments in the lamellipodia (lamellar extensions from cell that occur at the time of cell crawling) help in cell movement on a surface.
7. Actin filament interacts with integrin receptors to form focal adhesion complexes (FAC). FAC serve as points of traction with the surface over which cell pulls itself.
8. Microfilaments are also used by some molecular motors as tracks.

**Microtubules**

Microtubules are long hollow tubular structures (Fig. 4.11C) having diameter of about 25 nm, including the wall thickness. The inner cavity diameter of microtubules is about 15 nm. They are made up of subunits of globular proteins called tubulins that are arranged in a closely packed helical manner.

Tubulins in microtubules are of two types: α-tubulin and β-tubulin, except the tubulins in centrioles that are γ-tubulins. The α and β-tubulin subunits form heterodimers that aggregate to make tubular structures (protofilaments) of stacked rings. Each ring in microtubule usually contains 13 subunits (13 protofilaments) (Fig. 4.12).

**Special characteristics:**
1. A unique property of tubulin subunits is their property of disaggregating (disassembly) and re-aggregating (assembly). Therefore, microtubules form a dynamic cytoskeletal framework of the cell. Microtubules are polar in nature with assembly predominating end (+ve end) and disassembly predominating end (–ve end). The process of assembly and disassembly may occur simultaneously.
2. Many drugs act by inhibiting microtubule assembly (Clinical Box 4.4)
3. Interaction with GTP facilitates microtubule formation.
4. Microtubule growth is temperature sensitive with cold conditions favoring disassembly.
5. In cells with cilia and flagella, microtubules extend into these structures.
6. Kinesin and dynein are microtubule-based molecular motors.

**Functions**

1. Microtubules serve as cytosolic guide rails for transport of substances within the cytoplasm or transport of secretory granules to the cell membrane. They help in transport of vesicles and organelles from one part of the cell to another.
2. They contribute to the maintenance of cell strength and cell shape.
3. They help in the formation of spindles that move chromosomes during mitotic cell division.
4. They are the pillars for structure and function of cilia.
5. They contribute to cell motility.

**Cilia:** Cilia are hair-like outgrowths of cells of the epithelial membrane that characteristically beat in a synchronous whip-like fashion. Therefore, cilia allow a directional flow. Each cilium is an outgrowth of a basal body situated beneath the cell membrane, which has the property of reproducing itself. In each cilium, there is an axoneme that typically consists of nine doublets of microtubules that run circumferentially from base to the tip while a single pair of microtubules runs centrally (9 + 2 arrangement).

Clinical Box 4.4

Cytotoxic drugs act by inhibiting microtubular functions: Many cytotoxic drugs act by inhibiting the microtubular activity. For example, anticancer chemotherapeutic agents such as vincristine and vinblastine promote disassembly of microtubules. Paclitaxel, another anticancer drug binds with microtubules and stabilize them against depolymerization. The stabilized microtubules function abnormally and do not undergo dynamic changes necessary for cell cycle completion. It prevents formation of mitotic spindles, and cells die. Colchicine inhibits microtubule assembly.
Intermediate Filaments

These are filamentous structures made up of various sub-units (Fig. 4.11B). The average diameter of these filaments varies from 8 to 14 nm.

**Functions:**
1. They connect the nuclear membrane to the cell membrane and also membranes of cell organelles. Therefore, the major function of these filaments is to integrate the organelles within the cytoplasm.
2. They form supple skeletal network for the cell and resist rupture of cell from external pressure. In the absence of microfilaments, cells easily rupture. Blister formation in skin is common in humans when these filaments are absent or abnormal.
3. They are used as cell markers (Clinical Box 4.5)

**Clinical Box 4.5**

*Intermediate filament proteins are cell markers:* Proteins of intermediate filaments are cell specific. Therefore, they are frequently used as cellular markers. For example, cytokeratin is the marker of epithelial cells, whereas vimentin is the marker of fibroblast.

Molecular Motors

Molecular motors help in the movement of various cell parts, proteins and organelles within the cell cytoplasm. They are 100-kDa ATPases. They have two domains: The domain that attaches with cargo (the cell part to be moved) and the other domain attaches with microtubules or actin filaments. The domain attaching with microtubules or actin is the head part that contains ATPase, which causes hydrolysis of ATP to provide energy for movement of molecules. Molecular motors can be broadly divided into two categories: Microtubule-based and actin-based.

**Microtubule-based Molecular Motors**

Microtubule-based molecular motors make movement of molecules along the microtubules. They are mainly kinesin and dynein.

**Kinesin**

The *conventional kinesin* is a double-headed molecule that transports its cargo toward the negative terminal of microtubules. One head attaches with microtubule and the other head with the cargo. Some kinesins move cargo toward the positive terminal of microtubules. Other kinesins are involved in cell divisions such as mitosis and meiosis.

**Dynein**

Dynein is also a double-headed molecule. There are two types of dynein: Cytoplasmic form and axonemal form.

**Cytoplasmic Dynin:** It functions like that of conventional kinesin that moves cargo toward the negative terminals of microtubules.

**Axonemal Dynein:** Cilia and flagella contain dynein-based molecular motors that are axonemal type. Thus, these dynein molecules are responsible for beating cilia and flagella.

Actin-based Molecular Motors

Actin-based molecular motors make movement of molecules along the actin filaments. These are mainly myosin I–V. However, there are 18 types of myosins. In myosin II, the head binds with actin and pulls actin by bending the neck region. In myosin V, the heads of myosin molecules walk on the microfilaments one after another. Myosin molecules perform various functions like muscle contraction, contraction of intestinal villi, cell migration etc.

The Nucleus

**Structure of Nucleus**

All living cells in humans except red blood cells contain nuclei. Platelets are cellular fragments. Most cells are uninucleated and the nucleus is commonly located at the center of the cell as round, intensely stained structure. However, there are variations in the size, shape and location of the nucleus within the cell, especially in different types of leucocytes and muscle cells. Nucleus is bound by a bilayer nuclear membrane that surrounds the nucleoplasm. The nucleus contains nucleoplasm and nucleolus.

**Nuclear Membrane**

The nuclear membrane is a double-layered membrane (Fig. 4.13). The space between the two membranes is called perinuclear cisterns. In some cells, nuclear membrane is in continuity with the membrane of endoplasmic reticulum. There are circular openings in the nuclear membrane known as nuclear pores that serve as passages for the exchange of materials between the cytoplasm and the nucleoplasm, especially for the transport of mRNA and proteins. There are two special transport proteins in the nuclear membrane, known as importins and exportins.

![Fig. 4.13: Structure of nucleus and nuclear envelope.](image-url)
that regulate transport of molecules across nuclear membrane. Another nuclear membrane protein known as Ran, plays organizing role in these transport mechanism.

**Nucleoplasm**

The nucleoplasm is the nuclear matrix, which is a gel-like ground substance that contains genetic material in the form of DNA. When cell is not dividing the genetic material is present in the form of tangled mass called nuclear chromatin and when cell division begins, the tangled mass unwinds and appears as distinct strands known as chromosomes. The nuclear chromatin is made up of coiled strands of DNA, bound to large quantities of basic proteins (histones).

**Nucleolus**

The nucleus contains nucleolus, a patchwork of granules rich in RNA. There may be multiple nucleoli in a nucleus, especially in developing cells. Nucleoli synthesize ribosomes.

**Functions of Nucleus**

Nucleus regulates cell functions. It contains DNA that is responsible for transmission of hereditary features. It also contains RNA that is essential for protein synthesis. Nucleus is the main regulator of cell divisions. Details of the functions of DNA and RNA are discussed in the next chapter “Physiology of Genetics”.

**INTERCELLULAR JUNCTIONS**

In tissues, junctions formed between the cells are called intercellular junctions or intercellular connections. The cells in tissues are usually held together by the extracellular matrix.

1. In connective tissues such as fibroblasts, cartilage and bones, the extracellular matrix is abundant, and therefore the cells are sparsely distributed within the substance of the matrix.

2. In other connective tissues such as muscle, the cells are held together by cell to cell adhesions.

3. In epithelial tissues that line the free surfaces such as skin, and basement membrane of tubular structures and cavities of the body such as alimentary tract, kidney tubules and urinary bladder, the cells are bound tightly together by specialized intercellular junctions (Fig. 4.14).

4. In epithelial and connective tissues, the normal space between cells (intercellular space) is 20–25 nm. In epithelial tissues, the extracellular matrix is reduced to a thin layer known as the basal lamina.

**Types**

Functionally, intercellular connections or junctions are of two types: junctions that tie cells together and Junctions that allow transfer of ions and small molecules (Table 4.5).

**Tight Junctions**

Tight junctions are commonly found in the epithelium of the GI tract, nephrons, urinary tract, hepatobiliary tract, and choroid plexus. They are also called zonula occludens.

**Special features of tight junctions:**

1. Tight junctions are typically located toward the apical region of the cells (Fig. 4.15).

2. At tight junctions, the outer layer of the cell membrane of neighboring cells fuse with each other that obliterate the intercellular space close to their apical margin.

3. They are made up of ridges, half of which is contributed by both neighboring cells and each half is bound tightly to each other. Therefore, they practically form the barrier for transport of solutes and solvents from the lumen into the interstitial space and between cells.

4. They contain ion and water channels that make them selectively leaky, though the degree of leakiness varies in different epithelia.

5. The membrane proteins that contribute to formation of tight junctions belong to three main families: occludin, claudins and junctional adhesion molecules (JAMs).
Chapter 4: Cellular Organization and Intercellular Connections

Fig. 4.15: Schematic representation and locations of specialized junctions connecting the cells.

6. Many other membrane proteins from cytosolic side interact with tight junctions.

**Functions of Tight Junctions**
1. In general, they form selective permeability barrier that prevent transport of macromolecules from the luminal fluid into the interstitial space. Thus, macromolecules pass only through the epithelial cell as vesicles (vesicular transport).
2. Due to the presence of leaky channels, small size water-soluble particles are permitted through tight junctions. However, the degree of permeability varies. For example, in the gut, Na⁺ ions pass fairly freely, while in the urinary bladder, the passage for sodium is almost nil. Furthermore, the permeability of a substance through tight junctions can be increased, depending on the osmolality gradient across the epithelium. This forms the paracellular transport of solutes and solvents.
3. In the brain, tight junctions between endothelial cells of cerebral blood vessels contribute to the effectiveness of blood-brain barrier.
4. In the ciliary bodies, they form blood-aqueous barrier between the cells of inner non-pigmented epithelium.

**Anchoring Junctions**

Anchoring junctions are of two types: Cell to cell anchoring junctions and cell to basal lamina anchoring junctions.

**Cell to Cell Anchoring Junctions**

Cell to cell anchoring junctions are desmosome and zonula adherens.

**Desmosomes**
1. Desmosomes are the junctions characterized by focal thickening of two adjacent cell membranes (Fig. 4.15). The thickened area is the presence of dense layer of proteins on the cytoplasmic surface of the membrane.
2. Thickened area of two sides is separated by a gap of 25 nm.
3. Intermediate filaments from cytosol are attached to the thickened areas.
4. The intercellular space between the two membrane thickenings also contains filamentous cell adhesion materials such as desmogleins and cadherins (Fig. 4.16).

**Zonula Adherens**

Zonula adherens is located below the base of tight junctions (Figs. 4.17A and B). It is the major site of attachment for intracellular microfilaments. Cadherins are present in the intercellular space at this junction.

**Cell to Basal Lamina Anchoring Junctions**

Cell to basal lamina anchoring junctions are hemidesmosome and focal adhesion.

**Hemidesmosomes**

In appearance, they look like half of desmosomes, and therefore are called hemidesmosomes. Microfilaments are attached to it intracellularly. In contrast to presence of cadherins and desmogleins in desmosome, hemidesmosomes contain integrins.

**Focal Adhesions**

Focal adhesions (focal spots) connect cell to the basal lamina. Intracellularly, they are associated with actin filaments. Therefore, they assist in cell movement.
Section 1: General Physiology

Gap Junctions

Structure

Gap junctions are called nexus between the cells at which the intercellular space is narrowed from its 25 nm diameter to 3 nm (Figs. 4.18A and B).

Special Features

1. Gap junctions are made up of special transmembrane proteins known as connexons. The connexons from the membrane of two adjacent cells are lined up with one another (Fig. 4.19A).
2. Each connexon is formed by six identical protein subunits called connexins. Connexin surrounds an aqueous channel and when connexon of adjacent cells are aligned, the aqueous channels of both cell membranes become a continuous one (Fig. 4.19B). This allows substances of adjacent two cells to pass through the channel without passing through the ECF. The diameter of the channel is about 2 nm.
3. As connexons of one cell membrane are aligned with the connexons of the adjacent cell membrane and they connect the cytoplasm of adjacent cells through their aqueous channels, water, ions, amino acids, sugars and hormones can pass from cell to cell through them.
4. As connexons keep the adjacent cell membranes at a fixed gap, the junction is named as “gap junctions”.
5. There are 20 different connexon genes (Clinical Box 4.6).

Functions

1. Electrical synapses: As the pores of gap junction are larger than ligand-gated or voltage-gated channels, passage of substances is easier through them. Gap junctions easily allow ions to pass through and serve as electrical synapses, as they permit rapid propagation of electrical activity from cell to cell. Therefore, tissues with gap junctions between cells behave as physiological syncytium (Application Box 4.5).
2. Gap junctions also permit passage of organic solutes such as sugars and amino acids with molecular weight up to 1000 from cell to cell.
3. Chemical messengers and hormones are also exchanged between cells through gap junctions.

Regulation of Gap Junction Functions

Though transport of ions through gap junctions is not an active process, they do not just act as mere passive conduits. Their activities are regulated by intracellular calcium concentration and cytosolic pH. Increase in any of these parameters can prevent transport through gap junctions by closing their channels.

Application Box 4.5

Functional syncytium: Gap junctions are present abundantly in heart muscle. As they serve as electrical synapses, electrical impulses pass easily from cell to cell in cardiac muscle. Thus, stimulation of one muscle cell in heart results in activation of all muscle cells. This makes the ventricular and atrial muscle as functional syncytium. However, ventricular and atrial muscles are two separate functional syncytia as ventricles and atria are separated by non-conducting septa. Gap junctions are also present in visceral smooth muscles that conduct electrical impulses from cell to cell. Hence, visceral smooth muscles also have syncytial behavior.

Cell Adhesion Molecules

Cells are attached to each other and to the basal lamina by cell adhesion molecules (CAMs) that are present...
abundantly at intercellular connections (Fig. 4.20). By their property of adhesions between the cells, they provide stability to the tissue.

**Systems of Binding**

They have both extracellular and intracellular bindings.

**Extracellular Binding**

Many of CAMs bind to membrane proteins called **laminins**. Laminins are cross-shaped large membrane molecules that have multiple receptor domains on the extracellular matrix. CAMs bind to these extracellular receptor domains.

**Intracellular Binding**

Cell adhesion molecules (CAMs) pass through the cell membrane to expose into the interior of the cell and attach with the cytoskeleton inside the cell. This intracellular binding of CAMs with cytoskeletal structures enhances strength of cell adhesions.

**Nature of Binding**

Cell adhesion molecules (CAMs) exhibit both homophilic and heterophilic bindings.

**Homophilic Bindings**

In homophilic bindings, CAMs attach with similar molecules present on the other cells.

**Heterophilic Bindings**

In heterophilic bindings, CAMs attach with different molecules of other cells.

**Types of CAMs**

Though there are confusions on classifying CAMs, they can be broadly categorized into four varieties: Integrins, IgG superfamily proteins, cadherins and selectins.

- **Integrins**: Integrins are heterodimeric proteins that bind to various receptors.
- **IgG superfamily proteins**: CAMs belonging to IgG superfamily are immunoglobulins.
- **Cadherins**: These are calcium dependent molecules that mediate homophilic binding.
- **Selectins**: They have carbohydrate binding domains, that resemble lectin-like structure.

**Functions of CAMs**

1. They zip cell to cell. Cell adherence is strengthened by CAMs.
2. For their attachment with cytoskeleton, they play role in cell movement.
3. Cellular signals are transmitted out of the cell or extracellular signals are transmitted into the cell via CAMs.
4. They play significant role in inflammation and wound healing.
5. CAMs prevent apoptosis. Loss of cellular contact from extracellular matrix due to defects in CAMs hastens the process of apoptosis.

**CHAPTER SUMMARY**

The cell is the structural and functional unit of tissues. A cell consists of cell membrane, cytoplasm and nucleus.

1. The cell membrane is the lipid bilayer that forms the boundary in all animal cells and is selectively permeable to the substances.
2. Cells are bound to each other by means of intercellular junctions and cell adhesion molecules. In the upper apical part are the tight junctions and in the base are hemidesmosome and focal adhesion. In the middle of the cells are desmosomes and gap junction. There are many other proteins in the cells like actin and myosin that provide strength and mobility to the cell and also the mechanisms for adhesion to other cells.
3. Gap junctions allow ions to pass from cell to cell much faster. Therefore, they are called electrical synapse. Gap junctions provide the physiological basis for syncytial nature of a tissue like, cardiac tissue.

**Important to Know (Must Read)**

1. **Long Questions** are usually not asked from this chapter.
2. **Cell membrane, Mitochondria, Lysosomes, Cytoskeleton, Molecular motors, Gap junctions, CAMs, Intercellular junctions**, may come as **Short Questions**.
3. In **Viva**, examiner may ask... cell membrane, cell organelles, cytoskeletal proteins, molecular motors, intercellular junctions and gap junctions, and cell adhesion molecules.
Section 1: General Physiology

Physiology of Genetics and Apoptosis

CHAPTER 5

PHYSIOLOGY OF GENETICS

Physiology of genomics is a developing branch of medicine. It deals with the understanding of the concept of gene and gene therapy in the treatment of genetic disorders.

Genetics is the science of heredity, dealing with resemblances and differences of related organisms resulting from the interaction of their genes and the environment. Application of knowledge of genetics to understand the heritable basis of the diseases and to improve the management of diseases through gene intervention, is called medical genetics. Mendel’s work in 1886 that hereditary characteristics are transmitted to offspring by separate units laid the foundation of genetics. Later, Johannied, the Danish botanist in 1909 termed these units as genes and, Morgan, the American geneticist established that the hereditary characteristics are transmitted on chromosomes.

Chromosomes

The term chromosome was coined by Waldeyer in 1888. Chromosomes transmit the genetic information from parents to offspring. There are 46 chromosomes in cells of all tissues except gametes that contain 23 chromosomes. Autosomes are present in somatic cells and sex chromosomes in gametes.

Structure of Chromosomes

Each chromosome consists of two chromatids that are connected at the centromeres (or kinetochore). Each chromatid is composed of two chromosomes (Fig. 5.1). Typically, the centromere is not midway between the two ends of chromatids. When chromatid has a short arm and a long arm, the chromosome is called submetacentric. If two arms of the chromatid are of equal length, the chromosome is metacentric, if one arm is too short the chromosome is acrocentric and if centromere lies at one end (each chromatid has only one arm), the chromosome is telocentric (Figs. 5.2A to D). Chromosomes are distinguishable only during mitosis. In the interphase (between successive mitoses), chromosomes elongate and assume the form of a long thread called chromonemata (Application Box 5.1). Though chromosomes are formed mainly by DNA, they also contain RNA, the basic protein histones, complex proteins, organic phosphorous compounds and inorganic salts.
**Application Box 5.1**

**Karyotyping:** Identification of each chromosome and mapping out the chromosomes is called karyotyping. Karyotyping is done for studying the morphology and number of chromosomes. Though karyotyping can be done in any nucleated cell, lymphocytes are preferred. The study is done by arresting the dividing cells in metaphase by colchicine and spreading them on glass slide and staining them with Giemsa stain. In many cases, chromosomal abnormalities can be correlated with specific diseases.

---

**The DNA**

Deoxyribonucleic acid (DNA) is found in bacteria, and in nuclei and mitochondria of all eukaryotic cells. DNA is the component of chromosome. Chromosome appears in pairs, except in germ cells. Chromosomes are made up of a mammoth molecule of DNA, which is about 2 m in length. However, DNA is accommodated in the nucleus as most part of it at intervals is wrapped around histone proteins to form **nucleosomes**. About 25 millions of nucleosomes are present in a nucleus. The complex of DNA and the histone protein is called **chromatin**. As cell division begins, acetylation of histone loosens the coiling and pairs of chromosomes become visible.

---

**Important Note**

**DNA Content of a Cell:** It has been estimated that total DNA content of a cell (all chromosomes put together) is represented by about $6 \times 10^9$ nucleotide pairs. Of these, $2.5 \times 10^8$ is present in Chromosome 1, which is the largest chromosome. The Y chromosome, which is the smallest chromosome, contains $5 \times 10^7$ nucleotide pairs.

**DNA Nucleotides**

A molecule of DNA is made up of two strands of polynucleotides linked together in the form of a double helix (Fig. 5.3). A nucleotide consists of a nitrogenous base, a sugar molecule (deoxyribose) and a phosphate molecule. In DNA, the nitrogenous bases are **purines** (adenine and guanine) and **pyrimidines** (cytosine and thymine). Nucleotides in DNA from a polymer of polynucleotides through covalent bonds between the sugar molecules. [Nitrogenous bases are often designated by their first letter i.e. A for adenine, T for thymine, G for guanine and C for cytosine]. The purine and pyrimidine bases encode **genetic message** (Application Box 5.2).

**Application Box 5.2**

**The Genetic Message:** The genetic message is encoded by purine and pyrimidine bases in the nucleotide chains of DNA. The amino acid sequence in the protein synthesized in the cell decides the text of the message. The RNA transfers the message form DNA blueprint to the ribosome where protein synthesis occurs. The proteins formed from DNA blueprint include all enzymes that control cell metabolisms.

**Important Note**

**Gene and Proteins:** A **gene** is defined as the amount of information necessary to specify a **single protein** molecule. Proteins determined by a single gene may divide to form different proteins with various physiological actions. Also, different mRNAs may form from a single gene that can guide formation of various proteins.

**Double Helix Structure**

In the double helix, the sugar phosphates form the backbone with all the bases being present inside the helical structure. Each nucleotide consists of a sugar deoxyribose,
Section 1: General Physiology

30

a molecule of phosphate and a base (Fig. 5.4). The bases on one strand pair up by means of hydrogen bonds with bases on the other strand. Linkages in nucleotide form one strand of DNA (Fig. 5.5), and linkages of two chains of nucleotides form the DNA double helix (Fig. 5.6). The paring occurs in such a way that the purine base like guanine in one chain always pairs with the pyrimidine base cytosine in the other chain. Similarly, adenine always pairs with thymine. These base pairs are referred to as complementary base pairs.

Functions of DNA

1. DNA as part of chromosome transmits genetic characteristics (hereditary features) from generations to generations.

2. It possesses information required for the synthesis of RNA and cell proteins (including enzymes).

3. It controls cell division.

The Genome

Each chromosome contains only one type of long-chain DNA molecule. DNA is the component of chromosome that carries the genetic message (blueprint of heritable characteristics) of the cell (Refer, Application Box 5.2).

1. The total genetic information stored in chromosomes of a cell is known as the genome.

2. The human genome contains about 3 billion nucleotide pairs, and in diploid cells they are organized into 23 pairs of chromosomes (all cells of the body, except the gametes).

3. In each pair, one is derived from the mother and the other from the father. However, in males, the X chromosome is inherited from the mother, and the Y chromosome from the father. The X and Y chromosomes are concerned with the determination of sex, and therefore they are called sex chromosomes.

4. The XX are necessary for development of the female and XY pair is necessary for development of the male. As stated in Lyon hypothesis, in female, one of the two X chromosomes (paternal or maternal derived), is
inactivated during embryogenesis. This inactivation is passed to all the somatic cells, while the germ cells in female remain unaffected. That means ovary will have always active X chromosome.

5. The inactive X chromosome in the somatic cells in female lies condensed in the nucleus and is called as sex chromatin. This phenomenon in females helps in nuclear sexing (Clinical Box 5.1).

6. Gametes (sperm and ovum) have half this number of chromosomes, and therefore are said to be haploid cells.

7. During fertilization of an ovum by a sperm, the diploid number is restored, so that each cell carries 23 chromosomes from each parent.

Clinical Box 5.1

Nuclear Sexing: Determination of sex by identification of sex chromatin in the nucleus of somatic cells is called nuclear sexing (Fig. 5.7). This is done for genetic female testing by preparing and staining the smears of squamous cells scraped from oral cavity or by identifying Barr body attached to nuclear lobes in the circulating neutrophil, in females. A minimum of 30% cells positive for sex chromatin indicates the person as female genetically.

Chromosomal Disorders

Chromosomal abnormalities may be either due to the defect in autosomes or in sex chromosomes, and are accompanied by congenital abnormalities.

1. Trisomy 21: The commonest abnormality of autosomal chromosome is the presence of three instead of two chromosomes in the number 21 pair. The condition is known as trisomy 21. The resulting clinical condition is called mongolism, or Down’s syndrome, which is characterized by mental retardation, congenital anomalies and abnormal physical features (Fig. 5.7A).

2. Turner and Klinefelter syndromes: The common sex chromosomal abnormality in female is Turner syndrome in which one X chromosome is absent (i.e. XO), and in male is Klinefelter syndrome in which an extra X chromosomes is added (XXY). In these conditions, the subject is sterile, and has peculiar physical abnormalities. Klinefelter’s syndrome that occurs in males, presents with gynecomastia, osteoporosis, and testicular atrophy (Fig. 5.7B). Turner’s syndrome that occurs in females presents with short stature, webbed neck, small breast size and primary amenorrhea (Fig. 5.7C).

3. X-linked Disorders: An abnormal gene located in an autosome leads to an autosomal trait; whereas location of abnormal gene in a sex chromosome gives rise to sex-linked traits. However, all the known sex-linked genetic disorders are due to the defective genes located on one X chromosomes, and therefore they are called as X-linked disorders. Very few of them are X-dominant, but most are X-recessive. Therefore, many X-linked disorders do not manifest in females who have normal X chromosome allele. However, sex linked genetic disorders at all times manifest in males as they do not have normal neutralizing X allele.

Fig. 5.7A to C: Clinical features of three important chromosomal abnormalities. (A) Down’s syndrome; (B) Klinefelter’s syndrome; (C) Turner’s syndrome.
**Section 1: General Physiology**

Common examples of *X*-recessive disorders are:
- Hemophilia
- G-6-PD deficiency
- Nephrogenic diabetes insipidus.

Rarely do they manifest in females, such as females with Turner’s syndrome.

**The Genes**

The gene is the functional unit of DNA. A gene is defined as the portion of DNA responsible for the production of a single RNA molecule. Each chromosome contains myriad of genes. The genes do not exercise their powers all the time. The inherent control mechanisms are such that only selected genes are switched on at any given time. Though, the DNA of each cell in a multicellular organism has same DNA sequence and same genetic capabilities, the difference between different cell types lies in the differences in genetic expression.

**Gene Expression**

The genetic expression of each cell type is selective, and therefore, the protein synthesis is different in different tissues. Genetic expression occurs in two broad steps: transcription and translation (Flowchart 5.1).

**Transcription**

Transcription is the process in which RNA is synthesized from DNA. In this process:
1. The genetic information stored in DNA is transferred to the RNA.
2. During the process of formation of RNA, the relevant part of the DNA double helix unwinds and exposes the gene unit, which is then copied.
3. The DNA strand that directs the synthesis of mRNA through complementary base pairing is called template strand (also called, coding strand or sense strand) and the other DNA strand is called noncoding strand or antisense strand.
4. The enzyme RNA polymerase carries out transcription by binding to a site on DNA called promoter site.

**Translation**

This is the process by which genetic message transferred to mRNA from DNA is converted into polypeptide chain containing specific sequence of amino acids.

1. Post-transcription: The mRNA is processed from the primary RNA transcript; the process known as maturation in which released introns join with two adjacent exons.
2. Only the exons and introns contain the genetic code.

**Gene Unit**

Each gene unit is organized into three components: regulatory DNA sequence (repressor, promoter and operator), exons and introns (Fig. 5.8). Out of these, introns are removed during post-transcriptional events and adjacent exons join. Regulatory DNA sequence plays major role in transcription.

The regulatory DNA sequences are non-coding sequences that ensure that the gene is transcribed at the right time and in the proper cell. There are three types of regulatory nucleotide sequences per gene.

1. The promoter DNA sequence that contains a sequence of Thymine-Adenine-Thymine-Adenine (T-T-T-A) nucleotides. This acts as the recognition site for the enzyme RNA polymerase to attach with nearby transcription start site before it can move forward to begin transcription of the exons and introns.
2. The promoter separates from the exons and introns by about ten nucleotides known as the operator. The operator should be free of attached molecules for the RNA-polymerase to reach the exons and introns.
3. A repressor nucleotide sequence located ahead of the promoter region is known as 5’ region, which codes for a repressor protein. This protein under certain conditions attaches itself to the operator that prevents the RNA-polymerase from moving towards the structural gene. There is often another regulatory nucleotide sequence at the other end known as 3’ region.

**Exons** are the DNA coding sequences that code for the formation of RNA.

**Introns** are DNA coding sequences inserted at intervals between segments of exons.
During the formation of RNA, both the introns and exons are transcribed, but the later one is translated into sequences of amino acids for the synthesis of a specific polypeptide within the ribosome.

**Steps of Protein Synthesis**

Protein synthesis occurs in three major steps.

1. **Transcription:** The two strands of DNA fiber separate from each other over the area bearing a particular cistron. Thus, the ends of the bases linked to the opposite strand become free. A molecule of mRNA is synthesized as a guide or a template. The code for the sequence in which amino acids are to be linked is passed on from DNA to mRNA (Fig. 5.9). This is called transcription, which occurs under the influence of RNA polymerase. The part of the mRNA strand that bears the code for one amino acid is called codon. The molecule of RNA now separates from the DNA strand and moves from nucleus to cytoplasm, where it attached with ribosome.

2. **Amino acid activation and translation:** On the ribosome, one side of tRNA attaches to amino acid, and on the other side bears a code for three bases (anticodon) that are complementary to the bases coding for its amino acid on mRNA. In the presence of enzyme aminoacyl tRNA synthase, amino acids react with ATP, get activated and attach with specific tRNA. Under the influence of the ribosome, several units of tRNA along with their amino acids become arranged alongside the strand of mRNA. In the sequence determined by the code on mRNA. This is called translation. Translation occurs in three steps:
   - **Initiation:** translation of mRNA with formation of initiation complex.
   - **Elongation:** elongation of polypeptide chain by sequential addition of amino acids to the growing end.
   - **Termination:** termination of polypeptide synthesis evoked by nonsense codon.

3. **Post-translational modification:** Post-translational modifications such as proteolytic degradation, hydroxylation, glycosylation, etc. make the protein more functional.

**Regulation of Gene Expression**

Gene expression is regulated by following mechanisms.

1. **Gene amplification:** Enhancement of gene expression can cause drug resistance. For example, amplification of the gene coding for dihydrofolate reductase causes development of drug resistance by cancer cells to chronic administration of methotrexate.

2. **Gene rearrangement:** This enhances the generation of antigen specific immunoglobulins.

3. **Regulation through transcription factors:** Transcription factor regulate interaction of protein with specific segments of DNA.

**The RNA**

Ribonucleic acid is made up of a single chain of polymers (polymer of ribonucleotides). Unlike DNA, which is double stranded, the RNA has a single strand. RNA is present in the nucleus, cytoplasm, ribosome and to some extent in mitochondria.

RNA differs from a DNA strand in many aspects such as:

1. RNA chain is much shorter in length than the DNA chains.
2. The sugar-phosphate that forms the backbone contains ribose instead of deoxyribose.
3. The base thymine is replaced by uracil.

**Types of RNA**

There are three types of RNA and they have different functions.
1. **Messenger RNA:** Messenger RNA (mRNA) is formed in the nucleus and enters cytoplasm for protein synthesis. It forms the template that directs the synthesis of protein molecules within ribosomes.

2. **Transfer RNA:** Transfer RNA (tRNA) conveys specific amino acids to the site of protein synthesis.

3. **Ribosomal RNA:** Nucleolus is the site of synthesis of ribosomal RNA (rRNA), which is associated with many proteins to form ribosomes, the protein-synthesizing machine.

**Application of Genetics in Medicine**

**Recombinant DNA Technology**

Recombinant DNA technology in genetic engineering refers to the process in which a DNA fragment of interest is transferred from one organism to a self-replicating genetic element such as a bacterial plasmid, which involves cutting, modifying and joining DNA molecules using enzymes such as DNA ligase and others. It is performed in four stages.

**Stage 1:** This is the stage of creation of a copy of gene essential for the purpose. This can be done by making a copy of the gene from its mRNA, by synthesizing the gene artificially or by chopping a part of DNA with restriction enzymes and searching for the part with the required gene.

**Stage 2:** This is the stage of joining the gene to a vector molecule, which is a DNA molecule with which the generated gene is attached for cloning. The usual vectors are plasmids, bacteriophages and cosmids.

**Stage 3:** This is the stage of introduction of vector DNA into the host cell to produce chimeric DNA or recombinant DNA.

**Stage 4:** This is the stage of cloning of chimeric DNA. The chimeric DNA contained in a vector is introduced into bacterial cells by the process called transfection. The host cell allows multiplication of the chimeric DNA of the vector that leads to production of large number of identical target cloned DNA molecules. The cloned DNA is released form the vector by cleavage, which is isolated, characterized and used for different purposes.

---

**Uses of Recombinant DNA Technology**

1. **Synthesis of hormones:** By recombinant DNA technology, hormones like insulin, growth hormone, erythropoietin etc, can be produced in large amount for therapeutic purposes.

2. **Laboratory diagnosis:** Diagnosis of diseases like AIDS has become simple by using recombinant DNA technology.

3. **Gene therapy:** It is useful in therapy for genetic defects.

4. **Use in forensic medicine:** DNA fingerprinting technique is useful in medicolegal cases.

5. **Use in agricultural purposes:** Recombinant DNA technology is used in generating genetically engineered plants to enhance the yield of crops.

**PCR and Blotting Techniques**

**Polymerase Chain Reaction**

Polymerase Chain Reaction (PCR) is a specific and very rapid method of amplifying a target DNA sequence. This involves denaturation of DNA (separation of double stranded target DNA into single strand by heating), cooling the single DNA strand and DNA amplification. The DNA amplification is achieved by formation of new DNA strand in the presence of enzyme DNA polymerase and the substrate deoxyribonucleotide triphosphate. PCR causes million fold amplification of target DNA.

**Scientist contributed**

Kary Mullis (Born 1944, North Carolina, USA)

Kary Mullis, PhD, who conceived PCR as a method to copy DNA and synthesize large amounts of a specific target DNA, was awarded the 1993 Nobel Prize in Chemistry.

**Uses of PCR**

PCR is highly sensitive and can detect the presence of even a single molecule of DNA. PCR is used for quick diagnosis of AIDS, DNA fingerprinting and sex identification.

**Blotting Techniques**

Blotting techniques are methodical techniques used for the identification of a particular DNA, RNA or a protein. There are three techniques: *southern blotting* (for DNA), *northern blotting* (for RNA) and *western blotting* (for protein).
Chapter 5: Physiology of Genetics and Apoptosis

Southern blotting
In southern blotting, DNA is extracted from the cells like leucocytes) and cleaved into fragments by restriction endonucleases.
1. DNA extracted and fragments are separated and denatured.
2. The DNA fragments are transferred into a sheet of nitrocellulose paper from the agarose gel by blotting.
3. Then DNA fragments are fixed to the membrane usually by ultraviolet cross-linking.
4. The labeled DNA is formed by hybrid complexes.
5. Following the hybridization reaction, the membrane is washed and regions of hybridization are identified by autoradiography.

Southern blotting is used for DNA fingerprinting and for detection of mutant gene that causes diseases like cystic fibrosis.

Northern blotting
Northern blotting is similar to southern blotting except that the RNA is used instead of DNA. Northern blotting is used for analysis of gene expression in a particular tissue.

Western blotting
Western blotting is used for identification of specific proteins. First, the SDS polyacrylamide gel electrophoresis is performed for the protein mixture, and then the electrophoresed protein bands are transferred from SDS polyacrylamide gel to a nitrocellulose membrane. Afterward, probing is performed using a labeled antibody probe. Western blotting along with ELISA is a confirmatory test for HIV.

Cloning
Cloning means production of many identical copies of a molecule. Generally, there are four types of cloning: Gene cloning, reproductive cloning, tissue cloning and embryo cloning.

Gene Cloning
Gene cloning, also referred to as DNA cloning or recombinant DNA technology is the process of transfer of a specific DNA fragment of one organism to a self-replicating genetic component of the cloning vector such as bacterial plasmid. Following transfer of the DNA fragment, the molecule is propagated in the host organism. Gene cloning is used widely in genetic engineering for sequencing genomes and in gene therapy.

Reproductive Cloning
Reproductive cloning is used to produce an animal having the same nuclear DNA from the existing animal. The Broad methodology:
1. The technique of reproductive cloning uses the principle of somatic cell nuclear transfer, in which genetic material from the adult donor cell is transferred to an egg from which the genetic material has been removed.
2. The new egg containing the DNA of the donor cell is allowed to divide by chemicals or electric current.
3. After attaining a suitable stage, the cloned embryo is transferred to the uterus of the host female where it grows into a complete fetus.

Reproductive cloning can be used to reproduce animals that are difficult to breed. The Dolly sheep is the first cloned animal (Roslin Institute in Edinburgh, Scotland, 1997).

Embryo Cloning
This is also called therapeutic cloning, which refers to the production of human embryos for research purposes. The aim of this is not to create a cloned human being, rather to yield stem cells to study human evolution and disease treatments. Stem cells are extracted in the blastocyst stage of development, which can practically generate any type of cells in the human body. Stem cells are used to replace degenerating cells as in Alzheimer’s disease, cancer, etc.

Tissue Cloning
This technique is called tissue culture, in which cells are allowed to grow in a suitable medium. The cloned cells are used to study of the action of hormones, antibiotics and pharmaceutical products.

Mutation
Mutation refers to a change in the DNA structure of a gene. Mutation is caused by mutagens, the factors that produce mutation. The known mutagens are X-rays, ultraviolet light, certain chemicals, etc. There are two major types of mutations: Point mutation and frame-shift mutation.

Point Mutation
In point mutation, one base pair of DNA replaces the other. This is of two types: transitions and transversion. Transition is the type of mutation in which one purine or pyrimidine is replaced by another purine or pyrimidine. In transversion type of mutation, a purine is replaced by pyrimidine or pyrimidine is replaced by purine.

Frame-shift Mutations
In this mutation, base pairs are either deleted or inserted into the DNA. Hence, this is also called deletion or inser - tional mutations. The deletion or insertion leads to change in the frame of mRNA. Therefore, mRNA becomes unable to recognize that a new base is added or missing. However, translation continues and proteins formed have many altered amino acid sequence.

Mutation results in diseases such as sickle cell disease, phenylketonuria, cystic fibrosis, etc.
Genetic Screening
Genetic screening is detecting the genetic variations in a human being. It is used for diagnosing diseases at various stages and for various purposes such as prenatal diagnosis, diagnosis of carrier states and prognostic diagnosis.

Prenatal Diagnosis
Prenatal diagnosis aims at identifying the health problems in the fetal stage and therefore has preventive values. This is performed by chorionic villus sampling, amniocentesis and pre-implantation diagnosis.

Diagnosis of Carrier States
A group of people carry and transmit the disease without suffering from it. The identification of such carrier people is important in preventing the spread of disease in the community. The examples of carrier states include sickle cell anemia, cystic fibrosis and phenylketonuria.

Prognostic Diagnosis
Some diseases like type II diabetes mellitus or Huntington’s chorea that are present in childhood are likely to occur in genetically susceptible individuals when they become adult or middle aged. Genetic screening of such people to identify the susceptibility of the disease helps in preventing the disease to occur.

Genetic Basis of Cancer
Some cancers such as cancer of colon and female breast, retinoblastoma, leukemia etc. have hereditary predisposition. Defective DNA and chromosomal abnormalities are among the etiological factors in the genesis of cancers like acute myeloid leukemia and Burkitt’s lymphoma. Ionizing radiations like exposures to ultraviolet rays produce cancer by causing mutagenesis (damaging the genetic constitution) of the individual.

Cancer Genes
There are genes that predispose to cancer and genes that prevent cancers. Cancer producing genes are oncogenes and defective P53 gene. Genes preventing cancer are tumor suppressor genes (or antioncogenes) and RB gene.

Oncogenes
Cancer causing genes are called oncogenes. There are more than 100 oncogenes have been described so far. The proto-oncogenes are normal genes that encode proteins controlling normal cell functions. Many factors stimulate conversion of proto-oncogenes to oncogenes. The factors that promote this conversion are:

1. Chromosomal translocation: In this, a part of chromosome is translocated to other chromosome. For example, an area of chromosome 8 in patients with Burkitt’s lymphoma is translocated to either of the chromosome 2, 14 and 22.
2. Missense mutation: In this, amino acid sequence of proto-oncogene changes that helps the protein to convert into oncogene.
3. Gene amplification: Amplification of some of the genes to become oncogene has been implicated in the genesis of lung, breast, stomach and colon cancer.

Defective P53 Gene
Normally, stimulation of P53 gene results in formation of P53 protein. P53 protein serves as a transcription factor for many physiological functions that prevent malignancy. These are:
1. P53 protein activates genes that promote DNA repair.
2. It activates genes that arrest cell division.
3. It also stimulates genes that help apoptosis.
   About half of malignancies are associated with defects in P53 gene.

Mutator Genes
Normally, damage to DNA is repaired by caretaker genes. Mutator gene is the faulty caretaker gene that has lost normal surveillance function and therefore helps in genesis of cancer.

Telomerase
Telomerase recognizes telomere in cell divisions. Cancer cells express more telomerase that promotes telomere lengthening and this helps in cancerous proliferation.

Genes preventing cancer
RB Gene
Retinoblastoma (RB) gene serves as cancer suppressor. Mutation or deletion of this gene results in retinoblastoma.

Tumor Suppressor Gene
These are also called anti-oncogenes that prevent genesis of cancer. More than ten such genes have been identified. These genes are inactivated by mutation. Thus, mutation causes cancer.

Gene Therapy
Hereditary disorders occur due to transmission of defective genes. Gene therapy aims at providing the correct copy of the gene concerned. This is achieved by:
1. Gene replacement: Replacement of a mutant gene with a normal gene
2. Gene correction: Correction of the specific bases of DNA
3. **Gene augmentation**: Insertion of a foreign DNA into the genome of a cell to rectify the genetic defect

### Somatic Cell Therapy

In humans, somatic (nongametic) cells are used in the gene therapy as changes in these cells cannot be inherited.

The broad steps are:

1. Cells are isolated with the defective gene from the patient and grown in culture.
2. Grown cells are transfected with a remedial gene construct.
3. Transfected cells are then transfused back into the patients.

It is successfully tried in **cystic fibrosis** of the lung and **severe combined immunodeficiency syndrome**. Without ADA (adenosine deaminase), the child develops SCID and dies of infection in the early childhood.

In **cancer**, gene therapy is very useful, in which oncogenic gene is inactivated by introducing a gene like tumor suppressor gene. This selectively kills the cancer cells.

### APOPTOSIS

Apoptosis is the **programmed cell death**. Apoptosis is a Greek word meaning 'falling off' or 'dropping off', first described 1972. It is a distinct process from necrosis. It is a form of coordinated and internally planned cell death, which is of greater significance in a variety of physiologic and pathologic conditions.

Apoptosis is the programmed cell death that has genetic control. **Genes of the own cells** play important role in this programmed cell death. Apoptosis is a natural process, and examples are:

1. Death of neurons in central nervous system during brain development and synapse formation is an example of apoptosis.
2. During fetal development, degeneration of many tissues like web in the fingers is other example.
3. Many blood cells like eosinophils undergo apoptosis.

### Mechanisms of Apoptosis

#### Stimuli

Activation of cysteine proteases in the cell called **caspases** triggers apoptosis. Normally, caspases are present in the inactive form in the cell, and stimulated by external and internal stimuli.

**Internal stimuli**: Mitochondria release cytochrome and a protein called *smac* that causes activation of the *caspase 9*, which induces apoptosis. In mitochondria, apoptosis inducing factor is located in the intermembrane space that migrates to nucleus and destroys DNA.

**External stimuli**: External stimuli are various ligands that bind with cell surface to activate apoptosis. One such factor is tumor necrosis factor that activates the enzyme *caspase 8*. Activation of caspase promotes DNA fragmentation and chromatin condensation.

### Molecular Mechanisms of Apoptosis

#### Initiation of Apoptosis

Stimuli signaling programmed cell death act either on the cell membrane or intracellularly.

(a) Usually it is triggered by absence of stimuli that are normally required for normal cell survival such as absence of certain hormones, growth factors, cytokines, etc.

(b) Activation of receptors like receptors of TNF initiates programmed cell death.

(c) Intracellular stimuli may include heat, radiation, hypoxia, etc.

(d) Genetically programmed events.

### Regulation of Apoptosis

Once apoptosis is initiated, certain intracellular proteins provide signal for the final programmed cell death, which actually determine the outcome. These **regulatory proteins** include the following:

(a) **BCL-2**: BCL-2 is a protein which is equivalent to CED-9, the cell death gene found in nematodes. BCL-2 is located in the outer mitochondrial membrane and control apoptotic process by binding to various cytosolic proteins. Usually it binds to BAX and BAD proteins that are known to promote apoptosis. It may also bind with BCL-XL protein that inhibits apoptosis. Another binding protein present in the cytosol is the pro-apoptotic protease-activating factor (apaf-1), which is a mammalian counterpart of gene CED-4 of nematode. Thus, apoptosis depends on binding of BCL-2 with pro-apoptotic and anti-apoptotic proteins.

(b) **Other apoptotic regulator proteins**: Other regulator proteins of apoptosis are TP53 (p53) protein, caspases, BAX and certain viruses such as adenovirus, papilloma virus, hepatitis B virus, etc.
**Steps of Apoptosis**

Apoptosis occurs in following major steps (Flowchart 5.2).

(a) **FAS receptor activation**: CD 95 or FAS, the surface receptor present on cytotoxic T cells when comes in contact with the target cell, is activated. This leads to activation of caspases and subsequent proteolysis.

(b) **Ceramide generation**: Hydrolysis of sphingomyelin on the cell membrane generates ceramide. Ceramide causes mitochondrial injury.

(c) **DNA damage**: Damage by various agents and activated oxygen species like free oxygen radicals leads to apoptosis. DNA injury influences nuclear protein TP53 that induces the synthesis of cell death promoting protein BAX.

(d) **Cell shrinkage**: Cell reduces in size and cytoplasmic condensation occurs.

(e) **Formation of apoptotic bodies**: Apoptotic bodies are formed as described below.

(f) **Phagocytosis**: The dead apoptotic cells and their fragments are identified and engulfed by phagocytes.

**Physiologic and Pathologic Processes**

Apoptosis is a biologic phenomenon, which has both physiologic and pathologic processes.

**Physiologic Processes**

Physiologic processes occur in three steps (Flowchart 5.3). They are influenced by many factors and examples are:

1. Physiologic involution of cells in hormone-dependent tissues such as endometrial shedding in menstrual cycles, regression of lactating breast after cessation of breast-feeding.
3. Involution of the thymus after childhood.

**Pathologic Process**

Pathologic processes are initiated by following factors.

1. Tumor cell death on exposure to chemotherapeutic agents.
2. Transplant cell death by cytotoxic T cells that cause transplant rejection.
3. Cell death induced by viral infections as occurs in viral hepatitis.
4. Pathologic atrophy following withdrawal of stimuli. For example, prostatic atrophy after orchietomy.
5. Cell death induced by radiation, hypoxia and thermal injury.
6. Degenerative diseases of CNS such as in Alzheimer’s disease, Parkinson’s disease, etc.

**Changes in Apoptosis**

**Pathophysiologic Changes**

Changes in apoptosis confuses with the changes in necrosis. In necrosis, cytoplasm is homogenously eosinophilic, and nuclear changes are pyknosis (condensation and clumping of nucleus), karyolysis (disintegration of the nucleus) and karyorrhexis (nucleus fragments into small bits and disperses into cytoplasm). In apoptosis, there is condensation of nuclear chromatin and cell fragments into apoptotic bodies that are phagocytosed by macrophages (Fig. 5.10).
The characteristic changes in apoptosis include the following:

1. May involve single cells or a cluster of cells. The apoptotic cells become round or oval and reduce in size. The cytoplasm becomes intensely eosinophilic containing condensed or fragmented nuclear chromatin material. Typically, inflammatory response around apoptosis is absent.

2. Though cytoplasm is reduced, organelles remain almost normal.

3. Cell membrane convolutes with formation of membrane-bound spherical structures called apoptotic bodies that contain compacted organelles.

4. Chromatic condensation occurs around the periphery of nucleus.

5. Phagocytosis of apoptotic bodies occurs by macrophages.

Biochemical Changes

Biochemical changes include:

1. Proteolysis of cytoskeletal proteins.
2. Cross-linking of protein molecules.
3. Fragmentation of nuclear chromatin by activation of nuclease.
4. A glycoprotein molecule called thrombospondin and a phosphoprotein called phosphatidylserine appear on the outer surface of apoptotic bodies, which facilitate recognition by macrophages for phagocytosis.

Application

Identification of components of the cell death control and effector mechanisms and the linkage of abnormalities in cell death to human disease, in particular cancers, has unraveled the research for preventing the cell death. Understanding the concept of apoptosis has promising role in future regenerative medicine.

CHAPeR SUMMARy

Physiology of genomics is a developing branch of medicine. It deals with the understanding of the concept of gene and gene therapy in treatment of genetic disorders. Discovery of cancer genes (oncogenes) and genes preventing cancers has changed the concept and modality of treatment of malignancies. Understanding the concept of apoptosis has promising role in regenerative medicine.

Important to Know (Must Read)

1. Long Questions may be asked on ‘Recombinant DNA technology and PCR’ or ‘Mechanism of Apoptosis’ for PGs, but not for UGs.
2. Structure and function of DNA, protein synthesis, blotting techniques, cloning, genetic screening, gene therapy, and oncogenes, may be asked as Short Notes/Questions in exams.
3. In Viva, examiners usually ask on structure and functions of chromosomes, genome, chromosomal disorders, nuclear sexing, gene amplification, uses of recombinant DNA technology and PCR, types of cloning with examples, types of mutation, importance of genetic screening, types of oncogenes, tumor suppressor genes, types of gene therapy, and definition and changes in apoptosis.
Chapter 6

Transport Across the Cell Membrane

Leaming Objectives

On completion of study of this chapter, the student MUST be able to:
1. Name common ion channels in the membrane; and name different types of carrier proteins with examples.
2. Classify transport processes and list the differences between passive and active transport mechanisms.
3. Describe the mechanism, factors affecting and physiological application with example of each transport process, especially of diffusion and osmosis.
4. Explain the primary and secondary active transport processes with examples.
5. Describe the structure, mechanism of action and functions of Na⁺-K⁺ ATPase.
6. Describe the mechanism and importance of endocytosis, exocytosis and transcytosis.

The student MAY also be able to:
1. Describe the gating of ion channels.
2. Describe types of patch clamping.
3. Explain the properties of facilitated diffusion.
4. Define the concept of osmole and application of osmosis in clinical conditions.
5. Describe other types of ATPases.

Fluid and electrolytes on either side of the cell membrane pass through the membrane by various means due to the presence of different channels and carrier molecules. Selective membrane permeability generates the difference in composition between intracellular and extracellular fluids. Transport of specific substances, like drugs, chemicals and hormones also influence cell functions.

Passage of substances through the membrane can be broadly divided into two categories:

1. Direct passage without involvement of carrier molecules: Cell membrane is a lipid bilayer. Hence, lipid-soluble substances, such as gases, fatty acids, alcohol, ketone bodies, aldehydes and many small-uncharged molecules pass through the membrane easily. Water molecules also pass through membrane easily.

2. Passage through channels or carrier proteins: Though water passes easily through the membrane, water-soluble substances, such as electrolytes, glucose and amino acids do not penetrate membrane readily. There are two major means through which these substances are transported across the cell membranes: through water channels formed by integral proteins, and by combination with carrier molecules in the cell membrane.

Protein Channels in the Membrane

Proteins that constitute channels are selectively permeable. They are tubular structures that connect the exterior with the interior of cells. The permeability of channels depends on molecular size, shape and charge.

Types of Protein Channels

Broadly, they are of two types: ion channels and water channels.

Ion Channels

Ion channels are integral proteins that span the entire width of the membrane. Normally, they are formed by several polypeptide subunits.

Mechanism of working of ion channels:
Along the length of the integral protein, an aqueous pore is present, around which the polypeptide subunits are arranged. Ions pass through the aqueous pore from one side of the membrane to the other. Thus, ions cross the membrane without entering through the lipid bilayer of the membrane.

A polypeptide subunit forms a gate at one end of the channel that opens in response to a specific stimulus (Fig. 6.1).

Opening of the gate opens the channel and allows the ions to rapidly move ($10^8$ ions per sec) through the channel.

However, there is a selectivity filter that permits specific ions to pass through the channel. Therefore, ion channels are often selective.

Sodium and potassium channels are extensively studied membrane channels.

**Sodium Channels**

Sodium channels have been studied in detail among all the ion channels. It has subunits surrounding an aqueous pore of about 0.5 nm in diameter. The inner surface of the pore is negatively charged. It is selective for passage of sodium. Sodium channel is blocked by tetrodotoxin.

**Potassium Channels**

There are many types of potassium channels. They are about 0.3 nm in diameter. Potassium channels are blocked by tetraethyl ammonium or 4-aminopyridine.

**Calcium and Chloride Channels**

There are various channels for Ca$^{++}$ and for Cl$^-$.

Ca$^{++}$ channels can be voltage-gated, ligand-gated and stretch-sensitive (for details, refer to chapter 71). Cl$^-$ channels are dimeric (have two pores) and pentameric (e.g. GABA$_A$ and glycine receptors). CFTR protein is a Cl$^-$ channel.

**Water Channels**

Water channels are aquaporins. There are 13 types of aquaporins (for details, refer to ‘Water reabsorption from kidney’ in ‘Renal Physiology’).

**Gating of Ion Channels**

Some of the ion channels remain always open, and, therefore, they are referred to as nongated channels. However, many ion channels open and close by gates. Ion channels are provided with gate on either side of the channel, and opening or closure of the gate regulates the movement of various ions through them.

There are three general mechanisms of gating: voltage-gating, ligand-gating and mechanical-gating.

**Voltage-gating**

Change in the membrane potential beyond a certain threshold value opens or closes the gate of the ion channels. Therefore, they are called voltage-gated channels. For example, ion channels in excitable tissues, such as nerve and muscle are mainly voltage-gated channels like Na$^+$, K$^+$ and Ca$^{++}$ channels. They are also present in pacemaker tissues in the heart and other organs. They are involved in generating and conducting action potentials.

**Mechanism of gating:**

1. The exact mechanism of voltage-gating is not known. It is proposed that alteration in membrane potential induces movement of some charged amino acids in helical segment of the channel protein that causes a conformational change of the channel protein, which in turn opens or closes the gate and allows the ions to pass through the channel rapidly.

2. For Na$^+$ channels, the gate is located on the outer end of the channel (Fig. 6.2A). The gate closes the outer opening of the channel when the cell is at RMP (–70 mV in nerve, –90 mV in muscle and –50 mV in pacemaker tissue). When inside becomes less negative, the gate opens and Na$^+$ influx occurs that leads to first, formation of local response and later, the genesis of action potential.

3. For K$^+$ channels, the gate is located on the inner end of the channel (Fig. 6.2B). The gate closes the cytoplasmic opening of the channel when the cell is at RMP. When interior becomes less negative and approaches towards positivity, more and more gates open and K$^+$ efflux occurs that leads to first, reversal of depolarization potential and later, the repolarization of action potential.

**Important Note**

Speed of opening of ion channel determines the slope of potential: Opening of K$^+$ channels is slower than the opening of Na$^+$ channels. Therefore, in action potential, the phase of repolarization, which is due to K$^+$ permeability, is less steep than the phase of depolarization.
**Ligand Gating**

Interaction of the channel with a ligand (hormone or neurotransmitter) causes opening or closure of the channel. Hence, the channels are called *ligand-gated channels*. As the ligand is a chemical agent, the gating is also called *chemical gating*.

**Mechanism of ligand gating:**
1. The chemical agent binds with the specific receptor protein on the membrane and brings about conformational change in the protein that, in turn, directly or indirectly opens the channel.
2. **Nicotinic cholinergic receptor** channel in postsynaptic neuromuscular junction is a ligand-gated ion channel. Acetylcholine released at the nerve ending binds with these receptors and opens the ion channels that generate postsynaptic potential.
3. Acetylcholine at the parasympathetic endings binds with *muscarinic cholinergic receptors* on the membrane of GI smooth muscle cells and activates G protein, which, in turn, activates the enzyme that causes production of *second messengers* such as cyclic AMP or Ca++. The second messengers activate enzymes like kinase that act on the ion channel by phosphorylation.
4. Other examples are the action of noradrenaline on β-adrenergic receptors on the smooth muscle cell.

**Direct opening of channels:** The receptor for the hormone or neurotransmitter may also be the channel itself, so that the action by the ligand is direct on the channel. For example, acetylcholine released at parasympathetic nerve endings acts on the receptor in the postsynaptic membrane in the cardiac pacemaker cells. This causes direct opening of K⁺ channels in the pacemaker tissue and causes hyperpolarization that decreases the discharge rate of the pacemaker.

**Mechanical Gating**

Some of the channels are *mechanosensitive* and they respond to stretch. Examples are *ion channels in hair cells*.
Types of Patch Clamping

There are three types of patch clamping: cell-attached patch, whole-cell patch and inside-out patch.

Cell-attached patch: In this clamping, the patch of the membrane remains attached with the cell.
Whole-cell patch: In this type of clamping, the patch of the membrane provides access into the interior of the cell.
Inside-out patch: In this method, the patch of the membrane is pulled from inside of the membrane to the outside of the membrane.

However, the patch of the membrane is small enough to contain one or two channels. The channel characteristics can be studied by changing the chemical and electrical gradients across the membrane.

Uses of Patch-clamp Technique

1. The patch clamp technique is an essential tool for scientists studying the activity and behavior of ion channels in cell.
2. This helped to understand how defective regulation of ion channels underlies a host of diseases, including diabetes and cystic fibrosis.
3. Mechanisms of action of drugs that use or block ion channels such as Ca$^{++}$ or K$^+$ channels blockers were studied using this technique.

Scientists contributed

Erwin Neher

Bert Sakmann

The 1991 Nobel Prize in Physiology or Medicine was awarded to two German scientists, Erwin Neher and Bert Sakmann for creating the experimental measuring device that conclusively proved the existence and function of ion channels.

Neher and Sakmann Model

An extremely fine glass pipette with a very small opening is used to make contact with a tiny area, or patch, of the cell's outer membrane that will contain only a single ion channel. Applying a small amount of suction through the pipette forms a seal tight enough such that ions can only flow from the channel into the pipette. By fitting the pipette with a highly sensitive electrode, Neher and Sakmann could record every minute change in current produced as ions flow through the clamped channel into the pipette.

1. With their recording device, they showed how these channels function by opening up and closing in nerve cell membranes to allow certain ions through one at a time.

Types of Carrier Proteins

There are three different types of carrier proteins: Uniport, symport and antiport (Fig. 6.4).

Uniport: Uniport is the carrier protein that transports only one substance. For example, Na$^+$ channels transport Na$^+$ and K$^+$ channels transport K$^+$.

Symport: Symport carriers transport two or more substances from one side of the membrane to the other in the same direction. Transport of Na$^+$ and glucose from the lumen of the intestine or kidney tubule into the epithelial cells through the same carrier protein is an example of symport mechanism. Such substances are said to be co-transported.

Antiport: Antiport carriers transport substances in opposite directions in which one substance is transported to the inside of the cell and other substance from inside the cell to the outside. Substances transported in opposite directions by one carrier are said to be counter-transported. Examples are:

1. A typical antiport carrier is the sodium-potassium pump, which is operated by Na$^+$-K$^+$ ATPase. It actively transports 3 Na$^+$ out of the cell, and 2 K$^+$ into cells for each molecule of ATP hydrolyzed.
2. Na$^+$-H$^+$ exchanger found in the proximal tubular cells of the nephron, for which the inward facilitated diffusion of Na$^+$ is coupled with the outward diffusion of H$^+$. 

Fig. 6.4: Types of carrier proteins in the cell membrane. Uniport transports one substance, symport transports two substances in the same direction and antiport transports two substances in the opposite directions.
Characteristics of Carrier-mediated Transport

Carrier-mediated transport systems exhibit two important properties: Competition for the carrier protein and the saturation of the transport process.

Competition inhibition: Presence of different molecules with similar structure competes for the same carrier protein for their transport, which results in competitive inhibition of the process. For instance, the presence of ketoses in intestinal content decreases the reabsorption of aldoses by the gut.

Saturation kinetics: The number of carrier proteins in a membrane is limited. Therefore, the rate of carrier-mediated transport reaches a maximum which is known as transport maximum or \( T_m \). The \( T_m \) cannot be exceeded by increasing the concentration of the substance. Thus, the carrier-mediated transport exhibits saturation kinetics.

TRANSPORT PROCESSES

Types

Transport mechanisms through cell membrane can broadly be divided into three types: passive transport, active transport, and vesicular transport (Table 6.1). There is another process of transport called transport across epithelia.

Special Features

Passive Transport

There are two common features of passive transport processes (Table 6.2). These are:

a. **Transport is downhill**: In passive transports, the substances pass through the membrane from both sides, however, net movement occurs down the electrochemical gradient;

b. **Transport does not require metabolic energy**: Passive transport does not require utilization of ATP.

Examples are simple diffusion, facilitated diffusion, osmosis, filtration, bulk flow and solvent drag.

Active Transport

Active transport differs from passive transport by its utilization of energy. The common features of active transport are (Table 6.2):

1. **Uphill transport**: Transport occurs against the electrochemical gradient of the substance.
2. **Requires energy**: Energy utilized for transport is derived from the breakdown of ATP. Hence, they are susceptible to metabolic poisons.
3. **Exhibits saturation kinetics**: This is because of limitation in the rate of availability of carriers or supply of energy.

The active transport mechanisms are:

1. Primary active transport.
2. Secondary active transport.

Vesicular Transport

This transport has no relation with the concentration gradient. However, it may utilize metabolic energy.

Vesicular transport mechanisms are:

1. Exocytosis.
2. Endocytosis.

SIMPLE DIFFUSION

Diffusion is the process of passive transport in which molecules move from the area of higher concentration to the area of lower concentration. In simple diffusion, molecules move due to their random movement. The examples of substances that pass through cell membranes by simple diffusions are transport of \( O_2 \), \( CO_2 \), urea, ammonia and ions. Across a membrane, diffusion of a molecule occurs when difference in concentration of the molecule exists on both sides of the membrane. The net movement of molecule ceases when the concentration of molecule on both sides becomes equal and a diffusional equilibrium is achieved.

Factors that Determine Rate of Diffusion

Factors determining the rate of diffusion across the cell membrane can be broadly divided into two categories: (a) properties of the substance and (b) the properties of the membrane.

Properties of the Substance

Properties of the substance that determine diffusion through membrane are mainly, (a) concentration and electrical gradients of the substance, and (b) permeability of the substance through the membrane.

Effect of Concentration and Electrical Gradients

The concentration or the chemical gradients of the substance is primarily responsible for the direction of transport of the substance (Fig. 6.5). The electrical potential difference (electrical gradient) also influences.

1. Normally, the cell membrane is polarized with the negative interior and positive exterior. Therefore, a positively charged molecule that diffuses from the outside to the negative interior is said to be moving along its electrical gradient, and its diffusion from inside to the outside is said to move against its electrical gradient.
2. Usually, substances move along both the electrical and chemical gradients (transfer along the electro-chemical gradients). Electrochemical gradient is mainly used for the ions.
3. For gases, concentration gradient is expressed as partial pressure, and for water as hydraulic pressure.

Thermal energy contributes to random motion: In a liquid or gas, all particles are in constant and random motion due to thermal energy. The motion varies directly with temperature. The motion is absent at absolute zero temperature. This random movement of particle provides the physical basis for diffusion of solutes and gas molecules in body fluids and across the cell membranes.

Unidirectional flux: When two liquids are separated by a semi-permeable membrane, the number of particles in the liquid striking a unit area from each side of the membrane at any given time is proportional to the concentration of the substance on that side. These particles succeed in passing through the membrane along the gradient, which is called unidirectional flux.

1. Unidirectional flux is proportional to the concentration of the substance in the liquid.
2. Similarly, the unidirectional flux of the particles in the opposite side of the membrane is proportional to the concentration of the substance on that side of the liquid.
3. Hence, net diffusion is the difference between the opposing unidirectional fluxes.
4. Diffusion across the membrane ceases when the balance between the fluxes from both sides becomes zero. A distinguishing feature of simple diffusion is the linear relationship between solute concentration and rate of diffusion (Fig. 6.6).

Permeability of the Substance

Permeability refers to the ease at which substances pass through the membrane.

The factors that determine the permeability are:

1. Lipid-solubility: As the membrane is a lipid bilayer, the permeability is proportional to their lipid solubility of the substance.
2. Molecular size: For water-soluble substances like ions that pass through aqueous channels, permeability is inversely proportional to their molecular size. For example, a cation like Na⁺ attracts more water in its hydration shell than K⁺. The atomic weight of Na⁺ is 23, whereas that of K⁺ is 39. However, the effective molecular size of the hydrated Na⁺ is larger than K⁺. Therefore, K⁺ permeability at rest is much more than the permeability of Na⁺.

3. Charge on the molecule: Since membrane is polarized with its negative interior, cations easily enter from outside into the cell and anions in the opposite direction.

4. Temperature: Rate of diffusion is high at higher body temperature as temperature facilitates motion of molecules in the solution.

5. Distribution of channels in the membrane: The number of protein channels for the substance in the membrane determines the permeability of the substance through the membrane.

6. Pressure gradient: In addition to the electrochemical gradients of the substance, the fluid pressure gradient also contributes to the diffusion of the membrane. Diffusion is more from high pressure to low pressure, as the pressure causes greater number of molecule to hit the membrane.

Properties of the Membrane

In addition to the concentration gradient of the substance across the membrane, the cross-sectional area and thickness of the membrane influence diffusion. These factors are governed by Fick’s law of diffusion. The rate of diffusion of a molecule through a membrane is proportional to the surface area (A) available for diffusion, and inversely proportional to the thickness of the membrane (T).

According to Fick’s law, for a substance whose inside and outside concentrations are respectively $C_i$ and $C_o$ mmol/l:

$$-\text{Net Rate of Diffusion (J)} = \frac{-DA}{T} \times (C_i - C_o),$$

where D is the diffusion coefficient.

The minus sign indicates that the direction is down the concentration gradient. As thickness of biological membranes is fairly constant at $10^{-6}$ cm, D/T simplifies to the permeability coefficient ‘P’ of the membrane, and

$$\text{Flux} = -P \times A \times (C_i - C_o)$$

Facilitated Diffusion

When diffusion is facilitated by a carrier protein in the membrane, the process is called facilitated diffusion. This is also called carrier-mediated diffusion as a carrier protein facilitates it. A typical example of facilitated diffusion is the transport of various sugars into red cells, adipose tissue, skeletal and cardiac muscles. Like simple diffusion, facilitated diffusion is also a downhill transport that does not require energy.

Features of Facilitated Diffusion

It differs from simple diffusion by four special features:

1. Faster rate of transport
2. Saturation kinetics
3. Competitive inhibition
4. Specificity.

Faster Rate of Transport

Carrier-mediated (facilitated) diffusion allows the transport of polar or hydrophilic molecules at a much faster rate than the rate expected from their partition coefficient. Therefore, inspite of saturation point for the transfer, the net transport is more than the simple diffusion (Table 6.3).

<table>
<thead>
<tr>
<th>Important Note</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Partition coefficient:</strong> Partition coefficient is the solubility of the substance in oil compared with the solubility in water. Lipophilic substances have high and hydrophilic substances such as ions and sugars have low partition coefficient. Therefore, hydrophilic molecules diffuse at a much faster rate through the membrane.</td>
</tr>
</tbody>
</table>

Saturation Kinetics

In simple diffusion, the rate of diffusion is proportional to the concentration of the substance and there is no saturation point. In facilitated diffusion, the number of carrier proteins available determines the rate of diffusion. When all the available binding sites on the carrier proteins are occupied, the system operates at the maximum capacity. This is called saturation point. However, the rate of diffusion is faster in facilitated diffusion compared to simple diffusion, as there is no involvement of carrier protein in simple diffusion. Thus, the net diffusion in facilitated type is more than in simple type (see Fig. 6.6).

Competitive Inhibition

Many substances share same carrier protein for their transport. When more than one such substance are present on the same side of the membrane, they compete to bind with the carrier protein. Thus, one substance decreases the transport of the other. For example, transport of D-glucose across the epithelial membrane slows down once D-galactose is present along with it as they share same glucose transporter. Also, Na⁺ and Ca⁺⁺ compete for the sodium-calcium cotransporter on the membrane and excess presence of one inhibits the transport of the other. However, it should not be confused with sodium-calcium exchanger and sodium-glucose cotransporter.

1. It should not be confused with sodium-calcium exchanger that promotes the transport of both ions, in which increased concentration of one on one side of the membrane increases the transport of the other from opposite side of the membrane.
2. Also, this should not be confused with carrier-mediated transport mechanisms by co-transporters like sodium-glucose cotransporter that are essentially facilitatory for transport of more than one substance (Application Box 6.1).
Chapter 6: Transport Across the Cell Membrane

Application Box 6.1

Salt is mixed with glucose in ORS: For example, presence of sodium in intestinal fluid increases the absorption of glucose from the gut content by the intestinal epithelial cells, which forms the physiological basis of adding sodium and glucose in equal proportion in the oral rehydration solution (ORS).

Specificity

The carrier proteins are specific for different molecules. For example, the carrier protein for protein does not transport cholesterol or fatty acid. However, specificity is not a rigid phenomenon as, more than one substance share the same carrier protein as for example, sodium-glucose co-transporter. Facilitated diffusion occurs through ion channels as occurs in sodium-glucose cotransport, in which glucose shares the sodium transport mechanism.

Factors Affecting Facilitated Diffusion

Factors that influence simple diffusion also affect facilitated diffusion as described above. However, the major factor is the number of carrier proteins available for the transport. Sometimes, facilitated diffusion is also operated by other factors like hormones. For example, transport of glucose by GLUT-4 into muscles and adipose tissue is insulin-dependent.

OSMOSIS

Definition: Osmosis is the process of movement of solvent from the solution with the lower concentration of solutes to the solution with higher concentration of solute, when both the solutions are separated by a semipermeable membrane.

Concept: Like solute particles, water (solvent) molecules are constantly influenced by thermal disturbance and, therefore, exhibit random movement (called thermodynamic activity of water).

1. They pass through a semipermeable membrane, and their passage is proportional to the solvent molecules on that side.
2. If the membrane that separates two solutions of different solute concentrations is semipermeable, which allows the passage of solvent and not the solute particles, the solution with higher concentration solute will have lower thermodynamic activity of water, and vice versa.
3. Net water movement will, therefore, be from the solution with a higher thermodynamic water activity to the solution with lower thermodynamic water activity, i.e., from the side with lower solute concentration to the side with higher solute concentration (Figs. 6.7A and B).
4. Thus, the net flux of water (or solvent) through a semipermeable membrane from a solution of lower solute concentration to that of higher solute concentration is known as osmosis.

Osmotic Effectiveness of a Substance

A substance to maintain a stable osmotic pressure should be confined to one side of the membrane. Therefore, a

Figs. 6.7A and B: The process of osmosis. (A) Compartment ‘a’ containing more number osmotically active solutes is separated by a semipermeable membrane from compartment ‘b’ that contains less number of solutes (solute particles are represented by black dots). Solvent movement from ‘b’ to ‘a’ is prevented by application of osmotic pressure on ‘a’. (B) Solvent (not the solute) moves from ‘b’ to ‘a’ (indicated by arrow mark) till osmotic equilibrium is reached, which results in increase in volume of ‘a’.
substance like urea, which can diffuse readily across cell membrane, cannot impart sustained osmotic effects. Hence, urea is said to be **osmotically ineffective**. Whereas a substance like glucose, which cannot freely diffuse through cell membrane because of its large molecular size, is osmotically active. However, glucose is not permanently osmotically effective as it is metabolized especially in blood, and, therefore, its effect is not sustained.

A better example of **osmotically most effective** substance is **plasma protein** as it is neither transferred from nor metabolized in the compartment. Other examples are various complex polysaccharides such as dextran. Sodium chloride is also osmotically effective even though Na⁺ and Cl⁻ ions can diffuse through the cell membrane (Clinical Box 6.1).

### Clinical Box 6.1

**Normal saline is effective in hypovolemia:** The application of osmotic effectiveness is important in the management of hypovolemia. A solution used to restore circulating blood volume should be the one whose active osmotic constituent remains within the circulation for a longer duration. Therefore, although 5 per cent glucose is isosmotic with plasma, it is usually not used to treat hypovolemia as it is rapidly metabolized, whereas 0.9% NaCl (the normal saline) is the satisfactory replacement for volume loss.

### Osmotic Pressure

Osmotic pressure is the minimum pressure applied to the solution with higher solute concentration to prevent osmosis. When the membrane is impermeable to an osmotically active solute, osmotic flow of water ensues and continues into the side containing the solute until either the membrane bursts (osmotic lysis of cells), or some hydrostatic pressure prevents further osmotic flow. The **hydrostatic pressure necessary to prevent osmotic flow of water** is known as the **osmotic pressure** of the solution.

Osmotic pressure depends on the number of molecules or the ions dissolved in a solution rather than the nature of chemical composition.

1. In case of **nondissociated solutes**, 1 gm mol wt of any substance shall contain similar number of molecules and, therefore, exerts similar degree of osmotic pressure (equal to 22.4 atmospheres).
2. In case of **dissociated solutes**, osmotic pressure depends on the number of molecules resulting from the dissociation.

Osmotic pressure in body fluid is mainly exerted by osmotically active solutes dissolved in the fluid such as **colloidal substances**. Hence, the osmotic pressure is called **colloidal osmotic pressure** (Application Box 6.2).

### Application Box 6.2

**Onctic pressure determines rate of capillary filtration:** In the plasma, the colloidal particles are proteins. The osmotic pressure due to presence of plasma proteins is called **onctic pressure**. The normal onctic pressure is **25 mm Hg**. Ongtonic pressure significantly contributes to filtration across the capillary membrane. Therefore, edema occurs in hypoproteinemia.

### Terms Used in Osmosis

**Mole**

A mole (standard SI unit) is the molecular weight (MW) of a substance in grams, i.e. the gram molecular weight. For example, the MW of glucose is 180, so its mole is 180 gm; and for NaCl, the mole is 58.5 gm.

**Osmole and Milliosmole**

The concentration of osmotically active particles is usually expressed in osmoles (Os). One osmole equals the gram molecular weight (i.e. one mole) of the substance divided by the number of freely moving particles each molecule liberates in solution. The **milliosmole** (mosm) is 1/1000 of 1 Os.

1. If a solute is a **non-ionizing compound** like glucose, one osmole is equal to 1 mole of solute particle. Thus, 1 molar solution of glucose has a concentration of 1 Os (1 osmole per liter).
2. If the solute is an **ionizing compound** like NaCl, each ion is an osmotically active particle. Therefore, in 1 molar solution of NaCl, NaCl would dissociate into Na⁺ and Cl⁻ ions, so that each mole in solution would supply two osmoles of solute per liter of solution. Similarly, one mole of CaCl₂ would dissociate into Ca²⁺, Cl⁻ and Cl⁻, and, thus, supplying 3 osmoles.

### Osmolality and Osmolarity

**Osmolality** of a solution refers to the number of osmoles (number of osmotically active particles) dissolved in a kilogram of water. **Osmolarity** refers to the number of osmoles in one liter of plasma.

1. Unlike osmolality, the value in osmolarity is affected by the volume of other solutes in the solution.
2. Osmolarity is also affected by temperature.
3. Though osmotic pressure is determined by osmolality, the difference between osmolality and osmolarity is negligible.
4. Osmolarity is frequently used in physiology for its easy measurement.

### Important Note

**Osmoles determine osmotic pressure:** Note that the important factor determining the osmotic pressure of a solution is the concentration of the particles released in solution (i.e. the osmoles), not the size, shape or charge of the particles.

### Plasma Osmolality

The total sum of all the particles in plasma determine its osmolality, and over 90 per cent of the osmolality of plasma is due to NaCl. The plasma proteins contribute very little, even though their molecules are large in size. The **normal plasma osmolality is 290 mOsm per kg**, out of which 270 mOsm is due to the effect of NaCl.
Measurement of Osmotic Pressure

By Freezing Point Depression

Osmometers are used to measure osmotic pressure. The molar concentration of a solute in a solution determines the osmotic pressure, and also the vapor pressure and freezing point. A nonvolatile solute will depress both the vapor pressure and the freezing point in a predictable manner, which provides the basis for determining the osmotic pressure of a solution by osmometers. One mol per liter depresses the freezing point of water by 1.86°C. For human plasma, the average freezing point is –0.54°C, which corresponds to an osmolality of 290 mOsm/kg.

Tonicity

Tonicity refers to the osmolality of a solution in relation to plasma (same osmotic pressure or freezing-point depression as plasma).

Isotonic
Solutions, which have osmolality same as that of plasma, like 0.9% NaCl, are said to be isotonic.

Hypotonic
Solutions with lower osmolality are said to be hypotonic.

Hypertonic
Solutions with higher osmolality than that of plasma are said to be hypertonic.

The solution of 0.9% NaCl is isotonic, and, therefore, red cells do not change their shape and size in this solution. In hypotonic solutions, red cells undergo osmotic lysis due to endosmosis and in hypertonic solutions, they shrink due to exosmosis (Clinical Box 6.2).

Clinical Box 6.2

Hypersmolal coma: In diabetes, increased plasma osmolality due to very high plasma glucose concentration causes shrinkage of cells. Especially, dehydration of brain cells leads to coma, which is an acute medical emergency. In chronic renal failure, very high urea and creatinine can cause encephalopathy.

A solution may be isotonic initially, but later becomes hypotonic if the osmotically active particles are transferred into the cell or metabolized. For example, 5% glucose solution is isotonic and remains so temporarily when infused intravenously. However, as glucose is rapidly metabolized, the net effect of infusion is like the infusion of a hypotonic solution. Therefore, infusion of normal saline (0.9% NaCl) is preferred in volume depletion, as described above.

Using Van’t Hoff Equation

The osmotic pressure produced by a concentration difference can be calculated by the Van’t Hoff equation, which is: \( p = C \times R \times T \), where \( p \) is the osmotic pressure (mm Hg), \( C \) is the difference in the concentration of particles between the two solutions (mOsm/l), \( R \) is the natural gas constant (62 mm Hg × 1/mmol × °K), and \( T \) represents absolute temperature (°K).

Measuring Equivalent Hydrostatic Pressure

In experimental set up, osmotic pressure can be measured by measuring the hydrostatic pressure applied to prevent water from entering the solution with higher solute concentration.

OTHER TRANSPORT PHENOMENA

Filtration, Bulk Flow and Solvent Drag

Passage of water and solutes through capillary wall is the example of filtration and bulk flow. Capillary wall separates plasma from interstitial fluid. Water moves out of capillaries when the net hydrostatic pressure exceeds net osmotic pressure and from interstitial space into the capillaries when the net osmotic pressure exceeds the net hydrostatic pressure. This is called filtration.

Filtration
Filtration is defined as the process by which fluid is forced through a membrane mainly because of the difference in hydrostatic and oncotic pressures on two sides.

Bulk Flow
When filtration results in movement of greater quantity of water, the process is called bulk flow.

Solvent Drag
During bulk flow of water, it carries with it, dissolved particles (solute), a phenomenon known as solvent drag.

Donnan Effect

Presence of nondiffusible ion on one side of the membrane affects the distribution of other ions to which membrane is permeable. This results in asymmetrical distribution of ions across the cell membrane.

Gibbs-Donnan Effect

The asymmetrical distribution of ions across the cell membrane at equilibrium has the following effects:

i. There will be an electrical difference across the cell membrane whose magnitude can be determined by Nernst equation.

ii. Because of presence of protein anions (prot- ) in the cells, there are more osmotically active particles in the cells than the interstitial fluid. This can lead to osmotic swelling and rupture, which is prevented by Na+-K+ pump that produces net movement of positive charge out of the cell and keeps the inside and outside of the cell in osmotic equilibrium. Thus normal cell volume and pressure depend on Na+-K+ pump.
**Nonionic Diffusion**

Ions are present either in undisassociated (nonionic) or disassociated (ionic) form. In ionic form they can not be easily transported across the cell membrane as membrane is charged. However, in their undisassociated (nonionic) form they diffuse through the membrane easily. This is called **nonionic diffusion**.

1. Many ions in the body pass the membrane in undisassociated form and then, they dissociate to their ionic form once they reach the other side of the membrane.
2. Nonionic diffusion occurs regularly along the epithelial membrane of kidney and GI tract.

**ACTIVE TRANSPORT**

The transport process that utilizes energy and occurs against the gradient is the active transport. By passive transport processes, the composition of intracellular fluid tends to equalize with that of composition of extracellular fluid. However, this should never happen practically, as it threatens cell volume and intracellular solute concentrations that are not compatible with life. Therefore, nature maintains inequality of fluid composition of intracellular and extracellular compartments by providing special transport mechanisms to the cell membrane that oppose these equilibrating transport processes. These transport processes are active processes. In these processes, substances are transported against their chemical and electrical gradients.

There are three common characteristics of active transport mechanisms:

1. **Uphill transport**: The transport occurs against the electrochemical gradient of the substance transported.
2. **Utilize metabolic energy**: Energy utilized for the active transport is derived from the breakdown of ATP. Therefore, mechanisms that prevent the supply of ATP hinder the active transport process. Especially, the process is susceptible to metabolic poisons.
3. **Exhibit saturation kinetics**: Like any carrier-mediated transport, this has also a saturation point for limitation in the rate of availability of carriers and the supply of energy.

There are two types of active transports:

1. Primary active transport
2. Secondary active transport

**Primary Active Transport**

Primary active transport is the transport mechanism that directly utilizes metabolic energy for the transport process. The mechanism is operated by **ion pumps**. The features are:

1. In this process, the solute is transported against its electrochemical gradient with the help of energy.
2. The energy is derived from ATP.

3. The ion pumps hydrolyze ATP to ADP and use energy in the third phosphate bond for the transport process. As the ion pumps hydrolyze ATP, these are also called **ATPases**.
4. The commonly occurring ATPase is **Na⁺–K⁺ ATPase** or **Na⁺–K⁺ pump**.
5. Other common ATPases are **Calcium ATPases**, **H⁺–K⁺ ATPase** and **H⁺-ATPase**. They are classified into P-type (phosphorylation type), V-type (vacular type), F-type (energy coupling factor type) and ABC transporters (Table 6.4).

**CFTR protein**: Cystic fibrosis transmembrane regulator protein involved in genesis of cystic fibrosis; MDR-1 protein: multidrug resistance 1 protein that pumps atrinancer drug out of cancer cell that causes drug resistance in treatment of cancer.

**Na⁺–K⁺ ATPase**

Na⁺–K⁺ ATPase is present in all eukaryotic cells. This is an antiport that pumps K⁺ into the cell and Na⁺ out of the cell against their concentration gradients. This antiport transport system is primarily responsible for maintaining the high K⁺ and low Na⁺ concentration inside the cells.

**Structure and its Functional Aspects**

The Na⁺–K⁺ ATPase is a heterodimeric protein made up of two subunits: an α and a β subunit.

1. The α subunit is larger catalytic subunit with molecular weight of about 100,000 and β subunit is the smaller one (mol. wt. of about 55,000) of unknown functions.
2. At the cytoplasmic side, the α subunit has ATPase activity and binding sites for 3 Na⁺, ATP and phosphate (Fig. 6.8). At the extracellular side, α subunit has binding sites for 2 K⁺ and ouabain.
3. Binding of three ions of Na⁺ and an ATP molecule with the carrier on its intracytoplasmic surface causes hydrolysis of ATP giving rise to ADP and Pi.
4. The phosphate group is bound to an aspartic acid residue of the α subunit.
5. On activation, Na⁺-K⁺ ATPase pumps three Na⁺ ions out of the cell and two K⁺ into the cell. Na⁺-K⁺ pump
catalyzed the hydrolysis of ATP to ADP, and uses this energy to pump three Na\(^+\) out of the cell and two K\(^+\) into the cell for each mole of ATP hydrolyzed. Therefore, Na\(^+\)-K\(^+\) pump is an **electrogenic pump** as it forces net positive charge out of the cell, and it has the coupling ratio of 3/2 (Application Box 6.3).

**Application Box 6.3**

**Importance of electrogenic pump:** Electrogenic pump creates the electrical potential across the membrane, which is the basic requirement in nerve and muscle fiber for transmitting electrical signal.

**Functions**

The Na\(^+\)-K\(^+\) ATPase is a P-type ATPase, as the carrier protein is phosphorylated during the process. It pumps three Na\(^+\) ions out of the cell and two K\(^+\) into the cell. It serves many important cellular functions:

1. **Cytosolic ion concentration:** Na\(^+\)-K\(^+\) pump opposes Na\(^+\) to accumulate in the cell and K\(^+\) to exit from the cell along their concentration gradient. Thus, Na\(^+\)-K\(^+\) pump maintains high concentration of K\(^+\) and low concentration of Na\(^+\) in the cell.
2. **Cell volume:** By maintaining ion concentration on both sides of the cell, Na\(^+\)-K\(^+\) pump regulates water movement across the cell membrane. This maintains intracellular water content and, therefore, the cell volume. Failure of Na\(^+\)-K\(^+\) pump activity can lead to cell swelling and rupture.
3. **Protein synthesis:** The primary function of Na\(^+\)-K\(^+\) pump is to maintain a high intracellular concentration of K\(^+\), which is essential for protein synthesis.
4. **Resting membrane potential:** Na\(^+\)-K\(^+\) pump also maintains resting membrane potential by maintaining ion gradients across the cell membrane.
5. **Hormone actions:** Na\(^+\)-K\(^+\) pump mediates action of many hormones on the cell. Some important examples are thyroxine, aldosterone and insulin.

**Mechanism of Action**

Being a P type ATPase, phosphorylation and dephosphorylation of the carrier protein lead to transfer of ions across the cell membrane.

1. Binding of three Na\(^+\) and one ATP molecule to their respective sites on a subunit activates ATPases that converts ATP to ADP. This causes phosphorylation of a subunit that changes its configuration and transfers 3 Na\(^+\) to ECF. K\(^+\) binds to K\(^+\) binding site on the extracellular surface that causes dephosphorylation of a subunit and transfers two K\(^+\) from ECF into the cell. Thus, three Na\(^+\) are pumped out for entry of two K\(^+\) into the cell, and one ATP is hydrolyzed.

**Scientist contributed**

The Na\(^+\)-K\(^+\) pump was discovered in 1957 by Danish physiologist Prof Jens Christian Skou of Aarhus University, who received the Nobel Prize for his discovery in 1997, which was the culmination of his four decades of research aimed at explaining the mechanism behind this vital motor of the cells. He received the **Nobel Prize in Chemistry** together with Paul D Boyer and John E Walker for his discovery of Na\(^+\)-K\(^+\)ATPase.

**Jens Christian Skou**

(Born: October 1918, Age 97 years)
4. Dephosphorylation, in turn, causes re-conformational change in the α subunit that transfers two K+ from outside to the inside of the cell.
5. Reconformational change of the carrier protein also returns to its original conformation.
6. Thus, during one cycle of conformational (phosphorylation) and re-conformational (dephosphorylation) change in the α subunit of Na+-K+ ATPase, three Na+ ions are pumped out of the cell and two K+ into the cell, and one ATP is hydrolyzed.

**Regulation of Na+-K+ Pump Activity**

**Activation of Na+-K+ Pump**

Many hormones, chemicals and drugs act by increasing Na+-K+ pump activity such as thyroxine, insulin, aldosterone, G-actin, etc.

**Inhibition of Na+-K+ Pump**

Many hormones and chemicals act by decreasing Na+-K+ pump activity such as dopamine, digitalis, metabolic poisons like DNP (2,4 dinitrophenol), etc. (Clinical Box 6.3). Hypoxia and hypothermia inhibit Na+-K+ pump activity.

**Clinical Box 6.3**

Digitalis inhibits Na+-K+ pump: Cardiac glycosides like ouabain, or digitalis that are routinely prescribed in the management of heart failure inhibit Na+-K+ pump by binding to the external surface of the α-subunit and interfering with the hydrolysis of the aspartic acid-phosphate bond. This accumulates Na+ inside the cell and prevents K+ influx. Intracellular accumulation of Na+ decreases Na+ gradient from outside to inside. Calcium efflux through sodium-calcium exchanger in the membrane utilizes sodium gradient. Hence, decreased sodium gradient decreases calcium efflux causing increase in cytosolic calcium concentration that promotes myocardial contractility.

**Other ATPases**

**Ca++ ATPase**

Other common example of primary active transport is the Ca++ pump, which is present in all cell membranes, membrane of endoplasmic reticulum, and sarcoplasmic reticulum in muscle cell.

Main features and functions Ca++ ATPase are:
1. This is a P-type ATPase.
2. The Ca++ pump present on the cell membrane actively transports calcium out of the cell, and, therefore, maintains a higher concentration of calcium in the ECF (10^-3 molar) compared to inside the cell (10^-7 molar).
3. The Ca++ pump present on the membrane of sarcoplasmic reticulum in muscle cell and endoplasmic reticulum in other cells transports calcium out of the cytoplasm into these organelles, and, therefore, maintains a low cytosolic concentration of calcium.
4. Also, it helps in storage of calcium in these organelles for ready availability of it at the time of need like muscle contraction.

**H+-K+ ATPase**

The H+-K+ pump is present on the luminal membrane of parietal cells of stomach and the intercalated cells of the distal nephrons.
1. In stomach, it pumps proton into the gastric lumen in exchange for K+. This is the primary step in HCl secretion in stomach. Thus, it maintains low pH of gastric content which is essential for gastric digestion and killing of micro-organism in the stomach.
2. In kidney, it secretes H+ into the tubular fluid and reabsorbs K+. Hence, it plays an important role in acidification of urine.

**H+ ATPase or Proton ATPase**

The H+ pump or the proton pump is located on the membrane of lysosome, endoplasmic reticulum and mitochondria.

In lysosome and endoplasmic reticulum: It is a V-type ATPase, named for its first discovery in the vacuoles and vesicles of the cells. It pumps H+ (proton) from cytosol into these organelles. Thus, interior of these organelles become more acidic, which is needed for their physiological activities.

In mitochondria: Proton pump is also located in the inner mitochondrial membrane, but it is F-type ATPase in this organelle. Its main function is to synthesize ATP in mitochondria by utilizing energy stored in the proton gradient created by respiratory chain.

**ABC Transporters**

ATP-binding cassette (ABC) transporters belong to members of a superfamily of membrane transport proteins that bind to ATP. The main features are:
1. They have 12 membrane-binding domains.
2. They use energy derived from ATP for transporting a variety of compounds out of the cells, those include ions, steroids, peptides, bile acids, drugs and xenobiotics.
3. As drugs are transported out of the cells, they are known as MDR 1 protein (multidrug resistance 1 protein). Cells that usually express MDR proteins are liver, kidney and GI tract cells.
4. CFTR protein (cystic fibrosis transmembrane regulator protein), a chloride channel protein involved in gene-expression of cystic fibrosis also belongs to this superfamily of ABC transporters (Application Box 6.4).

**Application Box 6.4**

ABC transporters produce drug resistance in cancer cells: ABC transporters cause expulsion of cytotoxic drugs from cancer cells. This decreases effective concentration of drugs in the cells needed for killing cancer cells. Hence, cancer cells become resistant to anticancer chemotherapy. Examples are MDR 1 protein (multi-drug resistance-associated protein 1) and BRCP (breast cancer resistance protein).
Secondary Active Transport

Many cells have several carrier mechanisms that transfer one solute against its concentration gradient by using the energy generated by gradient of another solute. Usually, Na⁺ is the driver solute for most of these mechanisms. Energy created by Na⁺ gradient is utilized for transport of other solutes. The Na⁺ gradient is generated and maintained by Na⁺-K⁺ pump. Though the transport system by itself does not directly utilize energy, it depends on the function of Na⁺-K⁺ pump. Therefore, when the pump is inhibited by a blocking agent, transport process stops.

Typical example of secondary active transport is reabsorption of glucose from the kidney tubule or intestine.

1. The primary active transport of Na⁺ out of the basal and basolateral membranes of the proximal tubules of the nephron and the small intestine by Na⁺-K⁺ pump leads to decreased concentration of Na⁺ in the cytosol of the epithelial cells.
2. This causes facilitated diffusion of Na⁺ from the lumen into the cells.
3. The carrier protein that transfers Na⁺ from the luminal fluid into the cell also transports glucose in the same direction (Fig. 6.10). Thus, the carrier protein is a symport that transports glucose simultaneously with sodium. The symport also transports amino acids and other solutes.

Fig. 6.10: Mechanism of secondary active transport. Na⁺-K⁺ pump located on basolateral membrane actively pumps sodium out of the cell that decreases cytosolic sodium and creates gradient for transport of sodium from lumen into the cell. The carrier protein (symport) that transports sodium also transports glucose into the cell. Thus, transport of glucose from lumen into the cell is the secondary active transport.

Important Note

The carrier protein may also be an antiport: The example of carrier protein being an antiport in secondary active transport is the counter-transporting hydrogen ion in the nephron out of the cell for bringing in sodium (Na⁺-H⁺ exchanger). Another example is Na⁺-Ca²⁺ exchanger in cardiac cell.

4. Since the transport depends on primary active transport of sodium by the Na⁺-K⁺ pump, it is known as a secondary active transport.
5. As the carrier protein for secondary active transport system is an integral membrane protein it exhibits competitive inhibition and saturation kinetics. However, it differs from the usual carrier transport for its exclusive dependence on primary transport mechanism (the pump) and for transporting against its own electrochemical gradient.

VESICULAR TRANSPORT

The transport process that occurs by either fusion of vesicle or formation of vesicle is called as vesicular transport. Fusion of vesicle with the cell membrane occurs in exocytosis and formation of vesicle from the cell membrane occurs in endocytosis. Special utilities of vesicular transport are:
1. Macromolecules such as large protein molecules cannot be transported by diffusion or active transport process. Therefore, they are transferred across the cell membrane mainly by vesicular transport.
2. Amino acids, sugars, waste products of metabolism, cellular secretions, hormones, neurotransmitters and organisms are transported by this mechanism.

Role of Vesicular Transport Proteins

In vesicular transport, formation and transport of vesicles are facilitated by some vesicular transport proteins. These proteins are: clathrin, coating proteins, dynamin and docking proteins.

Clathrin
Clathrin is a fibrillar protein located in the cell membrane beneath the receptor protein. There are two types of clathrins: AP-1 clathrin and AP-2 clathrin. AP-1 clathrin helps in transportation from Golgi apparatus to lysosome and AP-2 clathrin helps in transportation of endosomes.

Coating Proteins (COP)
There are two types of coating proteins: COP I and COP II. Coating proteins help in transportation of vesicles between endoplasmic apparatus and Golgi apparatus.

Dynamin
Dynamin helps in formation of vesicles from cell membrane, especially in clathrin-mediated endocytosis.
Docking Proteins

Before exocytosis of vesicles, docking of vesicles occurs. Docking proteins facilitate attachment of vesicle with membrane. Examples of docking proteins are \textit{V snare protein} and \textit{T snare protein} (For details, refer to the chapter ‘Synaptic Transmission’).

Types of Vesicular Transports

Vesicular transports are of three types: \textit{endocytosis}, \textit{exocytosis} and \textit{transcytosis}.

Endocytosis

Endocytosis is the process of transport in which a \textit{substance is taken into the cell by means of vesicle formation}.

1. A region of plasma membrane is pinched off to form an endocytic vesicle that causes internalization of the substance to the cell.
2. The vesicle may contain fluid and dissolved solutes or particulate material.
3. The size of the vesicle varies from 0.1 µm to 2 µm.

Mechanisms of Endocytosis

Endocytosis occurs by two mechanisms: constitutive and clathrin-mediated.

Constitutive Endocytosis

Endocytosis by \textit{constitutive pathway} occurs in almost all cells. It is called \textit{constitutive} as the process occurs continuously and does not require any specific stimulus. The steps are as follows:
1. The molecule or the substance makes contact with the cell membrane that invaginates to form an endocytic vesicle.
2. The non-cyttoplasmic side of the membrane then fuses and the vesicle is pinched-off into the cytosol.
Thus, it occurs in \textit{two major steps}: formation of vesicle and separation of vesicle from the membrane (Figs. 6.11A and B).

Clathrin-mediated Endocytosis

Clathrin-mediated endocytosis occurs at the specific site of the cell membrane where clathrin accumulates. \textit{Clathrin} is a fibrillar protein molecule having the shape of a \textit{triskelion} (three legs radiating from the central hub). Clathrin is located in the cell membrane beneath the receptor protein. Clathrin-mediated endocytosis occurs in the following steps:
1. The protein and other macromolecules attach to receptors on the membrane surface. Receptors for these molecules are normally concentrated in small pits called \textit{coated pits}, beneath which are located fibrillar proteins called \textit{clathrin}. Contractile filaments like actin and myosin are also attached to the coated pits.
2. The attachment of the macromolecules to the receptors stimulates the invagination of the coated-pit, enclosing the molecule and a small portion of the ECF in the form of a vesicle. Clathrin molecule forms a geometrical array that surrounds the vesicle (Figs. 6.12A to C). Once the vesicle formation is completed, clathrin molecules detach from the vesicle and recycle to the membrane.
3. The endocytic vesicle detaches from the cell membrane.
4. Fusion of the endocytic vesicle with lysosomes that empty their acid hydrolases into the vesicle leading to the digestion of the substances in the vesicle.

Clathrin-mediated endocytosis internalizes not only various organisms, but also substances like growth factors and lipoproteins. Cell membrane also contains \textit{caveolae}. Caveoli are membrane indentations coated with \textit{caveolin}, the protein that facilitates endocytosis of proteins.

Scientist contributed

\textbf{Discovery of receptor-mediated endocytosis:} Anderson is responsible for two discoveries that changed our view of cell physiology: (1) receptor-mediated endocytosis in coated pits and coated vesicles (Anderson et al., 1976; Anderson et al., 1977 a,b); and (2) identification of caveolin, the protein that lines the surface of caveolae (Rothberg et al., 1992).

\textbf{Richard GW Anderson} (1940–2011)

Types of Endocytosis

Endocytosis is of three types: phagocytosis, receptor-mediated endocytosis and pinocytosis.
**Phagocytosis**

Phagocytosis, otherwise called *cell-eating*, is the process of ingestion of large particles or microorganisms by specialized cells called *phagocytes*. In this process, the phagocytic cells, such as macrophages engulf bacteria, foreign particles and tissue debris and digest them. The **phagocytic vesicles** vary from 1–2 µm in diameter. Phagocytosis occurs in three broad steps:

1. Attachment of the foreign molecule with cell membrane.
2. Engulfment of the foreign molecule in the form of endocytic vesicle.
3. Killing of the organism or degradation of the vesicular content.

Phagocytic cells include neutrophils, monocytes, macrophages and other cells of mononuclear phagocyte system (for details of phagocytosis, refer to Chapter on “White Blood Cells” in hematology section)

**Receptor-mediated Endocytosis**

Receptor-mediated endocytosis is an efficient process of endocytosis in which the extracellular molecule binds with the specific receptor on the cell membrane. Special features in this process are:

1. Receptors are concentrated at a depression on membrane called *coated-pits*.
2. Once the external molecule attaches with receptor, the coated-pit pinches off from the membrane in the form of an **endocytic vesicle** causing rapid internalization of the molecule.
3. Hormones, growth factors, transport-proteins like transferrin, toxins, viruses, etc. enter cells by receptor-mediated endocytosis.

**Pinocytosis**

Pinocytosis is the **fluid-phase endocytosis** or ‘cell drinking’ by which substances in solution in extracellular fluid are internalized to the cell. It is a continuous process that occurs in most cells of the body. The stages in pinocytosis are the same as endocytosis except that the endocytic vesicle contains fluid instead of solid particles.

**Exocytosis**

Exocytosis is the process of export from the cell, which is reverse of endocytosis. By exocytosis, hormones, neurotransmitters, digestive enzymes and undigested foreign particles are released from cells. The steps of exocytosis are:

1. Before exocytosis, the molecules are synthesized in endoplasmic reticulum and packaged in Golgi apparatus to form the **transport vesicles**.
2. The vesicles then move to the cell surface and fuse with the cell membrane.
3. Release the content to ECF (Figs. 6.13A and B), which requires ATP and Ca$^{2+}$.

**Emiocytosis** is the term referring to exocytosis of specific hormones and granules.

**Mechanism of Exocytosis**

Exocytosis occurs in two pathways: **constitutive** and **regulated**.

**Constitutive Exocytosis**

This type of exocytosis is seen in almost all cells. By this mechanism, some proteins are continuously secreted by the cells. For example, secretion of mucus by goblet cells of small intestine.

**Regulated Exocytosis**

In regulatory exocytosis, macromolecules that are stored in the vesicles fuse with cell membrane and release their content in response to specific extracellular stimulus. This is the major mechanism of rapid secretion of hormones, neurotransmitters and digestive enzymes in response to specific stimuli. This is also called **non-constitutive exocytosis**.
Transcytosis
When vesicular transport is limited within the cell, the process is called transcytosis or cytopemisis. Vesicles are formed within the cell and transported in the cytoplasm.

TRANSPORT ACROSS THE EPITHELIUM
Epithelium is a layer of cells present on the basement membrane. Two special features of epithelium make it permeable to various solutes.

1. First, the basolateral membrane contains active transport systems that create gradients for transfer of ions from apical membrane, and various uniports and antiports that regulate exchange of other ions.
2. Second, tight junctions between cells allow selective ions to pass through and prevent large molecules like proteins to be transferred.

Thus, there are two mechanisms for transport across the epithelia:

a. **Transcellular transport** or transport through the cell i.e. from lumen through apical surface into the cytosol and from there through basolateral space or through basal membrane into the interstitial fluid.

b. **Paracellular transport**, which means transport through tight junctions between the cells bypassing the transport through cells (Fig. 6.14).

Reabsorption of sodium and glucose in kidney tubule and intestine is the example of transport across the epithelia.

Ultrafiltration through the glomerular capillary endothelium and Bowman’s capsule epithelium is a special transport mechanism through epithelia. However, in ultrafiltration, transfer of substances occurs mainly due to the difference in pressures across the epithelium.

CHAPTER SUMMARY

**Carrier Proteins**
There are three different types of carrier proteins: uniport, symport and antiport.

- **Uniport**: Uniport is the carrier protein that transports only one substance. For example, Na⁺ channels transport Na⁺ and K⁺ channels transport K⁺.
- **Symport**: Symport carriers transport two or more substances from one side of the membrane to the other in the same direction. Transport of Na⁺ and glucose from the lumen of the intestine or kidney tubule into the epithelial cells through the same carrier protein is the example.
- **Antiport**: Antiport carriers transport substances in opposite directions in which one substance is transported to the inside of the cell and other substance from inside the cell to the outside. Examples of antiport are Na⁺-K⁺ pump and Na⁺-H⁺ exchanger.

**Transport Processes**
Broadly they are of 2 types: Passive transport and active transport

- **Passive Transports**: Have two common features. 1. Transport is downhill (down the electrochemical gradient), and 2. Does not require metabolic energy (ATP is not utilized). Diffusion and osmosis are examples of passive transport.
- **Active Transport**: Active transport utilizes energy. The common features are: 1. Uphill transport (against the electrochemical gradient); 2. Requires energy; and 3. Exhibits saturation kinetics.
The active transport processes are of two types: primary active transport, and secondary active transport. Na⁺-K⁺ pump is the prototype of primary active transport. When a transport system by itself does not directly utilize energy, but depends on the function of a primary active pump (Na⁺-K⁺ pump), the process is called secondary active transport (SAT). Reabsorption of glucose from the kidney tubule or intestine is an example of SAT.

**Vesicular Transport**

The transport process that occurs by either fusion of vesicle or formation of vesicle is called vesicular transport. Fusion of vesicle with the cell membrane occurs in exocytosis and formation of vesicle from the cell membrane occurs in endocytosis. Macromolecules such as large protein molecules that can not be transported by diffusion or active transport process are transported by vesicular transport. Amino acids, sugars, waste products of metabolism, cellular secretions, hormones, neurotransmitters and organisms are transported by this mechanism.

**Important to Know (Must Read)**

In final examination, Long Questions are asked on ‘Passive transport processes (diffusion, facilitated diffusion, osmosis)’ or ‘Active transport mechanisms’.

Carrier proteins, facilitated diffusion, Gibb-Donnan effect, Na⁺-K⁺ pump, secondary active transport, exocytosis, endocytosis, are usually asked as Short Note Question in exams.

In viva, examiners usually ask about different types of ion channels in the membrane, types of gating of ion channels, patch-clamping, examples of uniport, symport and antiport, factors affecting diffusion, examples of facilitated diffusion, osmotic pressure, definitions of osmolality and osmolarity, definitions and examples of filtration, bulk flow and solvent drag, Donnan effect, structure and function of Na⁺-K⁺ ATPase, other ATPases, vesicular transport proteins, types of endocytosis and exocytosis with examples, definition of Transcytosis.
Chapter 7
Membrane Potential

Learning Objectives
On completion of study of this chapter, the student MUST be able to:
1. Understand the concept of resting membrane potential (RMP).
2. Explain the mechanism of genesis and maintenance of RMP.
3. Give the normal values of RMP of different excitable tissues and equilibrium potential of important ions.

The student MAY also be able to:
1. Explain the concept of Gibbs-Donnan Equilibrium.
2. Explain the concept of Nernst Equation.
4. Give the principle of recording of RMP.

An electrical potential difference exists across the membrane of all living cells with the inside being negative in relation to the outside. This potential difference is called membrane potential as ions arrange themselves along the outer and inner surfaces of the cell membrane. At resting state of the cell, the membrane potential is called resting membrane potential (RMP). RMP is also called transmembrane potential. Special features of RMP are:
1. The RMP is different in different tissues (Table 7.1).
2. In a nerve cell, the RMP is −70 mV.
3. When the neuron is stimulated, membrane potential changes and inside of the cell becomes positive due to depolarization. The membrane potential during this state of activation is called action potential.
4. RMP plays an important role in deciding the degree and duration of action potential, as the RMP is the level from where the phase of depolarization starts.
5. In some tissues like visceral smooth muscles, RMP is not stable (fluctuates).

Table 7.1: RMP of important excitable tissues.

Selective Permeability of the Membrane
The cell membrane is selectively permeable to ions and other solute particles. Some ions are highly permeable, some are less permeable and others are impermeable. The permeability mainly depends on the molecular weight and the radius of ions in their hydrated form (Table 7.2).
1. Though the ions like Na⁺, K⁺, Cl⁻ and HCO₃⁻ are diffusible through the membrane, the permeability is more for K⁺.

Concepts and Physiological Aspects
Membrane potential is mainly due to distribution of ions across the cell membrane, which results mainly from the selective permeability of the cell membrane to various ions at rest. However, this is influenced by various forces acting on the ion distribution. Understanding the following concepts help the students to learn the physiology of RMP:
1. Selective permeability of the cell membrane to various ions
2. Gibbs-Donnan equilibrium
3. Nernst equation
2. Though the particle size of K⁺ is large (atomic weight 39) as compared to Na⁺ (atomic weight 23), the permeability for K⁺ is 500 to 1000 times greater than that for Na⁺ for its effective radius.

3. The membrane is practically impermeable to intracellular proteins and organic phosphates.

**Gibbs-Donnan Membrane Equilibrium**

When two solutions containing ions are separated by a semipermeable membrane, at equilibrium, each solution will be electrically neutral. That means, the total quantity of cations will be equal to total quantity of anions. Also, the product of diffusible ions on one side of the membrane will be equal to product of diffusible ions on the other side of the membrane. This is called Gibbs-Donnan membrane equilibrium.

For example, two solutions A and B containing sodium and chloride ions are separated by a semipermeable membrane. Then, according to Gibbs-Donnan equilibrium, each solution should be electrically neutral (Fig. 7.1), which means:

\[
\text{(cations)}_A = \text{(anions)}_A \quad \text{and} \quad \text{(cations)}_B = \text{(anions)}_B
\]

or

\[
(\text{Na}^+)_{A} = (\text{Cl}^-)_A \quad \text{and} \quad (\text{Na}^+)_{B} = (\text{Cl}^-)_B
\]

The product of diffusible ions on both sides will also be equal, which means,

\[
(\text{diffusible cations})_A \times (\text{diffusible anions})_A = (\text{diffusible cations})_B \times (\text{diffusible anions})_B
\]

or

\[
[(\text{Na}^+)_{A} \times (\text{Cl}^-)_A] = [(\text{Na}^+)_{B} \times (\text{Cl}^-)_B]
\]

Thus, the ratio of diffusible ions will be:

\[
\frac{(\text{Diffusible cations})_{A}}{(\text{Diffusible cations})_{B}} = \frac{(\text{Diffusible anions})_{B}}{(\text{Diffusible anions})_{A}}
\]

or

\[
\frac{[\text{Na}^+]_{A}}{[\text{Na}^+]_{B}} = \frac{[\text{Cl}^-]_{A}}{[\text{Cl}^-]_{B}}
\]

Thus, there will be equal and balanced distribution of ions at equilibrium. However, when a non-diffusible ion 'X' is added on one side (let us say, side A), then as per Gibbs-Donnan equilibrium principle, the distribution of diffusible ions will change to maintain electroneutrality of both sides (Fig. 7.2).

**Nernst Equation**

As described above, in accordance with Gibbs-Donnan equilibrium, asymmetrical distribution of diffusible ions occurs across the cell membrane with more cation (K⁺) present inside. Therefore, K⁺ will try to diffuse into the ECF from ICF, which is opposed by the electrical gradient, created by presence of non-diffusible anions inside the cell. Thus, finally equilibrium is reached between the concentration gradient and the electrical gradient resulting in diffusion potential (equilibrium potential) across the cell membrane.

The degree of this equilibrium potential is determined by Nernst equation:

\[
E_{(m)} = \frac{RT}{2F} \ln \frac{\text{(Conc)}_A}{\text{(Conc)}_B}
\]
Section 1: General Physiology

Where,

\( E_{(m)} \): Equilibrium potential (in millivolts) of the ions at which efflux and influx of the ions are equal

\( R \): The natural gas constant (8.316 joules/degree).

\( T \): The absolute temperature

\( F \): The faraday constant (Number of coulomb/mole of charge = 96,500 coulomb/mole)

\( Z \): The valency of the ion

\( \ln \): Natural logarithm

\( \text{(Conc)}_i \): The concentration of the ions in the intracellular fluid

\( \text{(Conc)}_o \): The concentration of the ions in the extracellular fluid

At normal body temperature (37°C), converting from the natural log to the base 10 log and replacing some of the constants with numerical values, the equation can be simplified to:

\[ E_{(m)} = \pm 61 \log \left( \frac{\text{(Conc)}_i}{\text{(Conc)}_o} \right) \]

Thus, Nernst equation helps in calculating the equilibrium potential for each ion individually (Table 7.3).

---

**Goldman-Hodgkin-Katz Equation**

The magnitude of the membrane potential at any given time depends on the distribution of \( Na^+ \), \( K^+ \) and \( Cl^- \) and on the permeability of each of these ions. The role of different ions in the generation of membrane potential is accurately described by Goldman-Hodgkin-Katz (GHK) equation or also called Goldman’s constant field equation.

\[ V = \frac{RT}{F} \ln \left( \frac{P_{K^+}[K^+]_o + P_{Na^+}[Na^+]_o + P_{Cl^-}[Cl^-]_o}{P_{K^+}[K^+]_i + P_{Na^+}[Na^+]_i + P_{Cl^-}[Cl^-]_i} \right) \]

Where,

\( V \): membrane potential,

\( R \): gas constant,

\( T \): absolute temperature,

\( F \): Faraday constant,

\( \ln \): natural logarithm

\( P_{K^+}, P_{Na^+}, P_{Cl^-} \): permeabilities of the membrane to \( K^+, Na^+ \) and \( Cl^- \), and \( i \) and \( o \) refer to inside and outside of the cell respectively.

---

**Scientists contributed**

Sir John Carew Eccles, Alan Lloyd Hodgkin and Andrew Fielding Huxley

The Nobel Prize in Physiology or Medicine 1963 was awarded jointly to **Sir John Carew Eccles, Alan Lloyd Hodgkin and Andrew Fielding Huxley** for their discoveries concerning the ionic mechanisms involved in excitation and inhibition in the peripheral and central portions of the nerve cell membrane.

---

**Importance of Goldman Constant Field Equation**

1. Important ions that generate membrane potentials in nerve and muscle fibers are sodium, potassium and chloride. The voltage of membrane potential is determined by the concentration gradient of each of these ions.

2. The relativity of importance of each ion in determination of the voltage depends upon the membrane permeability of individual ion.

---

**Fig. 7.2:** When nondiffusible anion (\( X^- \)) is added to the solution A, more \( Cl^- \) is transferred to B to maintain balance of anion on both sides. Consequently, more \( Na^+ \) is transferred to solution A to maintain electroneutrality of both sides.

---

**Walther H Nernst**

*Born in Briesen, West Prussia, on June 25, 1864, notable for the development of the Nernst equation and winner of 1920 Nobel Prize in chemistry, was a major contributor to the study of membrane potential. He developed the Nernst equation to solve for the equilibrium potential for a specific ion. Goldman, Hodgkin and Katz furthered the study of membrane potential by developing the Goldman-Hodgkin-Katz equation to account for any ion that might permeate the membrane and affect its potential. The study of membrane potential utilizes electrochemistry and physiology to formulate a conclusive idea of how charges are separated across a membrane.*
Chapter 7: Membrane Potential

3. Cation concentration from inside the membrane to outside is responsible for electronegativity inside the membrane. Due to concentration gradient, cations diffuse to outside of the cell leaving the non-diffusible anions inside the cell.

GENESIS OF RMP

Resting membrane potential (RMP) is the membrane potential at rest. In neurons, the RMP is –70 mV.

The RMP is created due to following factors.

1. Permeability of the membrane to K⁺: Normally, K⁺ is more inside and less outside the cell (see Table 7.3). Therefore, a concentration gradient exists for K⁺ from inside to outside that facilitates K⁺ to diffuse out of the cell. At rest, permeability of the membrane to K⁺ is higher than any other ion. Therefore, K⁺ easily diffuses out of the cell (Fig. 7.3), though this is opposed by the electrical gradient. As, K⁺ is the major intracellular cation, its diffusion creates negativity inside the cell. The permeability of the membrane to K⁺ is the major cause of RMP.

2. Permeability of the membrane to Na⁺: At rest, ECF Na⁺ is more than the ICF Na⁺. Therefore, there is a concentration gradient for Na⁺ from outside to inside, for which Na⁺ diffuses into the cell. However, at rest membrane is less permeable to Na⁺ (Fig. 7.3) than to K⁺. Therefore, K⁺ exit is not balanced by Na⁺ entry (more K⁺ goes out). Hence, interior of the cell remains relatively negative.

3. Permeability to anions: Exit of more cations from the cell should be accompanied by proportionate exit of anion to maintain electroneutrality. However, exit of K⁺ (the cation) is not accompanied by exit of same amount of anions as permeability of anions at rest is also not same as that of K⁺. Therefore, more negative ions remain inside.

4. Role of Na⁺-K⁺ pump: The role of Na⁺-K⁺ pump is to maintain RMP rather than to generate it. However, Na⁺-K⁺ pump also contributes to the genesis of RMP, as it is an electrogenic pump. It pumps out three Na⁺ for two K⁺ to come in. Therefore, it pumps more cations out of the cell and less into the cell. Thus, less cations are taken inside, which in other words, a relatively negativity is created inside (Application Box 7.1).

Application Box 7.1

Negativity is only along the membrane: It should be noted that the number of ions that are responsible for membrane potential is a very small fraction of the total number of ions actually present inside the cell. In the cell, the cations and anions are present in equal proportion except along the membrane. Therefore, negativity is created and maintained only close to the membrane.

Maintenance of RMP

K⁺ diffusing out of the cell and Na⁺ diffusing into the cell will come to halt once the concentration gradient ceases to exist for both the ions. However, that does not happen, as Na⁺-K⁺ ATPase helps in building the concentration gradient. It serves to pump back the Na⁺ that diffuses into the cell and K⁺ that diffuses out of the cell. Thus, Na⁺-K⁺ pump plays an important role in maintaining RMP.

Recording of Membrane Potential

The membrane potential is recorded like recording of activity of any excitable tissue. This requires:

1. Microelectrodes
2. Electronic amplifiers
3. Cathode ray oscilloscope (CRO).

Basic Principle

Two microelectrodes are placed on the surface of a nerve fiber and connected to a CRO. When, one of the
Resting membrane potential (RMP) is the membrane potential at rest, which is created mainly by the permeability of the membrane to K⁺, and contribution of other factors are minimal.

1. **Permeability of the membrane to K⁺**: At rest, permeability of the membrane to K⁺ is higher than any other ion. Therefore, K⁺ easily diffuses out of the cell, though this is opposed by the electrical gradient. As, K⁺ is the major intracellular cation, its diffusion creates negativity inside the cell. The permeability of the membrane to K⁺ is the major cause of RMP.

2. **Permeability of the membrane to Na⁺**: At rest, membrane is less permeable to Na⁺. Therefore, K⁺ exit is not balanced by Na⁺ entry (more K⁺ goes out). Hence, interior of the cell remains relatively negative.

3. **Role of Na⁺-K⁺ pump**: The role of Na⁺-K⁺ pump is to maintain RMP rather than to generate it. However, Na⁺-K⁺ pump also contributes to the genesis of RMP, as it is an electrogenic pump. It pumps out three Na⁺ for two K⁺ to come in. Thus, less cations are taken inside, which in other words, a relatively negativity is created inside.

**Important to Know (Must Read)**

1. In examinations, when students are asked about the mechanism of RMP, promptly they answer the role of Na⁺-K⁺ pump, and this is wrong. They should answer that it is the permeability of the membrane to K⁺ that mainly contributes to the genesis of RMP.

2. Resting membrane potential comes usually as Short Note/Question in final exam.

3. In Viva, examiners usually ask about the genesis of RMP, and sometimes about the application of Nernst equation, Gibbs-Donnan equilibrium, and Hodgkin-Katz equation.
Body Fluids

Functions of cells depend on fluids present both outside and inside the cells. Unicellular organisms float in water or air and exchange their nutrients, waste products and gasses through their body surface, i.e., the cell membrane. However, multicellular organisms, especially organisms with complex body systems have no direct access to their immediate environment, and therefore, they contact outer environment through interstitial fluid and transport systems of their body. Therefore, body fluid is compartmentalized into intracellular and extracellular fluids in complex organisms. The body compositions and distribution of fluid in different compartment are as follows:

1. The body composition of a normal adult male on average consists of 15% fat, 18% proteins, 7% minerals and 60% water.
2. The total body water (TBW) as percentage of body weight on average is about 60% in adult males, which is about 10% more than adult females (Table 8.1).
3. In infants and children, though TBW as percentage of body weight is more than in adults, their absolute water content is significantly less.
4. In elderly people in both the sexes, TBW is about 10% less than their adult counterparts.
5. In females, TBW is less than males due to relatively greater amount of adipose tissue (subcutaneous fat) in them.

Of total body water, about two-third is present in intracellular compartment and one-third in extracellular compartment (Table 8.2).

**BODY FLUID COMPARTMENTS**

**Extracellular Fluid Compartment**

Fluid present in the spaces outside the cell constitutes extracellular fluid (ECF) compartment. This includes plasma, interstitial fluid and transcellular fluid.

**Plasma**

Plasma is the fluid part of the blood. It constitutes about 25% of the ECF, which is about 5% of the total body weight (Table 8.3).

Volume of plasma can be calculated from blood volume and PCV (packed cell volume) as:

\[
\text{Plasma volume} = \text{Blood volume} \times \frac{100 \text{ – Hematocrit}}{100}
\]

**Blood Volume and Red Cell Volume**

**Blood volume** is the plasma volume and blood cell volume. It is about 80 ml/kg of body weight or 8% of the total body weight.

### Clinical Box 8.1

**Dehydration is common and rapid in children:** Ratio of ECF volume to ICF volume is larger in infants and children than in adults. However, the total volume of ECF is much smaller in children than in adults. In addition, the regulatory mechanisms for maintaining ECF volume are not well developed in infants and children. Therefore, dehydration is more common and occurs rapidly in these age groups.

### Interstitial Fluid

It is ECF volume present in the space between the cells (ECF outside the vascular system). Interstitial fluid surrounds all cells except blood cells and includes lymph (lymph constitutes 2–3% of the total body weight). It is in constant motion throughout the body and is exchanged rapidly with the circulating blood.
1. Interstitial fluid volume is about 15% of body weight.
2. It can not be measured directly as substances used for it rapidly equilibrate with plasma.
3. It is calculated by subtracting plasma volume from ECF volume.

### Transcellular Fluid

Transcellular fluid represents fluid in the lumen of structures lined by epithelium.
1. It includes fluid in the secretion of exocrine digestive glands, cerebrospinal fluid (CSF), pleural, peritoneal, synovial and pericardial fluids, intraocular (aqueous and vitreous humors) fluids, bile, luminal fluids of the gut and fluid in the cochlea and kidney tubules.

### Intracellular Fluid Compartment

Intracellular fluid (ICF) is the fluid contained within the cells of the body. It constitutes about two-thirds of total fluid of the body. It can not be measured directly. It is measured by subtracting ECF volume from total fluid volume.

### MEASUREMENT OF BODY FLUID VOLUMES

**General Principle**

The volume of fluid compartment is usually measured by the *indicator dilution principle*, which is based on the following relationship:

\[ C = \frac{A}{V} \quad \text{i.e.,} \quad V = \frac{A}{C} \]

Where, A is the amount of a substance injected intravenously, V is the volume in which the substance is distributed and C is the final concentration attained.

**Characteristics of an Indicator**

1. Should be relatively easy to measure.
2. Should remain in the compartment being measured.
3. Should not change the fluid distribution in the compartment being measured.
4. Should be non-toxic.
5. Must mix evenly throughout the compartment being measured.
6. Should remain unchanged by the body during the mixing period or the amount changed must be known.

**Principle of Measurement**

Size of fluid compartment is measured by injecting a substance and then calculating the volume of fluid in which the test substance is distributed. This is called the *volume distribution* of the injected substance, which is equal to the amount injected divided by concentration of the substance in the sample.

If indicator *leaves the compartment by excretion or metabolism* during the time allowed for mixing, then calculation is done as follows:
Volume distribution = \frac{\text{Amount injected} - \text{Amount removed}}{\text{Final concentration of the substance}}

**Measurement of ECF Volume**

The ECF volume is difficult to measure, as the limit of this space is ill-defined, and few substances mix rapidly in all parts of the space while remaining exclusively extracellular.

**Methods of Measurement**

ECF volume is measured by volume distribution principle using inulin, a polysaccharide having molecular weight of 5200.

1. **Radioactive inulin** is prepared by substituting $^{14}$C for one of the carbon atoms of the molecule. Radioactive inulin levels are easily determined by counting the samples with suitable radiation detectors.

2. Also $^{36}$Cl, $^{38}$Cl, $^{82}$Br, mannitol and sucrose are used for measurement of ECF volume.

3. Cl$^-$ is largely extracellular. Therefore, radioactive isotopes of Cl$^-$ ($^{36}$Cl and $^{38}$Cl) are used for the purpose. However, ECF volume determined by using Cl$^-$ is greater than actual volume as some Cl$^-$ is also present in intracellular fluid.

4. $^{82}$Br, sulphate, thiosulphate, thiocyanate and ferrocyanide are also used for measuring ECF volume. As these ions interchange with Cl$^-$ in the body, they determine greater values for ECF.

5. Mannitol and sucrose have also been used to measure ECF volume.

**Measurement of Plasma Volume**

Plasma volume is measured by two dilution methods.

**First Method:** In the first method, the substance used neither leaves the vascular system nor penetrates red cells. Examples are:

i. **Evans Blue Dye** (T-1824) that remains bound to plasma proteins.

ii. **Radio-iodinated human serum albumin** (RISA) i.e. serum albumin labeled with radioactive iodine. It slowly escapes from circulation into the interstitial fluid. Suitable sample of injected solution and plasma samples obtained after injection are counted in a scintillation counter.

iii. **Radio-iodinated gamma globulin and fibrinogen.** These substances generally do not leak out of the blood stream.

**Second Method:** In the second method, **radio-isotopes of phosphorus ($^{32}$P), iron ($^{55,59}$Fe) and chromium ($^{51}$Cr)** are used that penetrate and bind to red cells. Therefore, the red cells volume, i.e. volume occupied by all the circulating RBCs in the body can be measured by injecting tagged red cells intravenously. After thorough mixing has occurred, fraction of the RBCs that is tagged is measured.

The red cell volume, i.e. volume occupied by all the red cells (RBCs), is measured by injecting tagged red cells intravenously. After thorough mixing has occurred, fraction of the RBCs that is tagged is measured.

Commonly used tag is $^{51}$Cr, which is attached to the red cells by incubating in a suitable ‘Cr’ solution. Then, plasma volume is calculated by using the formula:

\[
\text{Plasma volume} = \frac{100 - \text{PCV}}{100} \times \text{Blood volume}
\]

(PCV is packed cell volume, which is practically the red cell volume).

**Measurement of Interstitial Fluid Volume**

Interstitial fluid volume cannot be measured directly as it is difficult to sample and no substance penetrates exclusively in this compartment. Substance that equilibrates in interstitial fluid also equilibrates in plasma. Therefore, the interstitial fluid volume is estimated as the difference between ECF volume and plasma volume.

**Measurement of ICF Volume**

Intracellular fluid volume (ICFV) cannot be measured directly by dilution principle as no substance remains confined only to this compartment. It is determined indirectly by subtracting ECF volume from total body water (TBW). Thus, first TBW is measured.

**Measurement of TBW**

Measurement of TBW is performed by indicator dilution principle:

1. **Deuterium oxide** ($^{2}$H$_2$O, heavy water) is usually used as it has properties that are slightly different from H$_2$O. However, in equilibration experiments for measuring TBW, it gives accurate results.

2. **Tritium oxide** and aminopyrine can also be used for measuring TBW.

Measurement of red cell volume, plasma volume effective blood volume is described in next chapter.

**IONIC COMPOSITION OF BODY FLUIDS**

**Basic Features**

1. The distribution of electrolytes varies in body compartments.

2. Sum of the concentrations of the cations equals the sum of the concentrations of the anions in respective compartments. This makes the fluid in each compartment electrically neutral.

3. Na$^+$, Ca$^{2+}$, Cl$^-$ and HCO$_3^-$ are largely extracellular (Table 8.4) and K$^+$, Mg$^{2+}$, organic phosphates (PO$_4^{3-}$) and proteins (prot$^-$) are mainly intracellular.

4. Essentially, almost all the K$^+$ in the body is in the exchangeable pool, whereas only 65%–70% of the body Na$^+$ is exchangeable. Solutes that are exchangeable are osmotically active.

5. Almost all of the body Ca$^{2+}$ (in bone) and most of the body Mg$^{2+}$ (in bone and cells) are nonexchangeable.
CHAPTER SUMMARY

Key Concepts

1. Total body water (TBW) as percentage of body weight on average is about 60% in adult males, which is about 10% more than in females.
2. In infants and children, though TBW as percentage of body weight is more than in adults, their absolute water content is significantly less. Therefore, dehydration occurs faster and often may be fatal, if not treated early and adequately.
3. Measurement of body fluid volume is based on ‘indicator dilution principle’.

Equivalents

The equivalent is the standard unit for expressing the solutes in the body which are in the form of charged particles. One equivalent (Eq) is 1 mole of an ionized substance divided by its valency. One mole of KCl dissociates into 1 Eq of K⁺ and 1 Eq of Cl⁻. One Eq of K⁺ = 39 gm/1 = 39 gm; whereas 1 Eq Ca²⁺ = 40 gm/2 = 20 gm. The milliequivalent (mEq) is 1/1000 of 1 Eq.

The normality (N) of a solution is the number of gram equivalents in 1 liter. Therefore, 1 N solution of hydrochloric acid (HCl) contains 1 + 35.5 gm/L = 36.5 gm/L.

Osmolarity and Osmolality

The number of osmoles per liter of solution is called osmolarity, whereas the number of osmoles per kilogram of solvent is osmolality. Osmotically active substances in the body are dissolved in water. As the density of water is 1, osmolar concentration is expressed in osmoles per liter (Osm/L) of water. Details of osmole, milliosmole, osmolarity and osmolality are described in Chapter 6, under ‘Osmosis’. Regulation of composition, osmolality and volume of body fluid and the related applied physiology are described in in chapter “Regulation of volume, osmolality and composition of body fluid compartments”, in Volume II, Section 13 (Integrative Physiology).

pH of Body Fluids

The hydrogen ion concentration of body fluids is expressed as H⁺ or pH (negative logarithm of H⁺).

pH = –log₁₀[H⁺].

1. When pK (K is the ionization or dissociation constant) of a buffer system is known, it is possible to determine the effective pH range of the buffer. Hence, pK = negative log of K (–log K) and is equal to the pH at which half of the acid molecules are dissociated and half are undisassociated.
2. Blood pH is 7.35–7.45, at the range of H⁺ conc. 20–126 mEq/L.
3. Acidosis refers to blood < 7.35 and alkalosis refers to blood > 4.45.

Concept and mechanism of pH-buffer system and acid-base balance are described in detail last section of the book “Integrative Physiology” in chapter ‘Basic principle of acid-base homeostasis’.

Units for Measuring Solutes

The number of molecules, electrical charges, or particles of a substance per unit volume of a particular body fluid is frequently expressed in moles, equivalents or osmoles.

Moles

The mole is the standard unit for expressing the amount of substances in the SI unit system. A mole is the gram-molecular weight of a substance, i.e. the molecular weight of a substance, in grams. Each mole (mol) consists of approx. 6 × 10²³ molecules. Thus, 1 mole of KCl = 39 + 35.5 gm = 74.5 gm (i.e. sum of atomic masses of all the atoms in the molecule).

The millimole (mmol) is 1/1000 of a mole. Thus, 1 mmol of KCl = 74.5 mg.

The concepts are:

1. The concentrations of two different substances on the basis of number of grams per liter of solution do not indicate how many molecules of each compound are present. Therefore, concentrations in units of grams per liter are often used when the chemical structure of the solute is unknown.
2. When the structure of a molecule is known, concentrations are expressed as moles per liter. This provides a unit of concentration based upon the number of molecules of the solute in solution. Thus a solution containing 74.5 gm of KCl in 1 liter of solution is said to be one-molar (1M or 1 mol/L) solution of KCl.
3. Since 1 mole of any molecule will have the same number of molecules (6 × 10²³), 1M solution of KCl contains the same number of solute molecules per liter as 1M solution of glucose or any other substance.
4. K\(^+\) is more in ICF (140 mmol/L of water) and less in ECF (5 mmol/L of water), whereas Na\(^+\) is less in ICF (12 mmol/L of water) and more in ECF (145 mmol/L of water).

**Points to be Noted (Must Read)**

1. Measurements of plasma volume, blood volume and ECF volume are usually asked in written examinations.
2. In *Viva*, questions from the following topics/concepts are asked:
   - % of total body water in males and females in different age groups.
   - Principle of measurement of fluid volumes (indicator dilution principle).
   - Characteristics of an indicator.
   - Basic method of measurement of ECF and ICF.
   - Different isotopes/dyes used for measuring different fluid volumes.
   - Why is dehydration common in children?
   - Concept of moles, osmoles, equivalents, osmolality and osmolarity.

20. Platelets and Their Role in Hemostasis
“The spirit shall look out through Matter’s gaze
And Matter shall reveal the Spirit’s face
Then man and superman shall be at one
And all the earth become a single life.”

Sri Aurobindo (in ‘SAVITRI’)
Hematological investigations are commonly performed laboratory tests in medical practice because many bodily dysfunctions reflect through alteration in blood even in their early stage and hematological changes are reliable indices of the intensity and progress of the diseases. Moreover, blood is an easily accessible and readily available tissue sample for investigations, and many blood tests can be performed in physician’s office. Therefore, examination of blood is common and an essential component in patient management. Therefore, a student of medicine should have adequate knowledge in physiology of blood.

**Hematology** is the study of physiology of blood and blood disorders. Study of blood physiology includes the study of different components of blood, their formation, their role in different body functions and dysfunctions, and study of blood disorders includes the pathophysiology of diseases of blood and their management, and pathological alterations in blood in other (non-hematological) diseases.

Blood examination reveals two fundamental aspects of hematology:

1. If the bone marrow is producing adequate number of mature cells of hematopoietic lineages
2. If development of each hematopoietic lineage is qualitatively normal.

Though investigations on peripheral blood by different blood counts and smear examination help to answer these two major questions, study of bone marrow provides a better picture of the disease and adds to hematological diagnosis.

**BLOOD**

Blood is defined as liquid connective tissue that fills the heart and blood vessels. The normal blood volume in an average adult is 5–6 liters, which accounts for about 8% of the body weight.

**Composition of Blood**

Blood consists of two components: cells and fluid. The cellular component comprises of different formed elements, and the fluid component is the plasma.

1. The **formed elements** are red blood cells (erythrocytes), white blood cells (leucocytes), and platelets (thrombocytes).
2. The **plasma** consists of about 55% of the total blood volume which is made up of water and solid particles. When blood is collected in an anticoagulated tube and allowed to settle by centrifugation, **three layers** are
distinctly visible. The upper plasma layer is separated from lower red cell mass by a thin buffy coat (Fig. 9.1).

**Buffy Coat**

The thin middle layer that separates the upper plasma and lower red cell mass after centrifugation of blood is the buffy coat.

1. The buffy coat contains leucocytes and platelets.
2. In diseases, abnormal cells are found in the buffy coat like LE cells in systemic lupus erythematosus and atypical or primitive blood cells (atypical mononuclear cells, promyelocytes, metamyelocytes, blast cells, megakaryocytes etc.) in malignant or premalignant conditions (Clinical Box 9.1).

**Clinical Box 9.1**

**Buffy coat preparation:** The blood film may be prepared from buffy coat for the detection of the abnormal cells in blood. Also, buffy coat preparation is very useful for the detection of bacteria, fungi or parasites within neutrophils, monocytes or circulating macrophages.

**Functions of Blood**

1. **Respiratory functions:** Blood transports oxygen from lungs to tissues, and carbon dioxide from tissues to the lungs. Thus, by transporting gases blood serves an important function of respiration.
2. **Transport medium:** Blood acts as the transport medium for various hormones, chemical substances, nutrients, vitamins, etc. Hormones secreted from various endocrine tissues, and nutrients absorbed from GI tract circulate in blood and distribute to all tissues of the body. Thus, blood regulates growth and metabolism of the tissues.
3. **Temperature regulation:** Blood plays an important role in temperature regulation as it conducts heat from the interior of body to the surface through blood vessels. Temperature is continuously produced in the body. Blood absorbs this heat and transfers to the body surface. Therefore, vasoconstriction preserves body temperature and vasodilation facilitates heat dissipation from the body.
4. **Excretory function:** Blood helps in excretion of waste materials by transporting them from different parts of the body to the kidney.
5. **Water homeostasis:** Fifty-five percent of blood contains plasma and 92% of plasma contains water. Loss of water from body as occurs in diarrhea, vomiting, excessive sweating etc. results in decreased blood volume (hypovolemia). Persistent hypovolemia results in cellular dehydration. In response to hypovolemia, mechanisms are activated to increase the water content of blood that aims at maintaining cellular hydration. Thus, by maintaining blood volume, water homeostasis of the body is maintained.
6. **Acid-base balance:** Blood contains plasma proteins and hemoglobins. They (protein and Hb buffers) play important role in maintaining acid base balance of the body. Also, bicarbonate in blood buffers the acids.
7. **Immunology:** Blood forms a critical component of body immunity. It contains cells that play primary role in cellular immunity and also contains antibodies that play major role in humoral immunity. Blood also contains cells and chemicals that take part in nonspecific defenses of the body.
8. **Storage:** Blood is the storage site of electrolytes, nutrients, chemicals, hormones, etc.
9. **Body color:** Blood provides natural color to the body. In anemia and hypovolemia, body becomes pale.
10. **Oncotic pressure:** The albumin present in blood exerts osmotic pressure, known as oncotic pressure that controls capillary filtration and prevents edema formation (discussed more in ‘functions of plasma proteins’).

**Blood Volume**

The total blood volume can be roughly calculated as 70–80 ml/kg of body weight. In adult males, the total volume of blood is about 5 to 6 liters and in females about 4.5 to 5.5 liters. In children, though the absolute volume of blood present is significantly less than adults, the volume expressed per kg of body weight is more (80–90 ml/kg-BW). Blood volume is also expressed per square meter of body surface area, which is normally 2.8 lit/m² of the body.

**Determination of Blood Volume**

Blood volume is determined by determining the plasma volume and cell volume separately. The normal ratio of plasma volume to cell volume is 55:45.
Measurement of Cell Volume

Cell volume is measured by measuring the volume of red cells. The volume of leucocytes and platelets is ignored as they constitute a minor fraction of the total cell volume. Red cell volume is measured by radioactive isotope study.

Red cell volume

Red cell volume is the volume occupied by all circulating red cells.
1. It is usually calculated by subtracting plasma volume from total blood volume.
2. It is also directly calculated by injecting tagged red cells. The radioactive isotope of chromium is usually used as a tag, though isotopes of iron ($^{59}$Fe) and phosphorus ($^{32}$P) are also used.
3. The commonly used chromium isotope is $^{51}$Cr, which is attached to red cells through incubation of cells in the chromium solution.

Determination of Plasma Volume

Plasma volume is usually measured by using dyes. The dye used is Evans blue (T-1824). Plasma volume is also measured by injection of serum albumin labeled with radioactive iodine. An average plasma volume is about 3.5 L (5% of the body weight of a 70 kg man).

Total blood volume is calculated by multiplying plasma volume with 100/(100 – hematocrit). (Hematocrit is to be determined). If hematocrit is 40 and plasma volume is 3.5 L, then blood volume will be:

$$3.5 \times \frac{100}{100 - 40} = 5.8 \text{ L}$$

Effective Blood Volume

Effective blood volume = the total blood volume – the volume that is sequestered.

This means the volume which is present actually in the circulation that helps in perfusion of tissue. However, it is difficult to estimate the sequestered volume of blood in the visceral organs.

Specific Gravity and Viscosity of Blood

Specific gravity: Specific gravity or density of whole blood is approximately 1.050.

**PLASMA**

Plasma is the fluid component of blood which constitutes about 55% of the total blood volume. The remaining 45% is constituted by cells (formed elements). If the whole plasma is to be used for investigations, blood is collected with anticoagulants (anticoagulated blood). Plasma can be stored for years for future investigations (Application Box 9.1).

**Composition of Plasma**

Plasma constitutes water and solids (Table 9.1). Water content of plasma is about 92% of the total plasma. The major solute (solid) content is the plasma proteins, which constitutes about 7% of the plasma and other solutes make up the rest 1% (Fig. 9.2).

Serum
During blood coagulation, a soluble plasma protein called fibrinogen is removed from plasma as it is utilized in the formation of fibrin (the blood clot). Plasma without clotting factors is called serum.
1. Many biochemical tests are performed by separating serum from blood by allowing the blood to clot (coagulated blood) (Application Box 9.2).
2. Serotonin content of serum is high as platelets release serotonin during clotting.
3. Serum is not only used for biochemical investigations, but also as a supplement to cell culture media.
4. Serum ensures a better environment for growth of cells in vitro as it contains all nutrients, sugar, proteins, hormones and other factors.
5. Fetal calf serum is used often for growth of human cells.

Application Box 9.2
Separating serum: Plasma is separated by centrifuging anticoagulated blood. The serum is separated from blood by allowing the blood to coagulate (serum = blood – fibrinogen and other clotting factors).

PLASMA PROTEINS
Plasma proteins are the major solute constituents of plasma. The normal plasma protein concentration is 6–8 g/100 ml of plasma.

Types of Plasma Proteins
Plasma proteins are of three types: albumin (4–5.5 g%), globulin (1.5–3 g%), and fibrinogen (0.3 g%). Plasma proteins are formed mainly in the liver.

Albumin
This is the major constituent of plasma proteins.
1. Albumin is formed in the liver.
2. It has half life of about 20 days and its molecular weight is 66000.
3. Being smallest in diameter among the plasma proteins, in kidney diseases with glomerular injury it appears early in urine (albuminuria).
4. In kidney diseases, albuminuria decreases plasma protein concentration that leads to hypoalbuminemia. Hypoalbuminemia also occurs in in liver diseases due to decreased formation of albumin. In such conditions, decreased colloidal osmotic pressure (oncotic pressure) of plasma results in edema formation (see below).

Globulin
This is formed in the liver, cells of reticuloendothelial system and plasma cells.
1. Globulins are divided into three categories: α (α₁, α₂), β (β₁, β₂) and γ.
2. The molecular weight of globulins is 90000–156000.
3. Globulins include different transport proteins like transferrin, ceruloplasmin, hemopexin, etc.
4. They form different lipoproteins in combination with lipids in plasma.
5. Antibodies (immunoglobulins) are γ-globulins that are formed by plasma cells.
6. The normal albumin-globulin ratio (AGR) is 1.5 to 2.5:1. In many diseases, AGR is altered. Detection of AGR helps in diagnosing and assessing the prognosis of some diseases.
7. Albumin-globulin ratio (AGR) is important (Clinical Box 9.2)

Fibrinogen
The molecular weight is 340000. It is produced in the liver. It plays an important role in blood coagulation. It also contributes to the viscosity of plasma and determination of ESR.

Functions of Plasma Proteins
1. Osmotic pressure: Plasma proteins are osmotically active molecules, and the osmotic pressure of plasma due to plasma proteins is called oncotic pressure. The normal oncotic pressure is 25 mm Hg. This pressure helps in maintaining volume of the vascular compartment. Oncotic pressure retains fluid in the vascular compartment and, therefore, prevents loss of fluid from capillaries into the interstitial tissue space (functionally, it opposes the action of hydrostatic pressure). Therefore, when oncotic pressure decreases due to hypoproteinemia as occurs in liver and kidney diseases, edema manifests due to escape of water into the interstitial tissue space. The oncotic pressure is due to the presence of albumin in the plasma.
2. Viscosity: Plasma protein contributes to about 50% of the viscosity of blood (red cells account for rest of the viscosity). The viscosity depends on the molecular shape of the plasma protein. This is why fibrinogen molecules that are elongated and fibrillar in shape contribute more to blood viscosity than albumin molecules that are ellipsoid in structure.
3. Immunity: Antibodies are plasma proteins (gamma globulins). Antibodies mediate humoral immunity that protects the body from infections, especially extracellular pathogens and from the effect of toxic substances.
4. **Coagulation**: Blood clotting depends on concentration of fibrinogen that forms fibrin thread, the final step in blood coagulation. Also, other clotting factors like prothrombin are plasma proteins.

5. **Transport**: Plasma proteins serve as carrier molecules for transport of various substances like hormones, drugs, metals, etc.

6. **Buffering**: Plasma proteins form an important buffering system of the body called protein buffers. This helps in acid-base balance of the body.

7. **Protein store**: Plasma proteins serve as mobile protein reserve of the body, which can be utilized for tissue growth, especially in situations of protein depletion.

8. **Synthetic function**: Plasma proteins provide substrate for the synthesis of protein hormones like erythropoietin, etc. and various enzymes.

9. **Determination of ESR**: ESR mostly depends on the concentration of fibrinogen in the plasma. Fibrinogen facilitates rouleaux formation, which in turn increases the rate of sedimentation of red cells. Therefore, conditions in which fibrinogen concentration is more like acute inflammations, ESR becomes more (Details of ESR are described in chapter “The Red Blood Cells”).

**Separation of Plasma Proteins**

Plasma proteins can be separated by methods like salt separation, paper electrophoresis, Cohn’s fractionation, ultracentrifugation, immunochemical analysis, etc. Determination of concentration of various fractions is useful for estimation of albumin-globulin ratio (AGR) and for diagnosis and prognosis of different diseases.
Bone Marrow and Hemopoiesis

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:

1. Name the types of bone marrow and give their functions.
2. Comprehend the basic cellular architecture of bone marrow.
3. Appreciate the importance of myeloid-erythroid ratio in bone marrow.
4. Define hemopoiesis and name the sites of hemopoiesis in different stages.
5. Understand the difference between medullary and extramedullary hemopoiesis.
6. Name the sites of hemopoiesis in different age groups.
7. Name the types of stem cells and give their properties.
8. Outline the steps of different series (erythropoiesis, leucopoiesis and thrombopoiesis) of hemopoiesis.

The student **MAY** also be able to:

1. List the indications of bone marrow biopsy.
2. Understand the need for bone marrow aspiration.
3. Draw and describe the cells in hemopoietic series.
4. Describe the cellular patterns in bone marrow biopsy.

**Bone Marrow**

Bone marrow is the site of normal hemopoiesis after birth. Hemopoiesis (or hematopoiesis) describes the formation of blood cells, which is an active process that must maintain normal number of blood cells in peripheral blood and also should be able to respond to the increased demands in situations like hemorrhage or infections. During fetal life, hemopoiesis mainly occurs in the spleen and liver, and subsequently in red bone marrow present in the medullary cavity of all bones. From childhood, red marrow is progressively replaced by fat tissues (yellow marrow). Therefore, normal hemopoiesis in adults is restricted to vertebrae, sternum, ribs, clavicles, pelvic bones, skull and ends of humerus and femurs.

Bone marrow contains a range of hemopoietic precursor cells and a storage pool of mature cells for their release into peripheral circulation. All blood cells are derived from the pluripotent stem cells, referred to as hemopoietic stem cells (HSCs). HSCs sustain life long production of all blood lineages. HSCs provide homeostasis of blood cells through their ability to generate the hundreds of millions of red cells, white cells and platelets needed every day.

**Types of Bone Marrow**

There are three types of bone marrow: red marrow, yellow marrow and white marrow.

**Red Marrow**

The red marrow is the active marrow and is red in colour. It consists of many blood vessels that contain sinusoidal capillaries (vascular sinuses), and the marrow stroma (Fig. 10.1). **Marrow stroma:** The marrow stroma consists principally of a network of sinuses that originate at the endosteum from cortical capillaries and terminate in the collecting vessels that enter the systemic circulation. Hematopoiesis takes place in the **intersinus spaces.** The trilaminar sinus wall contains three components:

1. Endothelial cells
2. Thin basement membrane
3. Adventitial reticular cells.
The bone forming cells are present between the sinusoidal capillaries. The adventitial reticular cells are fibroblasts capable of transforming into adipocytes (fat cells). Endothelium and reticular cells are the sources of cytokines that profoundly influence hemopoiesis. All types of precursor cells (blast cells, progenitor cells, megakaryocytes) are present in the bone marrow trabeculae. Red cells are produced from the erythroid ‘nests’.

Red bone marrow is present in almost all bones of the body at birth. However, with advancement of age red marrow is replaced by fatty tissue and slowly becomes inactive. At the age of 20–30 years, red marrow of long bones cease to produce cells, and active marrow is limited to the membranous bones like skull bones, vertebrae, ribs, sternum and pelvic and pectoral girdles (Fig. 10.2).

Yellow Marrow

The yellow marrow contains less blood vessels and more fat cells and fibro-fatty tissue. The yellow marrow does not participate in hemopoiesis. Fat cells replace hematopoietic cells in the bones of hands, feet, legs and arm at about age of 20 years. Fat occupies 50% of the space of red marrow in adult and further fatty degeneration continues slowly with aging. Yellow marrow can revert back to hemopoietically active red marrow when prolonged demand persists as occurs in chronic hemolytic anemia. Differences between red and yellow marrow are listed in Table 10.1.

**White Marrow**

In very old individuals, a gelatinous transformation of fat to a mucoid material occurs in bone marrow. This type of marrow in elderly persons is called white marrow.

**Bone Marrow Examination**

Bone marrow examination is indicated in complex hematological disorders and malignant hematological conditions that require detailed analysis of cellularity and activity of the marrow. The bone marrow examination is done for the following types of assessments:

1. Cellularity of the marrow (normocellular, hypercellular or hypocellular)
2. Myeloid-Erythroid ratio
3. State of erythropoiesis, myelopoiesis and megakaryopoiesis
4. Number of lymphocytes (normal, increased or abnormal)
5. Plasma cells (normal or increased)
6. Other cells : Metastatic tumor cells, parasites (malaria, Leishmania Donovani, etc.), fungus or any other cells.
7. Iron stores evaluated by Persian blue reaction (normal, increased or decreased)

**Indications for Bone Marrow Examination**

Usual indications for bone marrow examination are:

1. Anemias: Aplastic anemia and refractory anemias
2. Aleukemic leukemia
3. Differentiation of leukemias
4. Myelofibrosis and myelosclerosis
5. Multiple myeloma
6. Agranulocytosis
7. Megaloblastic anemia
8. Thrombocytopenic purpura
9. Assessment of iron stores
10. Therapeutic (Bone marrow transplant)

**Procedure**

Bone marrow examination is usually done by needle aspiration and bone marrow trephine biopsy. Aspiration is a safe and easy procedure. Under local anesthesia, aspiration or biopsy needle is introduced into the center of the marrow and about 1 ml of marrow content is aspirated or the tissue is obtained, which is examined after preparing a stained smear. Staining is usually done by Romanowsky dyes or May–Grünwald–Giemsa stain. The usual sites of aspirations are sternum (sternal puncture), iliac crest and spinous process of vertebra.

**Bone Marrow Needle Aspiration**

The usual sites of aspirations are sternum, iliac crest and spinous process of vertebra (Clinical Box 10.1).

**Clinical Box 10.1**

Sites of marrow aspiration: Bone marrow aspiration is relatively an easy procedure. Commonly used needle is Salah Needle that has the provision of adjusting the depth of penetration into the marrow. The common sites of bone marrow aspiration are: sternum, posterior-superior iliac spine, iliac crest, anterior-superior iliac spine, and spinous process of lumbar vertebra. In infants, upper end of tibia is the ideal site for marrow aspiration.

**Sternal Puncture**

This is the commonest procedure for bone marrow aspiration, especially in adults. The needle is introduced into the marrow cavity of mid-manubrium sterni.

**Iliac Crest Puncture**

The iliac crest, particularly the region of the posterior spine is the preferred site for bone marrow aspiration, especially in children. It is also done in adults.

**Vertebral Puncture**

Spinous process of vertebrae of the lumbar segments is preferred when sternal puncture fails to reveal proper cytology or when sternum is otherwise contraindicated for the process.

**Bone Marrow Biopsy**

Bone marrow biopsy is performed by biopsy needle. This is called *trephine biopsy*. The sites of biopsy are same as for needle aspiration. Biopsy is more tedious and risky than aspiration.

**Features of Marrow Smear**

The examination of stained marrow smear is performed for assessing cellularity of the marrow, effectiveness of hemopoiesis (erythropoiesis, leucopoiesis and thrombopoiesis), myeloid-erythroid ratio, and presence of tumor cells, plasma cells, LD bodies (Leishman Donovan bodies as seen in Leishmaniasis), and malaria parasites.

**Cells in Bone Marrow**

In bone marrow, hemopoietic cells are observed in different stages. These include stem cells, CFUs, blast cells and other progenitor cells (Fig. 10.1). The stem cells normally constitute about 0.5% of marrow cells. In red bone marrow, cells are mostly of myeloid series that produce leucocytes (granulocytes and agranulocytes), and constitute about 70–75% of the cell mass. The erythroid series constitutes about 25% of the marrow cell mass. Thus, the myeloid-erythroid ratio (MER) in the bone marrow is 3:1 (Application Box 10.1). However, in the peripheral blood, red cells are much more than the white cells, *leucocyte-erythrocyte ratio* being 1:700.

**Application Box 10.1**

MER in bone marrow preserves leucocyte population in peripheral blood: The average life span of red cell is 120 days, whereas white cells stay in peripheral blood for few hours to few days. Therefore, to preserve white cell population in peripheral blood nature has provided more white cell precursors in bone marrow. This (more myeloid cells in the marrow) helps to replace adequate leucocytes in the blood as leucocytes have shorter life span than erythrocytes in circulating blood.

**Bone Marrow Transplantation**

Bone marrow transplantation (BMT) is the process of collection and infusion of hematopoietic stem cells obtained from the bone marrow or peripheral blood, of either of the other individuals or of the own hematopoietic stem cells (HSC).

**Important Note**

Sources of hematopoietic stem cells:

1. **Bone Marrow**: Bone marrow is the richest source of HSC.
2. **Peripheral Blood**: Few HSC are present in peripheral blood. They are mobilized into peripheral blood from bone marrow by administration of G-CSF or GM-CSF.
3. **Umbilical Cord Blood**: Collected following delivery. This is a rich source.

**Scientist contributed**

Dr E Donnall Thomas received Nobel Prize in Physiology and Medicine in 1990, for Bone Marrow Transplantation. Dr. Thomas and his colleagues pioneered the successful use of bone marrow transplantation. This procedure replaces cancerous cells and stem cells damaged by chemotherapy and radiation with donated healthy cells that engraft within a patient’s bone marrow. The discovery was a cure for leukemia and other blood cancers, and earned Thomas the 1990 Nobel Prize in physiology or medicine.
hematopoiesis. Blood cells are continuously destroyed in the body. Therefore, replacement of blood cells is also a continuous phenomenon and is an essential part of homeostasis of blood cells.

**Scientist contributed**

A Maximow is the first scientist to study the process of hematopoiesis. He studied the contribution of endothelium to blood regeneration (hematopoiesis). He especially studied the relation hematopoiesis with connective tissue and vascular endothelium.

**Alexander Maximow (1874–1928)**

**Sites and Stages of Hematopoiesis**

Location of hematopoiesis depends on the stage of hematopoiesis. During intrauterine life, hematopoiesis occurs first in the yolk sac, and later in the liver and spleen. After birth, hematopoiesis is confined to bone marrow. The environment in these organs (yolk sac, liver, spleen and bone marrow) where hematopoiesis takes place is called hematopoietic microenvironment. Hematopoiesis occurs in three stages: mesoblastic, hepatic and medullary.

**Mesoblastic Stage**

Mesoblastic stage is the stage of development of blood cells in the yolk sac and non-yolk sac regions during embryonic stage of intrauterine life. Yolk sac contains cells with multilineage differentiating capabilities that start functioning as early as second week of gestation. There are also few non-yolk sac regions that participate in hematopoiesis. Important among them are paraaortic splanchnopleura (PSP) and aorta-gonad mesonephros (AGM) regions. PSP region gives rise to B-cell progenitors and AGM region contains pleuripotent stem cells. Early lymphoid precursors have also been identified in the day-8 yolk sac. Also, lymphohematopoietic stem cells have been detected in vivo in the 9th day yolk sac.

**Hepatic Stage**

During second trimester of pregnancy, hematopoiesis takes place in the liver and spleen. This is called hepatic stage. In liver, hematopoiesis *starts as early as 5th week of gestation*, which reaches its peak in 5th month and ceases at birth (Fig. 10.3). In spleen, hematopoiesis *occurs mainly in the second trimester* and the degree of hematopoiesis is quite less than that in the liver. Normally, hematopoiesis *does not occur in liver and spleen during post-natal life* (after birth). However, when the demand for blood cells is more than the rate of production, hematopoiesis does occur in liver and spleen.

**Medullary Stage**

Formation of blood cells in the bone marrow is called medullary hematopoiesis. Marrow cavities in the bone appear as early as *5th month of fetal life*, and soon they become hematopoietic. In initial phase, bone marrow is the exclusive site for granulocytic and megakaryocytic proliferation, during which erythropoietic activity is confined to liver. Erythropoiesis in bone marrow occurs effectively towards the end of third trimester of pregnancy and then continues throughout life.

After birth, hematopoiesis stops in liver and gets confined only to the bone marrow. When hematopoiesis occurs in liver and spleen in postnatal life, it is called extramedullary hematopoiesis. Extramedullary hematopoiesis after birth is always non-physiological (Application Box 10.2).

**Application Box 10.2**

Extramedullary hematopoiesis after birth is abnormal: Hematopoiesis in liver and spleen is physiological during intrauterine life. However, hematopoiesis in these organs or in any other organ (extramedullary hematopoiesis) after birth is considered abnormal.

**Rate of Medullary Hematopoiesis**

Bone marrow is one of the largest organs in the human body. It produces about 6 billion cells (2.5 billion red cells, 2.5 billion platelets and 1 billion granulocytes) per kg of body weight per day in adolescents and adults. However, the rate of production is adjusted to the needs of day-to-day life. Different cell population and their rate of productions are listed in Table 10.2.

**Sites of Medullary Hematopoiesis**

Bone marrow is the sole site of erythropoiesis in human beings. In long bones, active marrow regresses rapidly after first decade of life and ceases to produce cells between 20–30 years of life (Fig. 10.2). Hematopoiesis continues to occur in active marrow of vertebrae, pectoral and
pelvic girdles, ribs, sternum and skull. However, with age the degree of hemopoiesis also decreases in these bones.

**Steps of Hemopoiesis**

Hemopoiesis occurs in the bone marrow from hematopoietic stem cells (Flowchart 10.1). The mother hematopoietic stem cell is the pluripotent stem cells (PPSC), also called as hemocytoblast. PPSC is the *multilineage stem cell* capable of producing two important groups of stem cells. These are myeloid stem cells and lymphoid cells. Lymphoid stem cells are unipotent stem cells (UPSC) that produce only lymphocytes, whereas myeloid stem cells are pluripotent in nature that from a group of different progenitor cells that are meant to produce red cells, granulocytes, monocytes and platelets. Thus, bone marrow contains two types of cells: stem cells and progenitor cells. In fact, stem cells develop into progenitor cells. The differences between these cells are listed in Table 10.3.

**Stem Cells**

**Properties**

Stem cells in the bone marrow have two important properties: self renewal and differentiation.

**Self Renewal**

This is the property of duplicating themselves. That means they renew themselves and therefore physiologically they do not die and at the same time they proliferate into different lineage of cells. Due to self renewal, the bone marrow never goes out of stock for stem cells. Stem cell reserve in bone marrow remains always adequate.

**Differentiation**

This is the property of developing into specific lineage of cells. Due to the property of differentiation, stem cells differentiate into progenitor cells of various cell lines. Thus, different cell lineages are formed from stem cells that give rise to specific blood cells.

**Scientist contributed**

Stem-cell scientists led by Dr John Edgar Dick was the first to study the details of properties and nature of stem cells. He has transformed the study of human hematopoiesis and leukemogenesis, with his development of methodologies for transplanting human bone marrow into immune-deficient mice, with resultant multilineage repopulation of murine bone marrow and other hematopoietic tissues. Using this approach, he has identified long-term repopulating human hematopoietic stem cells and generated mouse models of leukemia.

**Types**

There are two different stem cells: myeloid stem cells and lymphoid stem cells (Fig. 10.4).

**Myeloid Stem Cells**

Myeloid stem cells are pluripotent (tri-lineage) in nature that give rise to three types of different progenitor cells. These are erythroid progenitors that form erythroid series, the granulocytic progenitors that form granulocytes (neutrophil, eosinophil, and basophil), monocyctic progenitors form monocytes, and megakaryocytic progenitors that form platelets.

**Lymphoid Stem Cells**

Lymphoid stem cells are unipotent stem cells (UPSC) that produce only cells of lymphocyte series.

**Progenitor Cells**

Progenitor cells develop from stem cells. Progenitor cells form colony forming units (CFUs) that give rise to different types of blast cells. *Myeloid stem cells* differentiate into CFU-GEMM, i.e. CFU for granulocyte, erythrocyte, megakaryocyte and monocyte. CFU-GEMM develops into three major CFUs (Fig. 10.4).
Fig. 10.4: Types and stages of hemopoiesis and major cytokines influencing them. (SCF: Stem cell factor, BFU: Burst-forming unit, CFU: Colony-forming unit, CSF: Colony-stimulating factor, GM: Granulocyte-monocyte, IL: Interleukins, EPO: Erythropoietin, TPO: Thrombopoietin).

1. **CFU-E**: CFU-E is the CFU for erythroid series that form proerythroblast, which in turn develops into precursor cells of erythroid series.

2. **CFU-GM**: CFU-GM is the multilineage CFU that in turn forms CFU for granulocytes (CFU-G) and CFU for monocytes (CFU-M). CFU-G develops into myeloblast that differentiates into three lineage of granulocytes (neutrophil, eosinophil, and basophil). CFU-M develops into monoblast that differentiates into monocyte.

3. **CFU-Mega**: CFU-Mega differentiates into megakaryoblast that in turn forms platelets.

**Types of Hemopoiesis**

Hemopoiesis is broadly divided into three types: erythropoiesis, leukopoiesis and thrombopoiesis. Erythropoiesis is the development of red cells, leukopoiesis is the development of leucocytes and thrombopoiesis is the development of thrombocytes (platelets).

The PPSC differentiates into five major blast cells (CFUs are excluded here) that give rise to five different cell lines (Fig. 10.4).

1. The proerythroblast that forms erythroid series for final development of red cells.
2. The myeloblast that differentiates into three lineages of granulocytes series (neutrophil, eosinophil, and basophil).
3. The monoblast that differentiates into monocytes.
4. The lymphoblast that develops into lymphocytes.
5. The megakaryoblast that finally forms platelets.

Details of development of each cell line have been described in their respective sections.
Regulation of Hemopoiesis

Hemopoiesis is regulated by various cytokines. Cytokines that influence development of blood cells are called **hemopoietic growth factors** (HGFs). As many of them stimulate development of CFU, they are popularly called colony stimulating factors (CSFs). Many of them are nonspecific, influencing more than one cell line (Table 10.4), whereas few are very specific in their actions (for details of cytokines, refer the chapter “Immunity”). The major HGFs are:

1. **Erythropoietin**: It is secreted from kidney and stimulates development of erythrocyte precursors (for details, refer “regulation of erythropoiesis”).
2. **Interleukins (IL)**: There are many interleukins, IL_1_ to IL_7_. IL_1_ controls eosinophil development, IL_2_ and IL_6_ control lymphocyte development, IL_3_ and IL_7_ control monocyte-macrophage development, etc.
3. **Colony stimulating factors**: There are three major groups of CSFs: M-CSF, G-CSF and GM-CSF. M-CSF controls development of monocyte precursors, G-CSF controls growth of granulocyte precursors and GM-CSF promotes proliferation of both granulocytes and monocytes.
4. **Other growth factors**: Colony stimulating factor 1 (CSF 1) that influences macrophage development, leukemia inhibitory factor (LIF) that controls growth of megakaryocyte and stroma cell derived cytokine (SCDC) that influences B cell differentiation.

### CHAPTER SUMMARY

**Bone Marrow**

There are three types of bone marrow: red marrow, yellow marrow and white marrow.

- **Red Marrow**: The red marrow is the active site of hemopoiesis and is present in almost all bones of the body at birth. With advancement of age, red marrow is replaced by fatty tissue and slowly becomes inactive. At the age of 20-30 years, red marrow of long bones cease to produce cells, and active marrow is limited to the membranous bones like skull bones, vertebrae, ribs, sternum and pelvic and pectoral girdles.
- **Yellow Marrow**: The yellow does not participate in hemopoiesis. Fat cells replace hematopoietic cells in the bones of hands, feet, legs and arm at about age of 20 years.

**Bone Marrow Examination**

Bone marrow examination is indicated for detailed analysis of cellularity and activity of the marrow, which is done mainly for the following types of assessments:

1. **Cellularity of the marrow** (normocellular, hypercellular or hypocellular)
2. **Myeloid-Erythroid ratio** (Normal M/E ratio is 3:1)
3. **State of erythropoiesis, myelopoiesis and megakaryopoiesis**

**Hemopoiesis**

Hemopoiesis occurs in three stages: mesoblastic, hepatic and medullary.

- **Mesoblastic Stage**: Mesoblastic stage is the stage of development of blood cells in the yolk sac and non-yolk sac regions during embryonic stage of intrauterine life.
- **Hepatic Stage**: During second trimester of pregnancy, hemopoiesis takes place in the liver and spleen. This is called hepatic stage. In liver, hemopoiesis starts as early as 5th week of gestation, which reaches its peak in 5th month and ceases at birth. In spleen, hemopoiesis occurs mainly in the second trimester and the degree of hemopoiesis is quite less than that in the liver.
- **Medullary Stage**: Formation of blood cells in the bone marrow is called medullary hemopoiesis. Marrow cavities in the bone appear as early as 5th month of fetal life, and soon they become hemopoietic. Erythropoiesis in bone marrow occurs effectively towards the end of third trimester of pregnancy and then continues throughout life.

**Steps of Hemopoiesis**

Hemopoiesis occurs in the bone marrow from hematopoietic stem cells that are pluripotent stem cells (PPSC). PPSC is the multilineage stem cell capable of producing two important groups of stem cells: myeloid stem cells and lymphoid cells. Lymphoid stem cells are unipotent stem cells (UPSC) that produce only lymphocytes, whereas myeloid stem cells are pluripotent in nature that from a group of different progenitor cells that are meant to produce red cells, granulocytes, monocytes and platelets.

**Important to Know (Must Read)**

1. Stages, types and regulation of hemopoiesis, may come as a Long Questions.
2. Types of bone marrow, Stages of bone marrow, Stem cells, Regulation of hemopoiesis, Hemopoietic growth factor, may come as Short Questions.
3. In Viva, examiner may ask... types of bone marrow, structure of bone marrow, when hemopoiesis starts in different stages, medullary and extramedullar hemopoiesis, properties of stem cells, HGFs for different types of hemopoiesis.
CHAPTER 11

Red Blood Cells

Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Give the dimensions of red cell and normal red cell count in different age groups in males and females.
2. List the functions of red cells.
3. Give the list of abnormal forms of red cells and the common condition in which these abnormalities are observed.
4. Appreciate the importance of specialties of red cell membrane.
5. Understand the meaning of red cell fragility and give the causes of increased and decreased fragility of red cells.
6. Give the values of hematocrit in males and females and common conditions of variations in hematocrit.
7. Explain the mechanism of erythrocyte sedimentation rate (ESR), list the factors affecting ESR, give the values of ESR in males and females, and list the physiological and pathological variations in ESR.

The student MAY also be able to:
1. Understand the importance of special type of metabolism in red cell.
2. Learn the types of abnormal red cells in common conditions.

The red blood cells (or red cells) are named as erythrocytes as they appear red (erythros means red) in a stained smear of peripheral blood.

1. The red color of erythrocytes is due to the presence of hemoglobin that accounts for approximately 90% of weight of red cells.
2. In a stained smear, the central part of red cells is pale that gives the appearance of a halo and peripheral part is more red, as in these cells the center is thin and periphery is thick.
3. Red cells are the major cellular elements of blood and perform transport of oxygen from lungs to tissues, and carbon dioxide from tissues to the lungs.

Structure and Functions

Structure

The normal human red cell is a circular, non-nucleated and biconcave disc (Fig. 11.1). The surface area of the red cell is much greater than that of a sphere of the same size. Therefore, exchange of oxygen and carbon dioxide is maximal with the biconcave configuration of red cells.

Red Cell Dimensions

<table>
<thead>
<tr>
<th>Shape</th>
<th>Biconcave</th>
</tr>
</thead>
<tbody>
<tr>
<td>Size</td>
<td>7.5 (7 to 8) µm</td>
</tr>
</tbody>
</table>

Fig. 11.1: Structure of a red cell. Note the biconcave dimension of red cell. The center is thin (minimum 0.8 µm), and periphery is thick (2 µm).
Thinness: 2 µm at the periphery and 1 µm at the center
Surface area: 140 µm²
Volume: 87 µm³ (78 to 94 µm³)

The advantages of biconcavity of red cells:
1. When exposed to hypotonic environment, red cells withstand lysis to a greater degree as they swell to a larger extent to attain spherical shape before bursting. Thus, they do not easily lyse when blood becomes hypotonic.
2. It increases the surface area for exchange of gases (oxygen and carbon dioxide).
3. It helps in easy folding of red cells and therefore, facilitates their movement through the narrow capillaries.

Red Cell Composition
Red cells are composed of water 62.5%, hemoglobin 35%, and other substances 2.5% that constitute glucose, lipids (cephalin, cholesterol and lecithin), proteins (glutathiones and albumin like insoluble proteins) and enzymes (glycolytic enzymes, carbonic anhydrase and catalase).

Red Cell Count
In adult males: 4.5–6 (average 5.2) millions per cu mm of blood
In adult females: 4–5.5 (average 4.7) millions per cu mm of blood
In newborns: 6–8 millions per cu mm of blood
In children: 3–5 millions per cu mm of blood

The count is more in infants mainly due to hemoconcentration. The count rapidly decreases to its lowest level at about 2–4 months. Then, count slowly increases from one year of life to reach about 5 millions/mm³ at about 10 years.

The decrease in red cell count is called anemia and increase in count is called polycythemia (for details, refer the chapter “Pathophysiology of Anemia and Polycythemia”).

Life Span of Red Cells
Red cells usually live for 120 days. Aged red cells are destroyed by tissue macrophage system. Life span of red cells can be measured by injecting radioactive iron or RBCs tagged with radioactive chromium (⁵¹Cr). The tagged red cells lose radioactivity as they are destroyed. Complete disappearance of radioactivity gives the life span of red cells.

Abnormal Red Cells

Based on Size
Normocyte, Microcyte and Macrocyte
1. Normocyte: A normal red cell is called a normocyte, the volume of which is about 87 µm³ (78–94 µm³). Red
cells are non-nucleated biconcave discs. The cell diameter is about 7.5 µm. The normal red cell is also called discocyte, as it is a smooth, biconcave disc (Figs. 11.2 and 11.3A).
2. Microcyte: When the volume of red cell is less than 80 µm³, is called a microcyte (Figs. 11.2 and 11.3B). Microcytosis occurs in conditions of decreased cell size like iron deficiency anemia.
3. Macrocyte: When the volume of red cell is more than 94 µm³, is called a macrocyte (Figs. 11.2 and 11.3C). Macrocytosis occurs in conditions of increased cell size like megaloblastic anemia.

Anisocytes
This means the red cells are of different sizes. Anisocytosis is seen in different types of anemias (Fig. 11.3E).

Hypochromic Cells
Hypochromic red cells (hypochromia) are cells with pale appearance. Hypochromia occurs either due to decreased hemoglobin concentration as seen in iron deficiency or due to abnormal thinning of red cells. Usually the cells are microcytic.

Based on Shape
Poikilocytes
This means red cells are of different shapes. Poikilocytosis is usually seen when older cells are present in circulation (Fig. 11.3D).

Spherocytes
When red cells assume spherical shape, are called spherocytes (Fig. 11.3F). This is seen in conditions like hereditary spherocytosis.

Elliptocyte
When red cells assume oval shape with varying degrees of elliptical aberration, are called elliptocytes (Fig. 11.3G). Elliptocytosis occurs in hereditary elliptocytosis, thalassemia and iron deficiency anemia.
Chapter 11: Red Blood Cells

Acanthocyte
When a red cell has irregular shape with 2 to 10 hemispherically tipped spicules of variable length and diameter is called acanthocyte. Acanthocytosis is seen in abetalipoproteinemia, alcoholic liver disease and malabsorptive states (Fig. 11.3H).

Drepanocyte (Sickle Red Cells)
Drepanocyte is the red cell having sickle shape (Fig. 11.3I). Drepanocytosis is seen in sickle cell anemia.

Echinocyte (Burr Cells)
A “burr cell” or crenated red cell is an echinocyte (Fig. 11.3J). Echinocytosis occurs in uremia and liver disease.

Dacryocyte (Tear Drop)
When the red cell assumes the appearance of a tear drop, is called dacryocyte (Fig. 11.3K). Dacryocytosis occurs in myelofibrosis with myeloid metaplasia, thalassemia and myelophthisic anemia.

Keratocytes
Keratocytes are red cells having a pair of spicule. Keratocytosis usually occurs by mechanical damage or by removal of a Hinz body by pitting action of the spleen. ‘Hamlet cells’ and ‘bite cells’ are also used to describe keratocytes (Fig. 11.3L).

Schistocytes
Schistocytes are fragments of red cells (see Fig. 11.3M). They are smaller than red cells and they have sharp angles and spurs. Schistocytosis (red cell fragmentation) occurs in thalassemia, mechanical stress (microangiopathic hemolytic anemia, cardiac hemolytic anemia, etc.), and thermal injury (severe burns).

Target Cells
When a red cell has a central deeply stained round area in addition to its normal feature, the cell is called target cell (see Fig. 11.3N). Target cells are seen in chronic liver disease, obstructive jaundice, iron deficiency anemia and thalassemia.
**Stomatocyte**
This is a red cell having a slit-like area at the center of the cell in a dried film. In wet film, cell appears like cup. *Stomatocytosis* occurs in hemolytic anemia, liver disease and alcoholism (Fig. 11.3O).

**Basophilic Stippling**
This means presence of numerous basophilic granules (coarse and dark-blue granules) in red cells (see Fig. 11.3P). This condition is called punctate basophilia. It is typically seen in lead and other heavy metal poisoning. It also occurs in thalassemia, megaloblastic anemia, infections and liver disease.

Sometimes in lead poisoning, Cabot’s ring (ring shape or figure of 8) at the periphery of red cells or Howell Jolly bodies (small nuclear fragments appear in cytoplasm) are found in erythrocytes. Nucleated red cells are seen in severe hemolytic anemia.

**Cell Membrane and Metabolism**

**Red Cell Membrane**
For its easy accessibility, red cell membrane is the most thoroughly studied biological membrane. Red cell membrane is made up of three major structural elements: lipid bilayer, integral proteins and membrane skeleton.

**Lipid Bilayer**
The lipid bilayer is primarily composed of phospholipid and cholesterol:
1. The lipid bilayer provides an impermeable barrier between cytoplasm and external environment.
2. It also helps to maintain a slippery exterior, so that the red cells do not stick to the vascular endothelium.

**Integral Proteins**
Integral proteins are embedded in the lipid bilayer. The important membrane proteins are band-3 protein (anion exchanger-1), the glycophorins, Rh D protein and various ion channels (Refer to Fig. 4.5; Chapter 4).
1. These proteins allow red cells to participate in wide range of functions including antigenic determination and cellular metabolism.
2. Band-3 is the major anion-exchanger (chloride-bicarbonate exchange) and also regulates metabolic pathways by sequestering key enzymes like enzymes of glycolytic pathways.
3. Glycophorins constitute more than 60% of negative surface charge of red cells; they modulate interaction between red cells and interaction of red cells to endothelium.
4. There are five different types of glycophorins: A, B, C, D and E. *Glycophorin-C* provides stability and shape to the red cell membrane, and its deficiency leads to elliptocytosis.

**Membrane Skeleton**
A membrane skeleton is present on the internal side of the red cell membrane. Two important proteins are part of membrane skeleton proteins: *ankyrin* and *spectrin*.

**Spectrin:** Spectrin is the most abundant skeletal protein and constitutes 75% of the mass of membrane skeleton.
1. Spectrin is composed of two subunits: α and β. The αβ heterodimers align and intertwine with each other in antiparallel fashion to form flexible rod like structure.
2. These dimers further self-associate to form tetramers that are composed of multiple repeats and provide a strong elastic filament to the overlying cell membrane via formation of lattice-like meshwork linked to integral membrane proteins. Thus, spectrin molecules maintain cellular shape, provide structural support to membrane lipid bilayer and regulate lateral mobility of integral membrane proteins.
3. Defect in association of αβ heterodimers results in hereditary elliptocytosis and poikilocytosis.

**Ankyrin:** Ankyrin is an asymmetric polar protein that provides primary linkage between membrane skeleton and lipid bilayer. Disruption of this linkage decreases membrane stability. Abnormalities of ankyrin are the most common causes of hereditary spherocytosis (Application Box 11.1).

**Application Box 11.1**

**Common membrane defects:** Presence of ankyrin and spectrin in the membrane provides biconcave shape, deformability, membrane stability and durability to the red cells. Therefore, deficiency of ankyrin and spectrin results in membrane defects like *spherocytosis, elliptocytosis* and *poikilocytosis*, etc. These defects also make the cells rigid so that the cells are destroyed prematurely.

**Deformability of Red Cells**
An important determinant of red cell survival is its deformability. Deformability is ascribable to the intrinsic deformability of the red cell membrane. When red cells become rigid, the viscosity of blood increases and cells are lysed while passing through the splenic pulp. The primary cause of decreased deformability is due to spherocytosis of the cell rather than stiffening of their membrane.

**Metabolism of Red Cells**
Red cells have no nuclei, mitochondria and ribosomes. Therefore, adequate synthesis of proteins and lipids does not occur in red cells.
1. Glucose is the primary fuel for red cells. Though enzymes for glycolysis are present, enzymes for TCA cycle are absent. ATP is formed by *Embden-Mayerhoff pathway* (EM pathway). The *HMP shunt* provides NADPH.
2. Glucose entry into the red cells occurs easily by facilitated diffusion, which is independent of insulin action. Red cells depend mostly on glucose metabolism for their energy supply.
3. 90% of glucose is oxidized by EM pathway and 10% by HMP shunt.

**EM Pathway**
Red cells metabolize glucose, usually by anaerobic glycolysis using EM pathway:
1. Two ATP molecules are generated by glycolysis through EM pathway.
2. 2, 3-DPG is produced in red cells. 2, 3-DPG influences oxygen affinity of hemoglobin and therefore, plays an important role in red cell function.
3. Hypoxia inhibits Kreb cycle and therefore, stimulates 2, 3-DPG formation, whereas, acidosis inhibits glycolysis and therefore, decreases 2, 3-DPG formation.

**HMP Shunt**
The enzyme in the red cell, glucose-6-phosphate dehydrogenase (G-6-PD) is the main enzyme for HMP shunt:
1. HMP shunt generates NADPH, keeps glutathione in reduced state, which is a strong reducing agent and prevents damage to the red cell.
2. Therefore, G-6-PD deficiency interferes with red cell functions (Clinical Box 11.1).

<table>
<thead>
<tr>
<th>Clinical Box 11.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>G-6-PD deficiency causes hemolysis: In the absence of G-6-PD, an <em>inborn error of metabolism</em>, red cells are susceptible to the damages due to oxidation. Therefore, hemolytic anemia is common in G-6-PD deficiency. Especially, hemolysis is facilitated on exposure to anti-malarial drugs, though these individuals are generally malaria resistant.</td>
</tr>
</tbody>
</table>

**Functions of Red Cells**
1. The most important function of red cell is to transport oxygen from lungs to the tissue. This is due to the presence of hemoglobin in the red cell which has high affinity for oxygen.
2. Hemoglobins also participate in carbon dioxide transport from tissues to lungs and maintenance of acid base balance.
3. Red cells contribute to 50% of viscosity of blood.
4. Antigen on red cell membrane helps in blood group classification.

**APPLIED ASPECTS**

**Red Cell Fragility**
The tendency of the cells to hemolyze is called fragility of the cells. There are 2 types of fragility: mechanical and osmotic.

**Mechanical Fragility**
Lysis of red cells due to mechanical stress and strain is called *mechanical fragility*. Red cell diameter is slightly less than the diameter of average capillaries. Therefore, when red cells pass through capillaries and splenic pulp, their membrane undergoes mechanical stress:
1. On average, a red cell passes about three lakh times though capillaries during its life span, which makes the cell more fragile.
2. Also, when red cells become older, the membrane becomes rigid. Increased membrane stiffness and mechanical stress make cell vulnerable to rupture.
3. Red cell membrane defects increase mechanical fragility.

**Osmotic Fragility**
Lysis of red cells on exposure to different osmotic solutions is called osmotic fragility. Osmotic fragility is defined as the ease with which the red cells are ruptured when they are exposed to hypotonic solutions. It assesses the integrity of red cell membrane. The *osmotic fragility test* helps in the diagnosis of anemia in which the physical properties of the red cells are altered. This test detects whether or not the red cells can easily be hemolyzed. The red cell membrane allows water to pass through while restricting solutes. This is called osmosis.
1. In an *isotonic solution*, the solution of equal concentration as that of red cell content, the red cells remain intact. Such a solution has same tonicity with that of plasma. Examples are 0.9% NaCl, 5% glucose, 10% mannitol and 20% urea.
2. When suspended in *hypertonic solution*, a solution with more tonicity (> 0.9% NaCl), red cells shrink due to loss of water from them by exosmosis.
3. Red cells absorb water by *endosmosis*, when kept in hypotonic solutions, a solution with less tonicity (< 0.9% NaCl). Endosmosis results in hemolysis due to swelling and rupture of the cells (Clinical Box 11.2).

**Clinical Box 11.2**
| Shape of red cell determine hemolysis: Increased osmotic fragility denotes decreased resistance of cells to rupture. As the resistance of the red cell membrane to rupture is related to its geometric configuration, red cells that are spherical demonstrate increased hemolysis, whereas red cells that are flat like sickle cells demonstrate decreased hemolysis. |

**Normal Value and Variations**
Normally, osmotic fragility begins at 0.45 to 0.50 and completes at 0.30 to 0.33.

**Conditions of Diminished Fragility**
- Iron deficiency anemia
- Thalassemia
- Sickle cell anemia
- Obstructive jaundice
- Post-splenectomy
Section 2: Blood and Immunity

Conditions of Increased Fragility
- Hereditary spherocytosis
- Congenital hemolytic anemia
- Other conditions in which spherocytes are found in the blood.

Packed Cell Volume (Hematocrit)
Hematocrit is the fractional volume of blood that erythrocytes occupy. Hematocrit or packed cell volume (PCV) is the amount of packed red blood cells following centrifugation. When blood is centrifuged in a tube the red cells are packed together at the bottom of the tube by centrifugal force, as cells are heavier than the plasma. The hematocrit is a macroscopic observation by which the percentage volume of the packed red blood cells is measured. Hematocrit is therefore known as PCV.

1. PCV is a reliable index of the red cell population. It provides useful information about the red cell mass which is correlated with red cell count and their hemoglobin content.
2. These measurements (PCV, red cell count and Hb content) are essential for determination of red cell indices that help in detecting and classifying the various types of anemias.

Normal Value and Variations
- Adult male: 46% (40–50%)
- Adult female: 42% (37–47%)

Hematocrit decreases in conditions of decreased red cell count and increases in conditions of increased red cell count. When cells are deformed as occurs in spherocytosis or sickle cell disease, more plasma is trapped between the packed cells, which gives a false high result.

Erythrocyte Sedimentation Rate
Red cells have the property of rouleaux (piling one on the other) formation (Fig. 11.4). The piled red cells are heavier than the individual red cells. Therefore, when whole blood is allowed to settle, sedimentation of erythrocytes is facilitated due to the presence of rouleaux. The rate at which the red cells fall (sediment), is known as the erythrocyte sedimentation rate (ESR).

Factors Affecting ESR
ESR depends on 3 major factors: (1) The shape and number of red cells, (2) Size of rouleaux, and (3) Plasma factors. Other factors also contribute.

Shape and Number of Red Cells
Shape of red cells: The most important factor determining ESR is the shape of red cells:
1. The biconcave shape favors rouleaux formation.
2. The alteration of shape of erythrocyte decreases rouleaux formation.
3. Therefore, ESR is less in hereditary spherocytosis and sickle cell anemia.

Red cell mass: Red cell mass contributed to blood viscosity.
1. Increase in cell mass increases viscosity of blood. Increase in viscosity decreases ESR.
2. Thus, ESR decreases in polycythemia and increases in anemia (except sickle cell anemia).

Size of Rouleaux
ESR depends on the mass of the falling particles, i.e. the size of rouleaux (the red cell aggregates). The larger the size of rouleaux, the faster is the fall. Therefore, the factors that increase the size of rouleaux facilitate ESR. Increase in red cell size without change in their shape increases the size of rouleaux.

Plasma Factors
The size and number of rouleaux mainly depends on the fibrinogen concentration of plasma. Globulin content of plasma also contributes:
1. In normal blood, red cells remain separate as they have negatively charged surface that tend to repel one another. When fibrinogen concentration increases...
CHAPTER SUMMARY

**Key Concepts**

1. Red cells are anuclear biconcave discs. The cells are highly deformable due to presence of ankyrin and spectrin in the membrane skeleton.
2. Deformability of the red cells allows them to pass through capillaries and splenic pulp.
3. Change in shape and rigidity of the membrane make the red cells susceptible to hemolysis.
4. Also, biconcave shape and membrane plasticity help red cells to resist osmotic lysis (less osmotically fragile).
5. PCV (hematocrit) is a reliable index of red cell mass.
6. Negative charges on cell surface inhibit bigger rouleaux formation. In infection, inflammation, malignancy and collagen diseases, the inflammatory or abnormal proteins produced by the disease neutralize the negative charge and facilitate rouleaux formation. This increases ESR in these conditions, which is a marker of intensity of the disease.

**Important to Know (Must Read)**

1. In examinations, usually Long Questions do not come from this chapter.
2. Osmotic fragility, ESR, and hematocrit may be asked as Short Notes in exams.
3. Many questions are asked in Viva from this chapter. Examiners invariably ask the dimensions of RBC, why is RBC biconcave and what are the benefits of it, normal red cell count, and the conditions of increase and decrease in count, common abnormalities of red cells, basics of red cell metabolism, types of fragility and factors affecting them, importance of PCV, factors increasing and decreasing ESR, common conditions of increase and decrease in ESR.
4. When a student fails to answer the size and shape of normal red cells, basics of red cells, and normal red cell count, it becomes difficult for examiner to give the pass marks.
The process of production of red cells is called erythropoiesis. Red cells have a finite lifespan of about 120 days. The new cells are formed at a pace that replaces the cells destroyed. Bone marrow precisely replaces the cells lost by senescence, hemorrhage or destruction. Red cell mass in a normal man is 26–32 ml/kg and in women 23–29 ml/kg of body weight. The volume of red cells (red cell mass) in the body is maintained and regulated by the bone marrow.

**SITES AND STAGES OF ERYTHROPOIESIS**

*Definition:* Erythropoiesis is defined as the process of formation of red cells. This is an important component of hemopoiesis.

**Stages of Erythropoiesis**

There are three stages of erythropoiesis: mesoblastic, hepatic and medullary.

**Mesoblastic Stage**

During intrauterine life, erythropoiesis first takes place in the mesoderm of yolk sac and mesoderm of the body. This is called mesoblastic stage. During this stage, erythropoiesis is intravascular.

**Hepatic Stage**

From the 5th week of gestation, erythropoiesis takes place in the liver and spleen (hepatic stage).

**Medullary Stage**

From the 5th month of intrauterine life, the bone marrow starts forming red cells (medullary stage). However, erythropoiesis in bone marrow is very slow in second trimester.

1. **Medullary erythropoiesis** becomes more effective towards the end of third trimester (Refer to Fig. 10.3; Chapter 10). After birth, bone marrow becomes the sole site of erythropoiesis.
2. *Extramedullary erythropoiesis in postnatal life is always considered abnormal.*
3. Till adolescent period, marrow cavities of all bones are involved in erythropoiesis, after which erythropoiesis regresses in the limb bones.
4. After the age of 20–30 years, erythropoiesis is mostly limited to sternum, ribs, vertebrae, skull, pelvic and pectoral girdles (Refer to Fig. 10.2; Chapter 10).

**Important Note**

*Extramedullary erythropoiesis after birth is abnormal:* After birth, erythropoiesis occurs only in bone marrow. Extramedullary erythropoiesis in postnatal life is always considered abnormal.
Chapter 12: Erythropoiesis

Steps of Erythropoiesis

There are four major cell-stages or steps of erythropoiesis: stem cells, progenitor cells, precursor cells and mature cells. Each stage has sub-stages. Red cells are formed from pluripotent hemopoietic stem cells, which give rise to committed stem cells. Committed stem cells form subsequent progenitor and precursor cells that finally produce reticulocyte and mature red cells (Fig. 12.1).

In general, during erythropoiesis, following cellular changes take place:

2. Size of nucleus and number of nucleoli decrease, chromatin material condenses and finally nucleus disappears.
3. Staining reaction of cytoplasm changes from deep basophilic to polychromatophilic (acidophilic plus basophilic) and finally to acidophilic type. This occurs mainly due to gradual reduction in quantity of RNA material.
Stem Cells

Pluripotent Stem Cells

Pluripotent stem cells are the mother stem cells that form stem cells for different cell lines. Stem cells (including committed stem cells) have two unique properties: 1. self renewal, and 2. differentiation. They have the capacity to renew themselves. Therefore, at no time, bone marrow is depleted of the stem cells. Also, they have the capacity to develop (differentiate) into the subsequent progenitor cells.

Committed Stem Cell

These cells develop from pluripotent stem cells. There are specific two categories of stem cells: stem cells for myeloid series and lymphoid series. Myeloid stem cells form erythroid series, megakaryoid series, monocytic series and granulocytic series (Fig. 10.4; Chapter 10). Erythroid stem cells give rise to progenitor cells for erythroid cell lines. There are two progenitor cells: BFU-E and CFU-E.

Progenitor Cells

There are two types of progenitor cells: 1) BFU-E, and 2) CFU-E. The BFU-E and CFU-E develop from a common progenitor CFU-Mg/E.

BFUs-E are burst forming units-erythroid progenitor cells that give rise to large number of CFU-erythroid cells. CFUs-E are colony-forming units-erythroid progenitor cells that give rise to moderate number of blast cells of erythroid series. Thus, BFU-E forms CFU-E, which, in turn, forms blast cells (erythroblasts).

Precursor Cells

As blast cells are first to be morphologically identifiable cells in the bone marrow in erythropoiesis, they are the true precursors for erythrocytic series. Hence, precursors for erythrocytes are called erythroblasts, also called normoblasts. Normoblasts develop from pronormoblasts. There are three successive forms of normoblasts: early, intermediate and late (Fig. 12.1).

Pronormoblast

Pronormoblasts (proerythroblasts) are the first blast cells to appear in bone marrow and the first identifiable cells of erythrocyte series. Following are the characteristics of pronormoblast.

1. This is a large cell, having diameter of about 15–20 µm. Cell is irregularly rounded or slightly oval.
2. The cytoplasm is less in amount, occupies about 20% of the cell. Presence of high concentration of polyribosomes makes the cytoplasm intensely basophilic. Cytoplasm has high content of RNA, which indicates vigorous protein synthesis in the cell.
3. The nucleus is large and occupies 80% of the cell. It contains multiple nucleoli.
4. Mitosis is present.
5. Hemoglobin is not yet formed in the cell.

Early Normoblast (Basophilic Erythroblast)

Early normoblast or early erythroblast is the first erythroblast to appear in bone marrow. The features are:

1. Diameter of these cells is 12–18 µm.
2. Cells exhibit active mitosis.
3. Cytoplasm is scanty, deep blue and basophilic. The basophilic cytoplasm is due to continuation of many polyribosomes in it. Therefore, early normoblast is also called basophilic erythroblast.
4. Nucleus is large and occupies three-fourth of the cell area. Nucleus is composed of dark violet heterochromatin clumps interspersed with pink clumps of euchromatin. The chromatin is connected by linear strands. This often gives nucleus the appearance of wheel spokes.
5. Hemoglobin appears first time in these cells in erythropoiesis.

Intermediate Normoblast (Polychromatic Erythroblast)

This is also called intermediate erythroblast. This appears following mitotic division of early erythroblast. Following are features of intermediate erythroblast.

1. The cell is smaller than the early normoblast, having the diameter of 10–15 µm. 
2. The cytoplasm changes from blue to pink as hemoglobin dilutes the polyribosome content. 
3. Nucleus is small and occupies about half of the cell area. The distribution of heterochromatin clumps in nucleus gives the appearance of checkerboard pattern. There are no nucleoli. 
4. Hemoglobin synthesis increases, which makes the cell acidophilic. The presence of RNA material makes the cytoplasm eosinophilic. Thus, mixture of acidophilic hemoglobin and eosinophilic RNA in cytoplasm makes it polychromatic. Therefore, intermediate normoblast is also called polychromatic erythroblast. 
5. Mitosis is sluggish in intermediate normoblast.

Late Normoblast (Orthochromatic Erythroblast)

This is also called late erythroblast. This is produced by final mitosis in the erythropoietic series. The features are:

1. This is smallest in the erythroblastic series (7–12 µm in diameter) and mitosis is absent.
2. Cytoplasm is deeply eosinophilic giving the appearance of an orthochromatic cell. Hence, this is also called orthochromatic erythroblast.
3. Nucleus is small and pyknotic at the beginning. Sometimes, dark nuclear chromatin materials are arranged in a typical pattern to give the appearance of a cart-wheel. Finally, the pyknotic nucleus disintegrates.
4. Hemoglobin synthesis increases and almost completes in this stage.

**Mature Cells**

**Reticulocytes**

Reticulocytes are the immediate precursors of red cells. Therefore, they are also called juvenile red cells.

1. They are mature cells with full complement of hemoglobin.
2. They are slightly larger than red cells.
3. They have a network of reticular nuclear material. The reticular network is nothing but the remnants of disintegrated organelles, and especially of the nuclear fragments. Due to the presence of reticular network, the cells are called reticulocytes.
4. The reticulum is stained by supravital stains.
5. Hemoglobin synthesis continues to some extent in some reticulocytes. The reticulocyte count is 0–1 per cent of red cells in adults (details of reticulocyte are given below).

**Erythrocytes**

Erythrocytes are the final cells in erythropoiesis. They are biconcave discs. They have the diameter of about 7.5 µm (for details of red cells, refer to the previous chapter).

**Duration of Erythropoiesis**

The total period for erythropoiesis occurs in 7 to 9 days. It takes 5 to 7 days for progenitor cells to become reticulocytes and another 2 days for reticulocytes to become red cells.

### REGULATION OF ERYTHROPOIESIS

There are many factors that effectively control erythropoiesis. In physiological conditions, total cell mass is maintained at its optimal size by the suitable adjustments in the rate of erythropoiesis.

**Feedback Controls**

In animals, spleen is the reservoir of red cells, but not in humans. Therefore, there is no specific origin of signals from a particular reservoir for the production of red cells and consequently, there is no anatomical tissue feedback for erythropoiesis. Hence, mechanisms controlling erythropoiesis can broadly be divided into two categories: the functional feedback and the end-product feedback.

**Functional Feedback**

The functional feedback is the feedback that originates from the tissues signaling the rate of their requirement which is normally served by red cells. Red cells supply oxygen to the tissues, and, therefore, oxygen requirement of the tissue is the major functional feedback for red cell production. Erythropoietin is the chief mediator of this functional feedback.

**End-product Feedback**

The end-product feedback is due to the products of red cell destruction. It is believed that the products released from red cell destruction (hemolysis) influence red cell production. This is supported by the observation that hemolytic anemia is associated with more erythroid hyperplasia and reticulocytosis than the hemorrhagic anemia of equal severity. However, the precise mediator of end-product feedback is not clearly identified, though in vitro studies have demonstrated the stimulatory effects of hemin on erythropoiesis.

**Factors Controlling Erythropoiesis**

The factors controlling erythropoiesis can broadly be divided into three categories: hormonal, dietary and others (Table 12.1).

**Hormonal Factors**

**Erythropoietin**

**History**

In 1906, French Professor Dr Paul Carnot and his associates suggested that hypoxia generates humoral factor capable of stimulating red cell production. In 1950, Kurt Ressmann provided strong support for existence of a hormonal mechanism, and few years later, it was named as erythropoietin. In 1957, Jacobson and coworkers found that the erythropoietin is produced by kidney.

| Table 12.1: Factors controlling erythropoiesis. |

| 2. Chemical factor |
| 3. Environmental factor (hypoxia) |
| 4. Drugs |
Source
Erythropoietin is produced mainly by the interstitial cells in peritubular capillary bed of kidney. To some extent, it is also produced by juxtaglomerular cells and extraglomerular mesangial cells of kidney. Kidney secretes about 85% of erythropoietin (Application Box 12.1). The rest 15% comes from liver. The nonparenchymal cells (Kupffer cells) of liver and perivenous hepatocytes produce erythropoietin. There are also evidences that erythropoietin is produced in brain, uterus and oviducts.

Application Box 12.1
Renal disease causes anemia: As kidney is the major source of erythropoietin, chronic renal diseases that reduce renal mass significantly produce anemia. Anemia is also produced following nephrectomy. In such conditions, erythropoietin produced by liver fails to meet the normal demand of erythropoiesis as the amount secreted from liver is not adequate.

Structure
Erythropoietin is a glycoprotein containing 165 amino acids. There are four oligosaccharide chains attached with polypeptide chain. These oligosaccharide chains are necessary for the physiological activity of erythropoietin. Erythropoietin has molecular weight of 34,000 dalton.

Mechanism of Action
Erythropoietin acts on erythropoietin receptors that belong to cytokine receptor superfamily. The receptor has tyrosine kinase activity. Binding of erythropoietin with its receptor initiates activation of a cascade of serine and threonine kinases that finally leads to activation of JAK-2 protein. Formation of JAK and other signaling proteins brings about changes in cell functions in a similar way to that of growth hormone.

Functions
Erythropoietin stimulates erythropoiesis in several ways:
1. It acts mainly on the progenitor cells and early precursor cells. It especially stimulates BFU-E and CFU-E to form pronormoblasts.
2. It decreases cell cycle length of precursor cells, and therefore, enhances mitosis.
3. It facilitates maturation of normoblasts.
4. It increases hemoglobin synthesis in normoblasts.
5. It acts on the stem cells to promote their transformation towards erythroid series.
6. It stimulates early release of immature erythrocytes (reticulocytes) into circulation.

Regulation of Erythropoietin (Ep) Production
Factors regulating Ep production can be divided into factors increasing and factors decreasing the production.

Factors that increase Ep production: Hypoxia, low blood volume, anemia, lung diseases and hormones like epinephrine, norepinephrine, androgen, thyroxine, prolactin, ACTH, etc. facilitate Ep production. Hypoxia stimulates erythropoiesis by increasing erythropoietin production. This is the mechanism of polycythemia that occurs at high altitude.

Factors that decrease Ep production: Estrogen inhibits erythropoiesis. Adenosine antagonist such as theophylline decreases erythropoietin secretion.

Metabolism
Ep is inactivated mainly in liver. The usual half-life of Ep in circulation is about 5 hours. However, if carbohydrate component, especially sialic acid residue of erythropoietin molecule is damaged (even partly), the half-life is shortened to 5 minutes.

Interleukins and GM-CSF
Interleukin 1, 3 and 5 that are produced mostly from T-cells act mainly on the stem cells to convert them to the progenitor cells. GM-CSF (granulocyte-macrophage colony-stimulating factor), which is produced from T-cells, endothelial cells, and fibroblasts stimulates production of committed stem cells.

Androgens
Androgens stimulate erythropoiesis. This is the major cause of higher red cell count in males than in females. Red cell count is same in both genders till puberty. Androgen stimulates erythropoietin production. Also, it directly stimulates erythropoiesis.

Estrogens
Estrogen inhibits erythropoiesis by inhibiting erythropoietin production and also by decreasing the response of stem cells to erythropoietin. Estrogen also decreases hepatic synthesis of globulin.

Thyroxine, Cortisol and Growth Hormone
1. Thyroxine stimulates erythropoiesis. Though the exact mechanism of thyroxine increasing red cell count is not known, it stimulates erythropoietin production.
2. Growth hormone increases the mitosis and maturation of erythroid precursors.
3. Cortisol produces mild erythrocytosis.

Dietary Factors
Iron
Iron is the raw material for synthesis of heme component of hemoglobin. Therefore, iron deficiency results in hypochromic microcytic anemia.

Vitamin B12 and Folic Acid
These two vitamins are necessary for maturation of red cell precursors as they promote DNA synthesis.
1. For synthesis of DNA, thymine is required and tetrahydrofolate is necessary for thymine synthesis, which is formed from folic acid.
2. Folate, after its absorption from intestine, becomes methyl-tetrahydrofolate in blood, which in the tissue
becomes 5,10-methylene tetrahydrofolate, the active form of tetrahydrofolate. This promotes formation of deoxythymidylate from deoxyuridylate, which is required for synthesis of DNA.

3. Therefore, folate deficiency leads to arrest of mitosis and chromosome division in the absence of DNA synthesis.

4. Vitamin B₁₂ promotes conversion of methyl-tetrahydrofolate to its active tetrahydrofolate (THF) form. Methyl-THF accumulates in the cell, which is known as methyl-THF trap. Therefore, vitamin B₁₂ deficiency also causes arrest of chromosomal division.

5. In fact, folic acid and vitamin B₁₂ interact with each other for synthesis of DNA (Fig. 12.2). Thus, in deficiencies of these two vitamins, megaloblasts are produced in the bone marrow instead of normoblasts (Fig. 12.3B). Therefore, the resulting anemia is called megaloblastic anemia (Clinical Box 12.1). Megaloblasts produce macrocytes that manifest as macrocytic anemia (Fig. 12.3A).
Megaloblastic anemia: Folate and vitamin B$_12$ deficiencies cause megaloblastic anemia. Patient usually presents with glossitis and neurologic manifestation (subacute combined degeneration of spinal cord and peripheral neuropathy). Macrocyes are seen in peripheral blood smear and megaloblasts are seen in bone marrow smear (Figs. 12.3A and B).

Protein
Protein is essential for synthesis of globin component of hemoglobin. Therefore, protein deficiency is invariably associated with hypochromic anemia.

Other Nutritional Factors
1. Vitamin C helps in absorption of iron. Therefore, vitamin C deficiency causes anemia.
2. Minerals like copper and cobalt influence hemoglobin formation. Thus, deficiency of these minerals leads to anemia.

Other Factors
Intrinsic factor
Intrinsic factor is secreted from oxyntic cells of stomach along with hydrochloric acid. It helps in absorption of vitamin B$_{12}$ (extrinsic factor of Castle) from terminal part of ileum. Therefore, intrinsic factor deficiency produces megaloblastic anemia (pernicious anemia).

Environmental Factors
Hypoxia due to any cause increases erythropoiesis by increasing erythropoietin production. Hypoxia occurs at high altitude, and is commonly seen in cardiac and respiratory diseases.

Drugs and Chemicals
Vasoconstrictor agents like catecholamines, nucleotides like cAMP, NAD, NADP, products of red cell destruction (hemolysates), cobalt salts and thyroxine stimulate erythropoiesis.

Effective vs Ineffective Erythropoiesis
Under normal conditions, most of the red cells produced in the marrow are actively alive or have the potential to live a normal life span. This is called effective erythropoiesis. However, a fraction of red cell production is ineffective with destruction of nonviable red cells either within the marrow or shortly after they are released into circulation. When percentage of production of these nonviable red cells is increased, the erythropoiesis is called ineffective erythropoiesis. Ineffective erythropoiesis is suspected when reticulocyte count is normal despite erythroid hyperplasia of marrow.

Reticulocytes
Structure
Reticulocytes are juvenile red cells in the bone marrow. They develop into mature red cells and few of them pass into circulation along with red cells.

Development
Reticulocytes are produced in the bone marrow from late normoblast (orthochromatic erythroblast).
1. The nucleus is removed from the late normoblast to become reticulocyte.
2. Reticulocytes lose their mitochondria and ribosomes, and basophilic tint to become mature red cells.
3. About 1% of circulating red cells is replaced everyday by newly formed red cells. 
4. With the release of young red cells into the circulation, a few reticulocytes are also released. When the bone marrow sends out red cells at an increased rate, more reticulocytes are released. Thus, the number of reticulocytes in the peripheral blood is an index of erythropoiesis, especially in anemia (Clinical Box 12.3).

Clinical Box 12.3

Reticulocytes indicate bone marrow activity: Reticulocytes are the immediate precursors of red cells. Therefore, when the demand for red cells in the body is increased, reticulocyte formation and release are also increased. Thus, reticulocyte count increases along with red cell count. Sometimes, the demand may be so high that nucleated red cells are also released from bone marrow.

Reticulocyte Count

The normal reticulocyte count in adult is 0–1% of the red cells. In newborns, the count is 2–6%. The number falls during the first year of life to less than 1% and then the level is maintained throughout life.

Reticulocyte Response

The reticulocyte count is performed to assess the therapeutic response of anemias to treatment in which the patient is deficient in one of the substrates essential for the synthesis of red cells. When therapy begins, new red cells are formed and released rapidly into the circulation before cells are fully matured. Therefore, many reticulocytes are also released with the release of young red cells. This results in increase in reticulocyte, which is called reticulocytosis. Increase in reticulocyte count is called reticulocytosis. This is seen in various physiological and pathological conditions.

Physiological: Newborns and infants have higher count than adults. Count is more at high altitude.

Pathological: Hemolytic anemia, acute hemorrhage, during treatment for deficiency anemias (reticulocyte response), and any condition that stimulates bone marrow to produce red cells.

Reticulocytopenia

There is no physiological reticulocytopenia. Reticulocytopenia always indicates diseased state. It is seen in aplastic anemia, myxedema, hypopituitarism and leucoerythroblastic anemia.

Leucoerythroblastic Reaction

The leucoerythroblastic reaction is used to describe the presence of immature myeloid cells and nucleated red cells in the peripheral blood, which occurs often as a consequence of disturbance of the bone marrow architecture by abnormal tissues. This is seen in secondary carcinoma of bone, myelofibrosis, postsplenectomy states, thalassemia major and multiple myeloma.

Reticulocyte Count in Ineffective Erythropoiesis

Reticulocyte remains almost normal in ineffective erythropoiesis. In fact, ineffective erythropoiesis is suspected when reticulocyte count is normal despite erythroid hyperplasia of marrow.

Reticulocyte Index

Effective erythropoiesis is estimated by reticulocyte count, which is normally expressed as the % of red cells. However, it can also be expressed as the total number of circulating reticulocytes per unit of blood, i.e.:

Absolute reticulocytes = reticulocyte percentage × red cell count

To use reticulocyte % as a measure of the rate of red cell production, the % may be corrected for the hematocrit. This is called reticulocyte index or corrected reticulocyte count.

Reticulocyte index = Reticulocyte % × ActualHct / NormalHct

Alteration in Reticulocyte Count

Reticulocytosis
**CHAPTER SUMMARY**

**KEY CONCEPTS**

1. Erythropoiesis occurs in 3 stages in fetal life: mesoblastic (in yolk sac), hepatic (in liver and spleen) and medullary (in red bone marrow). After birth, erythropoiesis is completely medullary. Extramedullary erythropoiesis after birth is always considered abnormal.

2. In erythropoiesis, hemopoietic stem cells become progenitor cells that, in turn, form precursor cells. Hb appears in early normoblast and completes in late normoblast. Nucleus becomes pyknotic and extruded in late normoblast.

3. Erythropoietin secreted mainly from kidney is the primary regulator of erythropoiesis. Hypoxia, low blood volume, anemia, lung diseases and hormones, like epinephrine, norepinephrine, androgen, thyroxine, prolactin, ACTH, etc. facilitate Ep production, and, therefore, these factors/conditions stimulate erythropoiesis.

4. Reticulocyte has no nucleus, but contains RNA materials that make the reticular appearance in cytoplasm in supravital stain. Reticulocyte count is about 1% in adults.

5. Reticulocyte count increases when vitamin B\( \text{subscript} 12 \) is administered as part of the treatment for pernicious anemia. The response is called reticulocyte response. It is also seen when iron therapy is given in iron-deficiency anemia.

6. Reticulocyte count is an index of effective erythropoiesis, especially in anemia.

**Important to Know (Must Read)**

1. In examinations, ‘steps of erythropoiesis and its regulation’ usually comes as a Long Question. This is a common question, very often asked in final exam. A student must not miss it.

2. Erythropoietin, regulation of erythropoiesis, reticulocyte, and reticulocyte response, are usually asked as Short Questions in exams.

3. In Viva, examiners usually ask stages of erythropoiesis, medullary and extramedullary erythropoiesis, factors affecting erythropoiesis, regulation of erythropoiesis, source and functions of erythropoietin, role of folic acid and vitamin B12 in erythropoiesis, differences between red cells and reticulocyte, reticulocyte response, and causes of reticulocytosis and reticulocytopenia.
CHAPTER 13

Destruction of Red Blood Cells

LEARNING OBJECTIVES

On completion of study of this chapter, the student MUST be able to:
1. Say the lifespan of normal red cell.
2. Give the site and mechanism of red cell destruction.
3. Describe the fate of destroyed red cells.
4. List the common causes of hemolytic jaundice.
5. Explain why hemolytic jaundice is common in newborns.

The student MAY also be able to:
1. Give the physiological basis of hemolytic jaundice.

The average lifespan of normal red cell is 120 days. After red cells live their normal life, they become less active and more rigid, and get trapped by cells of reticuloendothelial system, especially by the macrophages in the liver and spleen. These macrophages engulf red cells by phagocytosis and release hemoglobin. Also, the rigid cells get ruptured while passing through narrow capillaries.

MECHANISMS OF DESTRUCTION

There are two mechanisms of red cell destruction: intravascular and extravascular (Fig. 13.1).

Intravascular Destruction

Red cells are destroyed in the circulation, when their cell membrane is breached. Normally, intravascular demise of red cell is less frequent. The causes are:
1. The membrane of older red cells becomes rigid and becomes susceptible to rupture during circulation inside the blood vessel.
2. If there is a defect in the membrane, hemolysis in circulation is facilitated.
   For example, in paroxysmal nocturnal hemoglobinuria, complement complexes create holes in the red cell membrane that promotes intravascular hemolysis.
3. Intravascular destruction is also common in cardiac valve hemolysis and microangiopathic hemolytic anemia.

Extravascular Destruction

Macrophages differentiate young and senescent red cells. They ingest older red cells.

Two important changes occur in senescent red cells that make them vulnerable to mechanical destruction or phagocytosis by macrophages:
1. Decreased deformability
2. Alteration in surface properties.

Decreased Deformability

Deformability of red cells helps them to easily pass through the narrow capillaries and splenic pulps. The biconcave shape and to some extent the viscosity of hemoglobin solution in the cell facilitate the ability of red cells to deform. Therefore, decreased deformability due to change in shape as occurs in spherocytosis or elliptocytosis, and increased internal viscosity as occurs in sickle cell or Hb-C disease, make the red cells vulnerable to lysis while passing through the splenic pulp.

Alteration in Surface Properties

Binding of antibodies or complement components to the surface of red cells, changes the chemical composition of the membrane. Especially, binding of IgG or C3 causes oxidation of membrane components. This is detected by macrophages that ingest red cells.
Section 2: Blood and Immunity

FATE OF DESTROYED RED CELLS

Destruction of red cells causes release of Hb, which is then converted to heme and globin. Heme is converted to bile pigments. Fate of destroyed red cells depends on whether the cells were destroyed intravascularly or extravascularly.

Fate in Intravascular Destruction

Destruction of red cells in circulation releases Hb into plasma. In plasma, Hb binds with haptoglobin (Application Box 13.1). The Hb-haptoglobin complex is transported to liver, where the heme of Hb is converted to iron...
and biliverdin by heme oxygenase. CO is released during cleavage of heme by heme oxygenase. Biliverdin is further degraded to bilirubin (Fig. 13.1). Heme in the plasma binds with hemopexin, a plasma glycoprotein. When the capacity of hemopexin to bind with heme is saturated, heme binds with albumin to form methemalbumin.

### Application Box 13.1
**Plasma haptoglobin indicates hemolysis:** In intravascular hemolysis, Hb-haptoglobin complex clears haptoglobin from plasma. Therefore, haptoglobin content of the plasma is decreased in hemolysis and the degree of decrease is apparently proportionate to the rate of hemolysis. Therefore, estimation of plasma haptoglobin level is an index of hemolysis.

### Fate in Extravascular Destruction
In the phagocytic cells, red cells are degraded by lysosomes into lipids, proteins and heme. Heme is catabolized to bilirubin, and protein and lipids are reprocessed in their catabolic pathways.

1. Bilirubin formed from destruction of red cells regardless of their site of destruction is finally excreted through bile into the GI tract. In the intestine, bilirubin is converted to urobilinogen by bacterial reduction. Urobilinogen is further converted to stercobilinogen and stercobilin that are excreted in stool (Fig. 13.1).
2. A small fraction of urobilinogen is absorbed from intestine and excreted through urine as urinary urobilinogen.

### Important Note
**Assessment of hemolysis:** Estimation of fecal stercobilinogen and urinary urobilinogen content indicates the intensity of hemolysis as they are good markers of the rate of hemolysis.

### HEMOLYTIC JAUNDICE
Hemolytic jaundice occurs from increased destruction of red cells or their precursors in the marrow, causing increased bilirubin production (Table 13.1). Jaundice due to hemolysis is usually mild because the healthy liver can excrete a bilirubin load of six times of its normal concentration. However, this does not happen in newborn. Hence, hemolytic jaundice is common in newborn (Clinical Box 13.1).

1. Heme is converted to biliverdin by heme oxidase, and biliverdin is converted to bilirubin by biliverdin reductase (Fig. 13.2).
2. Unconjugated bilirubin bound to albumin enters liver and gets conjugated by the action of glucuronosyltransferase, to form bilirubin diglucuronide.
3. Following enterohepatic circulation, bilirubin is excreted through bile into intestine, where it is converted to urobilinogen by bacterial reduction.
4. A fraction of it is absorbed into blood from intestine and excreted in urine. Urobilinogen content of stool and urine indicates rate of hemolysis. As bilirubin is unconjugated, which is mostly bound to protein, there is no excretion of bilirubin in urine. Hence, hemolytic jaundice is called acholic jaundice.

![Fig. 13.2: Metabolism of bilirubin (hepatic phase and intestinal phase) and pathophysiology of hemolytic jaundice.](image-url)
5. Increased fecal stercobilinogen can cause **dark-brown colored stool**.
6. The plasma bilirubin is usually less than 6 mg% and liver function tests are usually normal. For details, refer Chapter 41 “Functions of liver and pathophysiology of jaundice” in GI System.

**Clinical Box 13.1**

**Hemolytic jaundice is common in newborn:** Normally, healthy liver can excrete a bilirubin load of six times of its normal concentration. However, in newborns as hepatic enzyme systems are not well developed, the bilirubin metabolism is not effective. Hence, hemolytic jaundice is common in them, especially in premature deliveries.

**CHAPTER SUMMARY**

**Key Concepts**

1. Red cells after their life span of 120 days (senescent red cells) are destroyed intravascularly or picked up and phagocytosed by the cells of reticuloendothelial cells (extravascular destruction).
2. Bilirubin released from macrophages enters liver for metabolism, and from there it enters intestine, where it is converted to stercobilinogen and excreted in feces.
3. About 20% of bilirubin enters kidney and excreted as urobilinogen.
4. Levels of stercobilinogen and urobilinogen indicate the rate of hemolysis.
5. Excess of hemolysis causes bilirubin accumulation, leading to hemolytic jaundice.

**Important to Know (Must Read)**

1. Usually, **Long Questions** are not asked from this chapter.
2. Mechanism of red cell destruction and hemolytic jaundice are usually asked as **Short Questions**.
3. In **Viva**, examiners usually ask the life span of red cells, fate of red cells, mechanism of hemolysis, bilirubin metabolism, causes of hemolytic jaundice, physiological basis of hemolytic jaundice, laboratory tests to detect hemolysis, and why hemolytic jaundice is common in newborns.

**5.** Increased fecal stercobilinogen can cause **dark-brown colored stool**.

**6.** The plasma bilirubin is usually less than 6 mg% and liver function tests are usually normal. For details, refer Chapter 41 “Functions of liver and pathophysiology of jaundice” in GI System.

Hemoglobin (Hb) is a conjugated protein present in red blood cells and it constitutes more than 90% of the dry weight of these cells. It transports oxygen from the lungs to the tissues, and carbon dioxide from tissues to the lungs. Hb also serves to destroy the nitric oxide molecule, which is physiologically important.

1. Oxygen affinity of Hb is an important property of Hb.
2. This affinity increases with oxygenation that makes the oxy-Hb dissociation curve sigmoid-shaped.
3. The oxy-Hb releases proton and deoxy-Hb binds proton.
4. The concentration of Hb within red cells of human beings is very high (34 g/dl), which increases its ability to carry adequate oxygen.

**Structure and Synthesis of Hb**

Hb is synthesized in the precursors of red cells during their development in the bone marrow. It appears in the early normoblast stage and attains maximum concentration in the late normoblast stage.

**Structure**

Hb is made up of heme and globin.

**Heme**

Heme is a complex molecule made up of a series of tetapyrrole rings, terminating in protoporphyrin, with a central iron atom. Following destruction of red cells, the components of hemoglobin undergo metabolic degradation (Flowchart 14.1).
1. The iron part of heme is recycled and used up again in the hemoglobin synthesis.
2. The only component of Hb that cannot be recycled is protoporphyrin, which forms bilirubin.

**Globin**

This is a protein substance that consists of two pairs of polypeptide chains. Each amino acid chain is attached to a heme moiety to form a single hemoglobin molecule. After the degradation of hemoglobin, the globin component breaks down into its amino acid constituents that are recycled for hemoglobin synthesis.
Synthesis of Hb

Formation of Hb requires heme and globin. Heme is formed in mitochondria and globin in ribosomes.

1. **Succinyl-CoA**, an intermediary product of TCA cycle combines with glycine to form α-amino-β-ketoadipic acid with the help of pyridoxal phosphate, which in turn forms α-amino-δ-levulinic acid (ALA) in the presence of ALA synthase (Flowchart 14.2).

2. ALA is converted to porphobilinogen, which forms protoporphyrin-IX.

3. Ferrous iron is introduced into protoporphyrin-IX and in the presence of heme synthase, heme is formed.

4. Globin, the protein component formed by ribosome combines with heme to form hemoglobin.

Types of Hemoglobin

Hemoglobins can be broadly divided into normal and abnormal types (Table 14.1).

**Normal Hemoglobins**

**Adult Hemoglobins**

Adult Hb are of two types: Hb A and Hb A₂.

**Hemoglobin A (Hb A)**

Hb A is the major Hb and comprises about 97% of hemoglobin in adult red cells. It consists of two α and two β chains with the structural formula α₂β₂. Hb A is detected in small amount in the fetus as early as the eighth week of intrauterine life. During the first few months of post-natal life, Hb A replaces Hb F and the adult pattern is fully established in 6 months.

**Fetal Hemoglobin (Hb F)**

Hb F is the major hemoglobin in intrauterine life. It has the structural formula of α₂γ₂. Hb F accounts for 70 to 90% of hemoglobin at term. It then falls rapidly to 25% in one month, and 5% in six months. The adult level of 1% is not reached in some children until puberty. Hb F concentration in adults increases in some types of anemia, hemoglobinopathies, and sometimes in leukemia.

Hemoglobin Bart’s (Hb Bart’s)

This is the minor hemoglobin present in fetal life. It consists of 4 gamma (γ) chains, γ₄. Hb Bart’s concentration increases in fetal life in thalassemia.
Chapter 14: Hemoglobin and Blood Indices

Embyronic Hemoglobins
These hemoglobins are confined to the very early stages (embryonic stage) of development. There are 3 embryonic hemoglobins:
1. **Gower Hb 1**: It consists of 2 zeta and 2 epsilon chains (ζ2ε2).
2. **Hb Gower 2**: It consists of 2 alpha and 2 epsilon chains (α2ε2).
3. **Hb Portland**: It consists of 2 zeta and 2 gamma chains (ζ2γ2).

Abnormal Hemoglobins
There are four clinically important abnormal hemoglobins: Hb S, Hb C, Hb D, and Hb E. These are present in different hereditary hemoglobinopathies.
1. The most commonly encountered hemoglobin is Hb S which consists of α2β2, but in the beta chain, valine is substituted for glutamic acid at the sixth position.
2. Hb S is present in sickle cell anemia.

Unstable hemoglobins: Unstable hemoglobins are hemoglobin variants that undergo denaturation, and precipitate in the red cells as Heinz bodies. Unstable hemoglobins are present in some form of congenital non-spherocytic hemolytic anemia.

Normal Values, Functions and Variations

Normal Values
**Adult males**: 14 to 18 (16 ± 2) g/dL of blood  
**Adult females**: 12 to 16 (14 ± 2) g/dL of blood

In newborns, hemoglobin concentration is normally 16 to 22 g/dL, which occurs mainly due to hemoconcentration. It decreases to 9 to 14 g/dL at about two to four months of age. By ten years of age, the normal hemoglobin concentration will be 12 to 14 g/dL. There may be a slight decrease in hemoglobin level after 50 years of age.

Functions of Hb
Hemoglobin serves three important functions.
1. It transports oxygen from lungs to the tissues by forming oxyhemoglobin and carbon dioxide from tissues to lungs by forming carboxyhemoglobin. When fully saturated, 1g of hemoglobin carries 1.34 ml of oxygen. Thus, **oxygen carrying capacity** of blood can be calculated easily if the value of blood hemoglobin concentration is known. For example, if Hb is 15 g%, 100 ml of blood will carry 15 × 1.34 = 20.7 ml of oxygen.
   - Iron component of Hb is essential for the primary function of the hemoglobin; i.e., the transport of oxygen.
   - When reduced hemoglobin is exposed to oxygen at increased pressure, oxygen is taken up at the iron atom until each molecule of hemoglobin has bound four oxygen molecules, one molecule at each iron atom. This is not a true oxidation-reduction reaction, and therefore, combination of hemoglobin with oxygen is known as **oxygination**.
     - The oxygen molecules combine with hemoglobin to form oxyhemoglobin.
     - Hemoglobin returning with carbon dioxide from tissues is called reduced hemoglobin.
2. Hemoglobin acts as a buffer in maintaining blood pH.
3. Hb serves to destroy physiologically important nitric oxide molecule.
4. It imparts red color to the blood. Erythrocytes look red due to the presence of hemoglobin in them, which is a red pigment.

Variations in Hb Concentration

Conditions that Decrease Hb Concentration

**Physiological**
Children have values lower than that in adults and women have values lower than that in males. Hb is less during pregnancy due to hemodilution.

**Pathological**
Hb is less in different types of anemia (for details, see next chapter). However, relative decrease in Hb concentration occurs in different pathological conditions that produce hemodilution like excess ADH secretion as occurs in pituitary tumors.

Conditions that Increase Hb Concentration

**Physiological**
Hb level is high at high altitude that occurs due to hypoxia. Hb is more in newborns. In excessive sweating, relative increase in Hb occurs due to hemoconcentration.

**Pathological**
Hb concentration increases in conditions that produce hemoconcentration like severe diarrhea, vomiting etc; and conditions that produce hypoxia like congenital heart disease, emphysema, etc. It may also be due to polycythemia vera (for details, see next chapter).

Hemoglobin Ligands (Complexes)

Besides its binding with oxygen to form oxyhemoglobin (and release of oxygen from hemoglobin to form reduced or deoxygenated Hb), Hb combines with other chemicals and gases to form Hb-complexes, some normally and some abnormally. Some commonly encountered complexes are nitrosohemoglobin, carboxyhemoglobin, methemoglobin, sulfhemoglobin, cyanmethemoglobin and glycosylated and glycated hemoglobins.

Nitrosohemoglobin
Nitric oxide (NO) is a physiologic ligand of Hb.  
1. NO stimulates a cytosolic heme protein, guanylate cyclase to from cyclic GMP that mediates many physiological
activities including vasodilation, inhibition of platelet aggregation and macrophage cytotoxicity.
2. Hb and myoglobin rapidly react with NO and prevent guanylate cyclase activation.
3. Binding of Hb with NO destroys NO and forms nitrosohemoglobin by formation of nitrosoheme.
4. Especially, stroma-free Hb inactivates NO. Therefore, stroma-free Hb as occurs in hemoglobinemia causes vasoconstriction.

**Carboxyhemoglobin**
Carbon dioxide (CO) is a physiologic ligand of Hb.
1. Binding of CO2 with Hb leads to formation of carboxyhemoglobin.
2. CO2 combines with globin, not with heme.
3. It helps in transport of CO2 from tissues to lungs.

**Carboxyhemoglobin**
Carboxyhemoglobin, also called carbmonoxyhemoglobin, is formed when heme iron of Hb combines with carbon monoxide (CO).
1. Hemoglobin has a much greater affinity for CO than for oxygen. Hb binds with CO about 200 times more strongly than it binds oxygen.
2. Therefore, it readily combines with CO even when CO is present in low concentration.
3. However, formation of carboxyhemoglobin is reversible, which means, once CO is removed from the blood, the hemoglobin combines back with oxygen.
4. Carboxyhemoglobin is found in very low concentrations in normal persons.
5. In smokers, its concentration is high, ranging from 1 to 10 g/dL. Therefore, tissue oxygenation is impaired in smokers.

**Methemoglobin**
Methemoglobin is Hb in which iron has been oxidized from ferrous to ferric state.
1. Methemoglobin is not capable of reversibly binding with oxygen. Therefore, in methemoglobinemia oxygen carrying capacity is grossly reduced.
2. Normally, its concentration is very low.
3. But, its formation increases in the presence of certain chemicals or drugs.
4. However, the formation of methemoglobin can be reversible.

**Cyanmethemoglobin**
Cyanmethemoglobin (hemiglobincyanide) is formed by the action of cyanide anion (CN−), for example potassium cyanide (KCN). However, the combination is reversible.
1. Hemoglobin is the hemoglobin in which the iron has been oxidized by cyanide to the ferric state.
2. Hemiglobincyanide is the methemoglobin bound to cyanide ions.

**Sulfhemoglobin**
Sulfhemoglobin is formed on exposure to some toxic agents, usually sulfur-containing drugs and chemicals.
1. In sulfhemoglobin, the iron is in ferrous state, but oxygen affinity is about 100 times lower than the normal Hb.
2. Sulfur is not attached with iron, rather is bound to porphyrin ring.
3. Once sulfhemoglobin is formed, it is irreversible and remains throughout the life of the carrier RBC.

**Glycosylated or Glycated Hemoglobin**
In our body, glucose gets attached to protein by enzymatic and nonenzymatic processes and hemoglobin being the major protein in circulation undergoes the same too. The resulting structure is called glycosylated hemoglobin. This is a natural physiological process of body.
1. The fraction of HbA, known as HbA1c is of actual clinical interest.
2. In HbA1c, glucose is attached to terminal valine in β chain.
3. In normal individuals, glycosylated Hb (HbA1c) is present in very less concentration, less than 4% of total Hb. The normal HbA1c is less than 4%.
4. As per WHO criteria, if HbA1c is more than 6.5%, it is considered abnormal (Clinical Box 14.1).
5. Its concentration increases in conditions in which blood glucose is chronically elevated like diabetes mellitus, Cushing’s syndrome, hyperthyroidism, etc.
6. As per ADA (American Diabetic Association) criteria:

<table>
<thead>
<tr>
<th>Clinical Box 14.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Glycated Hb (HbA1c) indicates persistent hyperglycemia: When blood glucose is chronically elevated for more than three months, glycated Hb is formed. Therefore, instead of fasting blood glucose, emphasis is given on estimation of glycated Hb. Thus, glycated Hb is an index of chronic hyperglycemia in diabetic subjects.</td>
</tr>
</tbody>
</table>

**In Oxidative Stress**
Currently, the term glycosylation is not used. The process is called glycation of proteins. The resulting hemoglobin is called glycated hemoglobin.
1. This nomenclature has been used recently to differentiate the nonenzymatic glycation from enzymatic glycosylation of proteins that occurs normally in the ribosome-Golgi complex.
2. Glycation requires two factors, increased level of sugars and increased level of free radicals that promote this type of addition in order to gain neutrality.
3. Hence, glycated hemoglobin has recently been considered to reflect the degree of oxidative stress (Clinical Box 14.2).

<table>
<thead>
<tr>
<th>Clinical Box 14.2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Importance of Glycated Hb: As noted above, glycated Hb is measured to detect the degree of hyperglycemia that is harmful to the body and it is also a measure of degree of oxidative stress. Oxidative stress is a potent inducer of aging.</td>
</tr>
</tbody>
</table>
**Applied Physiology**

**Hb Destruction**

Hb destruction occurs with destruction of red cells. When red blood cells are destroyed in the tissue macrophage system, or in the circulation, hemoglobin is degraded into heme and globin. Globin returns to the body’s metabolic pool where its amino acids are subsequently reutilized (Flowchart 14.1). The porphyrin ring of heme is cleaved by the microsomal enzyme, heme oxidase, yielding biliverdin. The biliverdin is further reduced to form bilirubin by biliverdin reductase (Refer to Fig. 13.2, Chapter 13). Therefore, excess hemolysis leads to jaundice (hemolytic jaundice) and hemoglobinuria (Application Box 14.1).

**Application Box 14.1**

**Tissue Hypoxia and ARF:** The primary function of hemoglobin is to carry oxygen from lungs to the tissues. Therefore, anemia-related hypoxia causes tissue hypoxia. The major effects of anemia are due to tissue hypoxia. In hemolysis, hemoglobin is released into blood (hemoglobinemia) and is filtered in the renal tubules and appear in the urine (hemoglobinuria). In the tubules, hemoglobin forms casts that block the renal tubules and cause acute tubular necrosis (acute renal failure). Hemoglobinemia also exerts osmotic effect and increases blood viscosity that affects cardiac output and alters dynamics of blood flow.

**Hemoglobin Estimation**

Hemoglobin estimation is the most frequently ordered laboratory test in clinical practice. It is performed as a routine investigation in outpatient departments and also as a bedside test in hospital patients. It is mandatory to assess the hemoglobin status of a patient prior to any surgical intervention. As it is more convenient, estimation of hemoglobin is preferred to the total RBC count to detect anemia. **Anemia** is said to be present when the hemoglobin level in blood is below the lower limit of the normal range for the age and gender of the individual (for details of anemia, refer to the next chapter).

**Blood Indices**

The values of hemoglobin, PCV and total RBC count are used to calculate red cell volume and red cell hemoglobin content and concentration. These are called **red blood cell indices**. The commonly estimated blood indices are:

1. Mean cell volume (MCV)
2. Mean cell hemoglobin (MCH)
3. Mean cell hemoglobin concentration (MCHC)

   The MCV defines the volume or size of the average RBC, the MCH defines the weight of hemoglobin in the average RBC, and the MCHC defines the hemoglobin concentration or color of the average RBC.

   Other direct quantitative measurements of red cell indices are the **mean corpuscular diameter** (MCD) and **red cell distribution width** (RCDW). Determination of these indices is of considerable clinical importance and is widely used in the classification of anemia.

**Mean Corpuscular Volume**

Mean corpuscular volume (MCV) is the average volume of an RBC expressed in femtoliters (1 fl = 10^{-15} L). If the PCV and the number of red cells per liter are known, MCV is calculated by dividing the volume of red cells per liter by the number of red cells per liter.

\[
MCV \text{ (fl)} = \frac{\text{Hematocrit (%) } \times 10}{\text{RBC count in millions/mm}^3}
\]

Where the factor 10 is introduced to convert the hematocrit reading (in %) from volume of packed red cells per 100 ml to volume per liter. For example, if the hematocrit reading is 40%, and the red cell count is 5 millions, then MCV is calculated as:

\[
MCV = \frac{40 \times 10}{5} = 80 \text{ fl.}
\]

**Normal value:** The MCV in normal adults is between 78 and 96 fl.

**Applied aspect:** The MCV is the **index of the size of red cells**. It depicts whether the red cells are microcytic, normocytic or macrocytic. If the MCV is less than 78 fl, the red cells are considered **microcytic** and if greater than 96 fl, they are considered **macrocytic**.

**Mean Corpuscular Hemoglobin**

The mean corpuscular hemoglobin (MCH) is the average weight of hemoglobin content in an RBC expressed in picograms (1 pg = 10^{-12} g). It is calculated by dividing the hemoglobin content of 1 liter of blood (in g/L) by the number of RBCs in 1 liter.

\[
MCH \text{ (pg)} = \frac{\text{Hb (g/dL) } \times 10}{\text{RBC count in millions/mm}^3}
\]

For example, if the hemoglobin content is 14 g/dL, and the RBC count is 5 millions:

\[
MCH = \frac{14 \times 10}{5} = 28 \text{ pg.}
\]

**Normal value:** The normal range for MCH is 27 to 33 pg. It may be as high as 50 pg in macrocytic anaemia, or as low as 20 pg or less in hypochromic microcytic anaemia.

**Mean Corpuscular Hemoglobin Concentration (MCHC)**

The mean corpuscular hemoglobin concentration (MCHC) is the average hemoglobin concentration per unit volume of packed red cells. It is expressed as g/dL, or percent.

\[
MCHC \text{ (%) } = \frac{\text{Hb (g/100 ml) } \times 100}{\text{PVC/100 ml}}
\]

For example, if the hemoglobin concentration is 15 g/dL and hematocrit is 45%:

\[
MCHC = \frac{15}{45} \times 100 = 33.3\%.
\]
Section 2: Blood and Immunity

CHAPTER SUMMARY

**Key Concepts**

1. The normal hemoglobin is HbA and HbA₂. Hb A constitutes 97% of total Hb, it has the structure of two α and two β chains with the structural formula α₂β₂.
2. Main function of Hb is the transport of oxygen from lungs to tissues and CO₂ from tissues to lungs.
3. Hb in males is 14 to 18 g%, and in females is 12 to 16 g%.
4. Persistent elevation in blood glucose manifests in increased HBA1c. If HBA1c is more than 6.5%, it is considered abnormal.
5. Blood indices (MCV, MCH and MCHC) are useful in classification of anemia.

**Important to Know (Must Read)**

1. In examinations, usually Long Questions are not asked from this chapter.
2. Structure of Hb, functions of Hb, abnormal Hb, all types of hemoglobin complexes, and all blood indices are usually asked as Short Questions in exams.
3. In Viva, examiners usually ask types of Hb, structure of Hb, normal values of Hb in males and females, conditions of increased and decreased Hb, broad steps of Hb synthesis, major steps of Hb degradation, Hb complexes and their clinical significance, importance of HbA1c, normal values and significance of all blood indices. These questions are very common in oral exam and students are expected to answer these questions related to Hb.

**Color Index (CI)**

This is the ratio of hemoglobin percent and RBC percent.

\[
CI = \frac{\text{Hb percent}}{\text{RBC percent}}
\]

100% of Hb = 14.8 g/100 ml.
100% of RBC = 5 millions/mm³.

**Normal value:** The normal range of CI is between 0.85 and 1.10.
CI less than 0.85 indicates hypochromic anemia.

### Normal value

The normal range of MCHC is between 33 and 37 g/dL (or %).

**Applied aspect:** MCHC above 40% indicates malfunctioning of the instrument or error in the calculation of the manual measurements used, as an MCHC of 37% is near the upper limits for hemoglobin solubility, thus limiting the physiologic upper limit of the MCHC. In hypochromic anemias, the hemoglobin concentration is reduced and values as low as 20% to 25% are not uncommon.

**Normal value:** The normal range of MCHC is between 33 and 37 g/dL (or %).

**Applied aspect:** MCHC above 40% indicates malfunctioning of the instrument or error in the calculation of the manual measurements used, as an MCHC of 37% is near the upper limits for hemoglobin solubility, thus limiting the physiologic upper limit of the MCHC. In hypochromic anemias, the hemoglobin concentration is reduced and values as low as 20% to 25% are not uncommon.

**Color Index (CI)**

This is the ratio of hemoglobin percent and RBC percent.

\[
CI = \frac{\text{Hb percent}}{\text{RBC percent}}
\]

100% of Hb = 14.8 g/100 ml.
100% of RBC = 5 millions/mm³.

**Normal value:** The normal range of CI is between 0.85 and 1.10.
CI less than 0.85 indicates hypochromic anemia.
CHAPTER 15
Pathophysiology of Anemia and Polycythemia

Learning Objectives
On completion of study of this chapter, the student MUST be able to:
1. Define anemia and polycythemia.
2. Classify anemia, and give the common causes of each category of anemia.
3. Give the salient blood picture of common types of anemia.
4. List the types and causes of polycythemia.

The student MAY also be able to:
1. Explain the causes and salient blood picture of iron-deficiency anemia, spherocytosis, sickle-cell anemia and thalassemia.
2. Briefly describe the blood picture and bone marrow picture of polycythemia vera.

Alterations in red cell count are grouped into two major types, anemia (erythrocytopenia) and polycythemia (erythrocytosis). Anemia is the decreased red cell mass and polycythemia is the increased red cell mass.

1. As anemia decreases oxygen-carrying capacity of blood, it is usually expressed in terms of hemoglobin concentration of blood, and the clinical features of anemia are primarily due to tissue hypoxia and hypoxia-induced compensatory mechanisms.

2. Polycythemia is better expressed in terms of hematocrit percentage because the clinical features of it are primarily due to the size of red cell mass and the degree of viscosity.

3. Though, defining strictly, polycythemia is the increase in all formed elements of blood, it usually refers to increased red cell mass as red cells are the major constituents of blood.

Anemia is defined as decreased red cell count or hemoglobin content of blood.

1. Detection of anemia is usually performed by estimating hemoglobin content of blood.
2. It can also be performed by performing either total RBC count of blood or by estimating packed cell volume (hematocrit).

3. Clinically, anemia is detected by assessing the degree of paleness usually by looking at the lower palpebral conjunctiva or nail beds.

4. Detection of morphological type of anemia depends on various blood indices (as described in the previous chapter).

Classification

Anemias can be classified either morphologically or etiologically. Common causes of anemia are:
1. Inadequate supply of nutrients resulting in deficiency anemias (deficiency of iron, vitamins and proteins)
2. Aplasia of bone marrow
3. Anemia associated with chronic diseases
4. Anemia associated with renal failure
5. Anemia due to inherited diseases (e.g. thalassemia)
6. Anemia due to blood loss
   However, they are best classified etiologically into two broad groups as decreased red cell production and increased red cell destruction (Table 15.1).

Morphological Classification

Morphologically, anemia are classified into hypochromic microcytic, normochromic, microcytic and macrocytic normochromic types (Refer to Fig. 11.3, Chapter 11).
Section 2: Blood and Immunity

Hypochromic Microcytic Anemia

MCV, MCH, and MCHC are below normal. Such subnormal red cell indices correspond to microcytosis and hypochromia of red cells in the blood film (Figs. 15.1A and B). Micro-normoblasts are seen in bone marrow examination. This occurs due to the result of a defect in red cell formation in which hemoglobin synthesis is impaired to a great extent. The common examples are:

- **Iron-deficiency anemia** in which there is inadequate iron for the formation of the heme component of the hemoglobin, and
- **Thalassemia** in which the formation of the globin component of hemoglobin is defective.

Normochromic Normocytic Anemia

MCV, MCH, and MCHC are within the normal range. Size and hemoglobin concentration of the red cells are normal in the blood film. It usually occurs in following conditions:

- Substantial blood loss (*blood loss anemia*),
- Hemolysis (*hemolytic anemia*) and
- Impairment of red cell production by bone marrow failure or chronic renal failure (*aplastic anemia*).

Macrocytic Normochromic Anemia

The MCV is above the upper limit of the normal. It corresponds to macrocytosis of red cells in the blood film. The red cells are usually normochromic, though they are macrocytic. Megaloblasts are seen in bone marrow examination (Fig. 15.2). Howell Jolly body, hypersegmentation of neutrophils, basophilic stippling are also seen (Refer to Fig. 12.3, Chapter 12). The typical example of this type of anemia is *megaloblastic anemia* that occurs due to deficiency of vitamin B_{12} or folic acid.

**Etiological Classification**

**Blood Loss Anemia**

Anemia due to blood loss mainly occurs due to acute hemorrhage or chronic hemorrhage.

*Acute hemorrhage*: Anemia due to acute hemorrhage depends on the extent of blood loss and the time that has lapsed since bleeding.

Figs. 15.1A and B: Microcytic hypochromic anemia. (A) Peripheral blood smear (note microcytosis); (B) Schematic picture of the smear (note presence of microcytes with hypochromia).

Chapter 15: Pathophysiology of Anemia and Polycythemia

1. In acute blood loss, usually there is a reduction in the total blood volume. Therefore, hemoglobin in the residual blood is normal.

2. However, when the compensatory mechanisms set in to expand the blood volume, hemodilution decreases hemoglobin content.

3. Therefore, estimation of hemoglobin after few hours of acute blood loss does not assess the actual degree of anemia.

Chronic hemorrhage: Chronic hemorrhage occurs mainly in gastrointestinal, genitourinary and respiratory tract diseases.

1. Gastrointestinal blood loss: Peptic ulcer, hemorrhoids, hiatus hernia, carcinoma of the stomach and colon, esophageal varices, chronic aspirin ingestion, ulcerative colitis, hookworm infestation, etc.

2. Respiratory diseases: Respiratory diseases that produce epistaxis, hemoptysis as occurs in pulmonary tuberculosis or bronchogenic carcinoma produce anemia.

3. Genitourinary diseases: Diseases that cause hematuria and hemoglobinuria produce anemia.

4. Diseases of genital tract: In females, loss of blood from genital tract like menstrual disorders (menorrhagia, metrorrhagia) and uterine pathologies produce anemia.

Aplastic Anemia

Aplastic anemia is the anemia due to impaired red cell production. Marrow examination shows a near absence of hematopoietic precursor cells. The common causes of aplastic anemia are listed in Table 15.2.

Hemolytic Anemia

Hemolytic anemia results from increase in the rate of red cell destruction. Defects causing premature red cell destruction may be divided into two broad categories: intracorpuscular, and extracorpuscular (Table 15.3).

Common Anemias

Iron-deficiency Anemia (IDA)

This is the commonest form of anemia in the developing countries. It usually occurs due to deficiency of iron in the diet. There are three major factors in the pathogenesis of IDA.

1. Increased physiological demand for iron as occurs in pregnancy, lactation, growing children. Therefore, in these groups, extra iron should be available in the diet; otherwise IDA occurs.
2. **Inadequate iron intake**, as occurs due to deficiency in the diet.

3. **Pathological blood loss** like bleeding peptic ulcer, piles, worm infestations, epistaxis, hemoptysis etc.

   Anemia of IDA is **microcytic hypochromic** type. Laboratory findings are decreased all blood indices (MCV, MCH and MCHC), microcytic hypochromic cells in blood smear (Fig. 15.1) and micronormoblasts in bone marrow, and decreased marrow iron store (Fig. 15.3).

### Hereditary Spherocytosis

This is a hemolytic anemia in which the fundamental abnormality is the increased defect of red cell membrane (due to decreased quantity of spectrin) that results in spherocytic shape of the cell. Spherocytes have a decreased surface area to volume ratio and the cells are more rigid (less deformable). Therefore, when cells pass through the splenic pulp, they are destroyed.

1. This is an **autosomal dominant disorder** which affects males and females equally.
2. The usual features are anemia, jaundice, enlarged spleen, and may present with gall stone.
3. The blood picture typically shows anemia with spherocytosis (Figs. 15.4A and B), increased osmotic fragility, hyperbilirubinemia, and reticulocytosis.
4. Usually, anemia is **normocytic and normochromic**.
5. Splenectomy helps in improving the condition.

### Sickle-cell Anemia

This is a hereditary disorder in which red cells contain an abnormal hemoglobin called Hb S. Hb S is the hemoglobin in which glutamic acid is replaced by valine at the 6th position of beta chain. In the deoxygenated state, conformational changes induced by Hb S makes the cell more rigid and deformed to take the shape of a sickle (Fig. 15.5). Therefore, cells undergo **intravascular hemolysis**.

1. Diagnosis is usually made by **sickle test** (demonstrating sickling of red cells when the blood is mixed with freshly prepared solution of a reducing agent like sodium metabisulphite) (Figs. 15.6), **hemoglobin solubility test** (relative insolubility of reduced Hb S in phosphate buffer), and **hemoglobin electrophoresis**.

**Fig. 15.3:** Iron deficiency anemia. Note microcytic hypochromic red cells in peripheral blood smear and micronormoblasts in bone marrow with decreased iron store.
2. Hyposplenism is usually associated, due to microinfarctions in spleen. Autosplenectomy may occur.
3. The anemia is usually normochromic and normocytic.

**Thalassemia**

Thalassemia is a genetically determined heterogenous group of commonest monogenic disorder in which the rate of synthesis of one or more types of hemoglobin polypeptide chain is decreased. Thus, there are two major classes of thalassemia: α thalassemia and β thalassemia, in which α and β globin genes are involved respectively. This causes decrease in the respective polypeptide chain of hemoglobin (Fig. 15.7).

**β thalassemia**

In β thalassemia (failure to synthesize β chain), which is more common, there is excess α chain production that damages red cell precursor and red cells.
1. There are many homozygous and heterozygous, and major and minor forms of the disease.
2. In β thalassemia major, anemia develops in first few months of life and becomes progressively severe.
3. Splenomegaly, hepatomegaly and skeletal deformities are common.
4. Though anemia is usually microcytic and hypochromic, all forms and combinations are not uncommon (Fig. 15.8).

**α-thalassemia**

Anemia of α-thalassemia (failure to synthesize α chain) is more hemolytic than dyserythropoietic.

The thalassemias are diagnosed by:

1. Hemoglobin electrophoresis
2. Demonstration of Hb-H inclusions (in the absence of sufficient alpha chains, excess of beta or gamma chains aggregate to form Hb-H)

3. Study of rate of globin chain synthesis
4. Alkali denaturation test
5. Acid elution test

**POLYCYTHEMIA**

Though polycythemia strictly denotes increase in all cell types of blood, traditionally it represents increase in number of red cells. It exists in two main forms:

1. The primary form, also called polycythemia vera, is a clonal neoplastic disorder of hematopoietic stem cells.
2. The secondary forms are conditions of increased red cell production that usually occurs due to appropriate or inappropriate increase in secretion of erythropoietin.

In primary form, the cause of the disease is the abnormality of hemopoietic stem cells characterized by uncontrolled proliferation of cells of erythroid, granulocytic and megakaryocytic series, resulting in increase of all forms of formed elements of blood. Thus, primary polycythemia is appropriate for the primary form.

In secondary forms, the cause of the disease is excess erythropoietin secretion that results in increase in red cell production (mostly without increase in granulocytes and platelets). Thus, secondary erythrocytosis is more appropriate than secondary polycythemia for the secondary forms.

**Types of Polycythemia**

Polycythemia is broadly divided into three forms (Table 15.4). The primary form is the polycythemia vera. The secondary
**CHAPTER SUMMARY**

**Key Concepts**
1. Anemia can be classified of morphologically and etiologically. Morphologically, anemias are classified into hypochromic microcytic, normochromic microcytic, and macrocytic normochromic types.
2. The commonest cause of anemia in the Indian subcontinent is nutritional deficiency anemia, especially the iron-deficiency anemia (IDA).
3. IDA manifests with microcytosis and hypochromic red cells in peripheral smear.
4. The next common anemia is megaloblastic anemia that occurs due to vitamin B<sub>12</sub> deficiency. In this, macrocytosis is seen in peripheral smear, and megaloblasts in bone marrow smear.
5. Polycythemia vera occurs due to hemopoietic stem cells producing more erythroid lineage, resulting in excessive production of red cells.

**Important to Know (Must Read)**
1. In examinations, classification of anemia with causes and blood picture may come as a Long Question.
2. Types of anemia, megaloblastic anemia, iron-deficiency anemia, thalassemia and polycythemia are usually asked as Short Questions in exams.
3. In Viva, examiners usually ask about types of anemia, causes of anemia, peripheral blood picture in common anemias, like IDA and megaloblastic anemia, and definition and types of polycythemia.
4. As anemia is common in India, questions are frequently asked from this chapter, and the student is expected to answer these questions.
CHAPTER 16
Blood Groups and Physiological Basis of Blood Transfusion

Learning Objectives
On completion of study of this chapter, the student MUST be able to:
1. List the uses of blood groups, classify blood groups and give the physiological basis of blood grouping.
2. Describe the agglutinogens, agglutinins in ABO system, give % distribution of ABO blood groups in population and understand the mechanism of inheritance of ABO blood groups.
3. Define Landsteiner’s law and give its physiological basis.
4. Describe the antigens and antibodies in Rh system, and the mechanism of Rh incompatibility.
5. Give the etiology, features, physiological basis of treatment and prevention of erythroblastosis fetalis.
6. Understand the concept of universal donor, universal recipient, and major and minor cross matching.
7. List the usual hazards of blood transfusion.

The student MAY also be able to:
1. Explain the role of H antigen in ABO typing.
2. Appreciate the importance of Bombay blood group.
3. Name the anticoagulants used for blood collection and list the changes in red cells following storage of blood.
4. Name the common diseases associated with various blood groups.
5. List the indications of blood transfusion and learn the procedure of transfusion.

BLOOD GROUPS

Human red cells contain numerous surface structures that are recognized as antigens by the immune system of the individual who does not possess them. These surface structures are called blood group antigens. Based on the presence of antigens on red cell membrane, usually corresponding antibodies are absent in the plasma of that individual. This forms the physiological basis of blood groups and principle of blood transfusion:
1. The blood group antigens are called agglutinogens and the antibodies against them are called agglutinins as the reaction between them results in clumping or agglutination of red cells.
2. There are more than 30 known blood group systems in our blood containing about 400 antigens (Table 16.1).
3. Many of them have cold antibodies that do not react at body temperature. Therefore, only few of them are immunologically active.
4. The blood group systems that are most important for blood transfusion are ABO and Rh systems.
5. Other major blood group systems that have medical and medicolegal importance are MNS, Lewis, Duffy, Kell, P and Lutheran systems.

Uses of Blood Groups

Red cells have traditionally been considered as less active cells that contain mainly hemoglobins. However, they play important role in many physiological processes of the body due to the presence of antigens on their surface:
1. Characterization of red cell antigen and antibodies forms the basis of compatibility testing for blood transfusion. When the blood group of an individual is known, in emergency situations, blood can be transfused immediately with the suitable blood. Therefore, ABO and Rh blood groups are usually displayed in the identity cards of individuals.
2. The blood group antigens have provided the scientific basis for understanding hemolytic diseases of the newborn and autoimmune hemolytic anemias.
3. Blood group antigens play a critical role in susceptibility to infections by malaria parasites, bacteria and viruses. Also, few blood groups provide resistance to some diseases (see above).

4. Red cell antigens are also associated with clinical disorders. Absence of certain red cell antigens is associated with specific dysfunctions, and certain inherited and acquired diseases are associated with alteration of red cell antigen expression. These associations have led to understanding of pathophysiology of these pathologic processes.

5. Medicolegal experts take the help of characterization of red cell antigen and antibodies in establishing the identity of the father in cases of disputed paternities (and also to identify the mother in cases of disputed maternity).

6. Specific blood groups have been reported to be associated with human behaviors. Therefore, blood groups are believed to contribute to the personality of the individual.

### ABO System

ABO system was the first blood group system to be known (described in 1901):

1. This is the most important system in transfusion medicine, as ABO agglutinogens are highly antigenic.
2. Physiologically, it is most significant of all blood group systems, because of natural occurrence of A and B antibodies in the plasma of individuals who lack corresponding antigen on their red cells.
3. In addition, transfusion of incompatible ABO blood groups instantly leads to serious consequences.

### ABO Agglutinogens

In ABO system, in essence there are two antigens, the antigen A and the antigen B. A antigen has two sub-types, A and A. The genes for antigens for ABO system are ABO genes located on chromosome 9.

### Occurrence

These antigens are present on the membrane of red cells:

1. They are also found in other tissues like salivary gland, testes, lungs, kidney and pancreas. Therefore, they are secreted in minute quantity in saliva, pancreatic secretion and seminal fluid.

2. Some individuals, especially blood group O, secrete blood group H antigens in saliva and other body fluids; they are called H secretors (see below, role of H antigen).

### Time of Appearance

ABO antigens are present since fetal life. They first appear at sixth week of intrauterine life. At birth, the concentration is about one-fifth of concentration in adults. Concentration rises slowly to reach a significant level at puberty and reaches maximum at 15–17 years of life (Application Box 16.1). Therefore, for collection of blood for blood transfusion, the age of the donor should be minimum of 15 years.

### Chemical Nature

Blood group antigen A and B are complex oligosaccharides. There is difference in their terminal sugars. For agglutinogen A, terminal sugar is N-acetylgalactosamine, and for agglutinogen B, terminal sugar is galactose.

### Blood Groups Based on Antigens

Based on the presence or absence of A and B antigens on the red cell membrane individually or in group, four blood groups have been described.
Section 2: Blood and Immunity

Group A : Antigen A is present
Group B : Antigen B is present
Group AB : Both A and B antigens are present
Group O : Neither A nor B antigen is present

Subtypes
As A antigen has two sub-types, A and A, the group A is subdivided into two groups: the group A containing A and A antigens, and group A containing A antigen alone. Similarly, the AB blood group is subdivided into A,B and A,B blood groups.

Distribution
In the Indian population, the approximate distribution of the ABO blood group is as follows:

A : 27%
B : 31%
AB : 8%
O : 34%

In the A blood groups, A is 75% and A is 25%.

Role of H Gene and H Antigens
The expression of A and B antigens are dependent on the presence of H genes. Most of the individuals are homozygous for the H gene. The sequence of events in the formation of A and B red cell antigens is:

1. A and B red cell antigens are glycoproteins and their formation starts with basic precursor substances (Fig. 16.1).
2. Basic precursor substance is first converted to H substance (by transferase) under the influence of H gene.
3. H substance is partially converted under the influence of A and B genes (and specific transferase) into A and B antigens. Some of the H substance remains unconverted.
4. Since O group individuals do not have A and B genes, neither A nor B antigen is formed, and these have only H substance (H remain unchanged). A, B and H antigens may be detected in the saliva and other body fluids also. Such individuals are called secretors, while the remaining without it are non-secretors.

Important Note
Secretors and Nonsecretors: The individuals who secrete A, B and H antigen substances in the saliva and other body fluids are called secretors and those who do not are called nonsecretors.

Bombay Blood Group
In 1952, Bhende, Bhatia and Deshpande discovered a new blood group called as Bombay blood group (Phenotype Oh). These individuals lack the H gene, and therefore the basic precursor substance can not be converted into H substance. This in turn results in failure to form A or B antigen. When their blood sample is tested for routine AB grouping, they will be labeled as blood group O. However, their serum contains anti A and anti B and anti H antibodies. These individuals therefore, should be transfused with only Bombay blood group.

ABO Agglutinins
In ABO system, agglutinins are of two types: anti-A (α) and anti-B (β). The α agglutinin has two subtypes, α proper and α.

Occurrence
These antibodies are found in plasma. Usually, specific antibodies are formed against a particular antigen, when they are exposed to that antigen. But, blood group antibodies are naturally occurring antibodies as they are formed without prior exposure to the antigens and are
present in the blood of individuals in whom the respective antigens are absent. However, the mechanism of development of blood group antibodies (as naturally occurring) is not known.

**Time and Mechanism of Appearance**

Anti-A and anti-B agglutinins are not formed during fetal life and are absent at birth. They appear in the second week of neonatal life and increase very slowly in concentration to attain the peak level at about 10 years of life:

1. The exact mechanism of formation of agglutinins in the absence of their corresponding agglutinogen is not clearly known. It has been proposed that intestinal bacteria and food contain antigens similar to that of blood group agglutinogens. Therefore, when the baby starts eating and food gets absorbed from intestine, antigens are absorbed into the blood.
2. As these antigens are recognized as non-self antigens by the body’s immune system, they stimulate antibody production.
3. However, these antigens are present in very low concentration and antibodies against them are produced very slowly; therefore, antigen-antibody reaction does not occur (Application Box 16.2).
4. Moreover, antigens are removed by phagocytic cells.

**Chemical Nature**

The α and β agglutinins are globulins and belong to Ig M category. Therefore, they do not cross the placenta. They function efficiently at low temperature, i.e. between 5° to 20°C. Therefore, they are called cold antibodies.

**Agglutinins Against Blood Groups**

Antibodies are directed against the antigens:

1. The individuals with blood group A antigen on the red cell membrane do not have anti-A antibody, rather possess anti-B antibody in their plasma.
2. Persons with blood group B do not contain anti-B, rather have anti-A antibody in their plasma (Table 16.2).
3. Individuals with blood group AB do not have any antibody.
4. Individuals with blood group O have both the anti-A and anti-B antibodies in their plasma.

These facts were first noted and described by Karl Landsteiner in 1900, and his theory is popularly known as Landsteiner’s law.

**Landsteiner’s Law**

This law states that if a particular agglutinogen is present on the red cell membrane of an individual, the corresponding agglutinin must be absent in his plasma. Conversely, if the agglutinogen is absent in the red cells, the corresponding agglutinin must be present in the plasma. This law holds good for ABO system. However, the second part of the law does not apply for Rh and many other blood group systems as there are no naturally occurring agglutinins in these systems.

**Antigen and Antibodies for ABO Blood Groups**

Thus, in ABO system, blood group A has antigen A on the red cell membrane and anti-B antibody in the plasma, blood group B has antigen B on the red cell membrane and anti-A antibody in the plasma, blood group AB has both antigens A and B on the red cell membrane and no antibodies in the plasma, and blood group O has no antigens on the red cell membrane and possesses both agglutinins anti-A and anti-B in the plasma (Table 16.2).

**Blood Grouping**

Blood grouping is performed by suspending the red cells of the person’s blood group to be checked in the anti-A and anti-B antisera that are commercially available. If the agglutination (clumping of red cells, as checked under the microscope) is present, red cells contain that particular antigen (Fig. 16.2)

**Inheritance of ABO Blood Groups**

Blood groups are genetically determined. Normally, presence of a blood group antigen is a dominant characteristic. Therefore, the antigen is present in the phenotype irrespective of the genotype (Table 16.3).
There are three types of genes: O, A and B. Therefore, a person can have any of the six possible genotypes: OO, OA, OB, AA, BB, and AB. Gene O is genetically not important. Therefore, the respective phenotype may be A or B or AB or O (Clinical Box 16.1). For example, if blood group of one parent is A and other parent is B, then there is possibility of child having any of the four blood group of ABO system (Fig. 16.3).

Clinical Box 16.1

Disputed paternity: The knowledge of inheritance of blood group is useful to solve the cases of disputed paternity. When the blood group of a child and the mother is known, it can be told whether the man in suspicion could have been the father of the child or not. However, blood group can never prove that a particular man is the father of a particular child. This is because the blood group of the man can be one out of several other possible men. Therefore, determination of blood group gene only helps to identify, not confirms the identity. MNS system is more useful in this regard.

Rh System

The Rh (Rhesus) system is the second most important blood group system in transfusion medicine. This was first described in Rhesus monkeys in 1940 by Landsteiner and Weiner; hence it is called Rh system (for Rhesus). First, it was discovered that injection of red cells of Rhesus monkey into rabbit results in development of antibody against rhesus red cells, later it was found that rabbit serum containing anti-Rhesus antibody agglutinate human red cells. This led to the discovery of Rh system in humans.

Rh Antigens

In Rh system, there are six antigens, but there are no naturally occurring antibodies. The antigens are C, D, E, c, d and e. Out of these six antigens, immunologically most active is the D antigen:
1. Thus, in Rh system, there are two blood groups: Rh positive (D antigen present) and Rh negative (D antigen absent).
2. The gene for Rh antigen is the RHD and RHCE genes that are located on chromosome 1.
3. The antigens of Rh system participate in cation transport and membrane integrity of red cells.
4. Rh antigens are membrane proteins found in red cell membrane, not in any other tissues.

Inheritance

Rh antigen is inherited as dominant gene:
1. In Indian population, 95 to 98% are Rh +ve and 2 to 5% are Rh –ve.
2. Rh +ve individual may have homozygous (DD) or heterozygous (Dd) genotypes. Usually, 60% of Rh +ve individuals have Dd genotype and 40% have DD genotype. The genotype of Rh –ve person is dd.
3. If one of the parents is homozygous positive and the other is homozygous negative, all offsprings will be heterozygous positives (Fig. 16.4).
4. Similarly, if the father and mother are homozygous negatives, all offsprings will be homozygous negatives, and when one of the parents is heterozygous positive and the other homozygous negative, 50% of offsprings will be heterozygous positive and 50% will be homozygous negatives.

**Rh Antibody**

The antibody in the system is called *anti-D antibody*, which is produced only when an Rh negative individual receives the Rh positive blood:

1. These antibodies develop very slowly in the first encounter, but form rapidly following subsequent encounters. Rh antibody is of *Ig G type*, which can cross placental barrier.
2. Hence, if antibodies are present in mother’s blood, can be transferred to the fetus.
3. Rh antibody is best reactive at body temperature, and therefore, designated as *warm antibody*.

**Rh Incompatibility**

Rh incompatibility occurs when an Rh negative individual receives Rh positive blood:

1. Normally, when an Rh negative person receives Rh positive blood, there will be no immediate reactions as Rh negative individual does not normally has anti-Rh antibody.
2. However, the donor’s red cells induce an immune response in the recipient to synthesize anti-Rh antibodies, which takes about two to four months to reach a significant titer. However, by that time the donor’s red cells die their natural death within 120 days. The anti-Rh antibody cannot produce any harm to the recipient’s red cells because the Rh negative recipient’s red cells contain no Rh antigens.
3. But, if the same Rh negative person who has already received a Rh positive blood before, receives a second Rh positive transfusion later, the anti-Rh antibodies are synthesized in large amount immediately by the memory cells. This antibody reacts against the donor cells and causes reactions of mismatch transfusion.
4. Thus, the Rh negative individual can safely receive Rh positive blood once in life time.

The similar Rh incompatibility occurs in pregnancies when Rh negative mother bears Rh positive fetus, which leads to *erythroblastosis fetalis*. The first child does not suffer. However, subsequent pregnancies carry risk for the fetus. The disorder is called erythroblastosis fetalis.

**Erythroblastosis Fetalis**

**Etiopathogenesis**

This is a *hemolytic disease of the newborn* which occurs due to Rh incompatibility when an Rh negative mother carries Rh positive fetus during pregnancy:

1. Usually, no reaction occurs in the first pregnancy. However, at the time of delivery during placental separation, a small amount of fetal blood leaks into the maternal circulation. This induces formation of anti-Rh agglutinins in the mother.
2. Therefore, in subsequent pregnancies, the anti-Rh agglutinin from mother, which is predominantly IgG type crosses placenta to enter into fetal circulation and causes hemolysis.
3. In third and subsequent pregnancies, the degree of hemolysis becomes severe.

**Clinical Features**

The features are mainly due to hemolysis. Hemolysis leads to anemia, extramedullary hemopoiesis and neonatal hyperbilirubinemia. If the hemolysis is severe, the fetus may die *in utero* or if the fetus is born alive, he may have the following features:

1. **Anemia**: Anemia is proportionate to the degree of hemolysis.
2. **Hemolytic jaundice**: Occurs due to hemolysis. Serum bilirubin level may be more than 25 mg% in severe cases.
3. **Generalized edema**: Edema occurs in the whole body due to anemia and hypoproteinemia. This is called *hydrops fetalis*.
4. **Kernicterus**: This is a neurologic syndrome with major motor deficits that occurs due to the *deposition of bilirubin in the basal ganglia*. Hyperbilirubinemia occurs due to hemolysis. Basal ganglia have more affinity for bilirubin. However, bile pigments cannot cross the blood-brain barrier (BBB) in adults. Therefore, *hemolysis in adults does not produce kernicterus*. As BBB is not fully developed in fetuses, infants and children, in them bilirubin enters brain and gets deposited in the basal ganglia. Therefore, *hemolysis in infancy and early childhood causes kernicterus*. The dysfunctions mainly manifests in the form of motor dysfunctions.
5. **Extramedullary hemopoiesis**: Due to severe anemia, extramedullary hemopoiesis occurs, for which *erythroblasts* (nucleated red cells) are released into the blood. Erythroblasts are seen in plenty in peripheral smear. Hence, the disease is called erythroblastosis fetalis.
Treatment
About 50% of the fetuses and newborns with erythroblastosis fetalis have mild hemolysis and do not require treatment. In severe cases, the major modalities of treatment are intrauterine fetal transfusion, exchange transfusion and phototherapy:
1. **Intrauterine fetal transfusion:** If the disease is diagnosed in fetus and found to be severe, the treatment is intrauterine fetal transfusion. Presently, the fetal transfusion is carried out by intraperitoneal route, which has replaced the direct intravascular fetal transfusion.
2. **Exchange transfusion:** The treatment of newborns with severe anemia, jaundice and hydrops is exchange transfusion soon after birth. Exchange transfusion removes sensitized red cells, bilirubin and maternal antibody from the plasma. A double-volume exchange transfusion (2 x 80 ml/kg) replaces 90% of the infant’s blood volume with antigen negative red cells. Blood chosen for exchange should be ABO negative, Rh negative and cross-matched against mother’s blood.
3. **Phototherapy:** Intensive phototherapy is very effective in reducing serum bilirubin level.

Clinical Box 16.2

**Phototherapy for neonatal jaundice:** Bilirubin in excess is toxic to the body, especially it produces neurotoxicity. However, on exposure to light bilirubin becomes nontoxic, which is the physiological basis of phototherapy. Bilirubin, on exposure to light undergoes structural and configurational isomerization and photo-oxidation. These changes in bilirubin make it less toxic and less lipophilic products that are excreted efficiently without hepatic conjugation. Therefore, phototherapy is the primary treatment for unconjugated hyperbilirubinemia in newborns. Neonatal jaundice is mainly hemolytic and unconjugated.

Prevention
Erythroblastosis fetalis is prevented by administering a single dose of anti-Rh antibodies in the form of Rh immunoglobulin during the postpartum period following the first delivery. The disease can also be prevented by passive immunization of the mother with a small dose of Rh immunoglobulins during pregnancy.

Other Blood Group Systems

**MNS System**
The MNS system of blood group was first described in 1927 (MN in 1927; S in 1947). This system has three antigens: M, N and S. The antigens are expressed in red cells and endothelial cells of renal capillaries. The MNS antigens are major contributor for negative charges on the red cell membrane. The common phenotypes are M, N, MN and S. This system is helpful for solving the paternity dispute. MNS groups are also useful for anthropological and genetic studies.

**H System**
In the H system, the common antigen is the H antigen. The expression of H antigen depends on the expression of ABO groups, especially O. The blood group O having H antigen in plasma or saliva is called OH group or Oh (if H is not dominant). The gene for H antigen is the FUT1 (H), located on the chromosome 19. The H antigen is present in plasma, most body secretions like saliva, sweat and semen, tissues and epithelial cells. Accordingly they are called secretors or nonsecretors.

**Lewis System**
The Lewis system was described in 1946. This system has two antigens: Le^a^ and Le^b^. These are not truly red cell antigens as they are produced in the plasma and then are absorbed into the red cells. Antigens are also present in body secretions and lymph. The gene for antigen Le^a^ is FUT3(Le) gene located in chromosome 19. The antigens of Lewis system serve as receptor for Helicobacter Pylori. The antibodies are of the IgM type. They do not cross the placental barrier and therefore, do not cause hemolytic disease of the newborn.

**Ii System**
Ii system was first described in 1956. There are two antigens in the Ii system, the ‘i’ and the ‘i’ antigens. The antigens are present in plasma, red cells, lymph and secretions. The Ii system differs from other blood groups in several ways:
1. At birth the I antigen is poorly developed, but red cells of fetus and neonate are rich in the i antigens.
2. There is gradual changeover from i to I antigen in the first two years of life.
3. In conditions like hemoglobinopathies, red cells show increased i antigens without any decrease in I antigens.

**PI System**
The PI system or also called P system was first described in 1927. There are three antigens in this system: P, P and P^k^.

**F Duffy System**
This system was described in 1950. There are three blood group antigens in this system: the Fya, Fyb, and Fyb. A close relationship between Duffy blood group and malaria has been well established. The Fyb blood groups is resistant to Plasmodium Vivax, whereas the Fya and Fyb are susceptible to parasitic infections.
vivax malaria. This is because, Fya and Fyb antigens serve as receptors for plasmodium if present separately on the red cell membrane, and thus increase their entry into the red cells.

Kidd System
This system was described in 1951. There are three antigens in this system: the Jk\(^a\), Jk\(^b\) and Jk\(^3\). The genes for these antigens are Jk (HUT11) genes that are located on chromosome 18. The antigens are specifically present on the red cell membrane (and in no other tissues). They are responsible for delayed hemolytic transfusion reactions.

Kell System
The Kell system was described in 1946. In this system, the common antigens are: K, k, Kp\(^a\) and Kp\(^b\). There are two sets of genes for these antigens: KEL and XK. The KEL genes are located on chromosome 7 and are expressed in red cells, bone marrow and fetal liver. The XK genes are located on X chromosome and are expressed in red cells, skeletal and cardiac muscles and neural tissues. People having K+ve blood group (containing K antigen on the red cell membrane) are susceptible to chronic granulomatous diseases.

Lutheran System
The Lutheran system was described in 1951. There are three blood group antigens in this system: the Lu\(^a\), Lu\(^b\) and Lu\(^3\). The genes for these antigens are LU genes that are located on chromosome 19. The antigens are distributed in red cells, brain, heart, kidney, lung, pancreas, placenta and skeletal muscles. In addition to antibody recognition, they play possible role in cell adhesion, receptor function and intercellular signaling.

Blood Group-associated Diseases
There are diseases that are prevalent in different blood groups. There are diseases that occur in the absence or alteration of blood groups (Table 16.4).

**PHYSIOLOGICAL BASIS OF BLOOD TRANSFUSION**
Transfusion of whole blood or a component of blood is common in medical practice. The common is the transfusion of whole blood or red cell concentrates that are required for the treatment of acute hemorrhage or severe anemia. However, one should be careful for the possibility of transmissions of infectious diseases like HIV and hepatitis, and other hazards of transfusions, when transfusion is given frequently.

**Indications for Transfusion**
1. **Acute blood loss:**
   - Whole blood is preferred.
2. **Chronic anemia:**
   - Packed red cells are preferred to whole blood.
3. **Bone marrow failure:**
   - Leukemia
   - Aplastic anemia
   - Bone marrow infiltration by neoplastic cells.
4. **Purpura:**
   - Platelet transfusion is preferred.
5. **Clotting factor deficiencies:**
   - Fresh frozen plasma is preferred. In hemophilia, cryoprecipitate (rich in factor VIII and fibrinogen) is given.
6. **Preparation for surgery and during surgery:**
   - If the patient is anemic, blood is transfused prior to surgery. During major surgeries, blood transfusion is routinely administered. Loss of 500 ml of blood is usually tolerated during surgery in a patient with normal Hb prior to surgery. If blood loss is expected to be more than this, transfusion is always planned.
7. **Burns:**
   - Plasma rich in protein is lost from the burn surface. This is corrected with plasma and colloids. If anemia is severe, packed red cells are transfused.
8. **Anemia:**
   - Usually, blood transfusion is not required in chronic stable anemia. In hemoglobinopathies like thalassemia and sickle cell anemia, blood transfusion is
the cornerstone of the treatment. Repeated and multiple transfusion in thalassemia and sickle cell disease not only aim to improve Hb content, but also to inhibit erythropoiesis so that defective cells are not produced. However, transfusional hemochromatosis limits usefulness of this treatment.

Procedure of Blood Transfusion

The first step in any transfusion is the identification of a healthy and appropriate donor. Blood grouping for Rh and ABO types of both recipient and the donor, and cross-matching of blood of both recipient and the donor are the next important steps in all blood transfusions to ensure safety and compatibility. In mismatch transfusion, agglutination (clumping) of red cells occurs in recipient’s blood leading to acute hemolysis, which may be life threatening. Therefore, a suitable transfusion should always include:

1. Selection of appropriate donor
2. ABO and Rh typing
3. Cross matching
4. Antibody screening of the patient (to detect the presence of clinically significant antibodies).

Selection of Appropriate Donor

Healthy donors free from transfusion-transmissible diseases should be identified for blood transfusion:

1. Ideally, the age of the donor should be 18 years or above and should not be above 60 years. Donor should be voluntarily willing to donate blood.
2. The hemoglobin status of the donor should be estimated. There should be minimum of 12 g% Hb in female, and 13 g% Hb in male donors.
3. Donor must be screened for AIDS, hepatitis, lymphomas, and protozoal organisms like malaria, filaria, etc.

ABO and Rh Typing

The two major blood group systems for transfusion are ABO and Rh systems. ABO incompatibility causes immediate reactions and may even kill the persons. The Rh incompatibility causes delayed reactions. Therefore, ABO and Rh compatibility must be ensured before any transfusion. The concept of universal donor and recipient helps in this process.

Universal Donor

The blood group O negative (O group and Rh –Ve) persons are considered to be the universal donor because their red cells contain no antigens. Therefore, their blood cells on transfusion to any individual do not cause agglutination reaction. Hence, blood group O –Ve can be given to any individual (Clinical Box 16.3).

Universal Recipient

Individuals having blood group AB positive (AB group and Rh +Ve) are considered to be the universal recipient because their plasma contains no antibodies. Therefore, they can safely receive blood from any one as they do not cause agglutination reaction against any blood cells.

Clinical Box 16.3

Cross-matching is a must before transfusion: Though technically the concept of universal recipient is true, transfusion of blood based on this concept alone may not provide full assurance of compatibility always as there are many other minor blood group systems. Therefore, prior to blood transfusion cross-matching should always be done to eliminate the possibilities of any form of mismatching. However, in an emergency condition, this concept may be used in selecting the donor, if the blood groups of donor and recipient are known without waiting for the report of cross-matching.

Cross-matching

There are two types of cross-matching: major and minor.

Major Cross-matching

In major cross-matching, the cells of the donor are directly matched against the plasma of the recipient:

1. As it is important to ensure that antibodies present in the recipient’s plasma do not harm the donor’s red cells, this cross-matching is called major cross-matching.
2. The ABO agglutinogens are highly antigenic and produce agglutination even in low concentration. Therefore, though donor’s red cells are less in quantity than the recipient, they produce agglutination reactions.
3. ABO agglutinins do not react highly, as they are cold antibodies. Moreover, donor’s agglutinin is diluted in large volume of recipient’s plasma; hence not capable of inducing agglutination reaction.
4. Therefore, it is important to match donor’s agglutinin (red cells) against recipient’s agglutinin (plasma).

Minor Cross-matching

In minor cross-matching, the donor’s plasma is checked against the red cells of the recipient:

1. It is called minor cross-matching, because it is not very important to assess the reactivity of donor’s agglutinin against recipient’s cells.
2. This is because; small volume of the donor’s plasma is diluted in a large volume of the recipient’s plasma.
3. Therefore, the agglutinin titer of donor’s plasma falls to such a low level after transfusion that they are unlikely to damage the red cells of the recipient.
4. However, for full compatibility, minor cross-matching should also be performed.

Antibody Screening of the Patient

The patient who receives transfusion, his serum should be screened for various antibodies like autoantibodies that
may react against the donor’s cells and cause hemolysis. Therefore, it is ideal to do the antibody screening of the patient.

**Blood Collection and Storage**

**Collection of Blood**

Venipuncture is done to collect blood:

1. Ideally, not more than 350 ml of blood is collected from a single donor at a time.
2. From antecubital vein, blood flows freely into a collecting bottle or bag that contains anticoagulant.
3. The usual collection time is 7–10 min.
4. The blood mixes with 50 to 70 ml of anticoagulant consisting of citrate, phosphate and dextrose (CPD). *Disodium hydrogen citrate* is used instead of trisodium citrate as anticoagulant, because this favors fall of pH which is required for survival of red cells.
5. BP and heart rate are monitored after collection, especially before they get up from the supine posture.
6. Normally, some degree of diaphoresis, bradycardia, hypertension and dizziness accompany this bleeding.
7. Donors are advised not to go for work for rest of the day and should also avoid exercise.
8. They are also advised not to donate blood for at least next three months.

**Autologous Donor Blood**

When the donor is the recipient himself, the blood collected is called autologous donor blood and the transfusion is called autologous transfusion:

1. Autologous transfusion was not practiced before. However, AIDS epidemic has increased the necessity and importance of autologous transfusion in transfusion medicine.
2. This can be done prior to a planned surgery.
3. The Hb of the person should be more than 12.5 g%.
4. Blood is collected every 72 hours up to 72 hours prior to surgery or till the Hb level has not gone below 11 g%.
5. Usually 2 to 4 units of blood of 250 ml each can be collected. Then, the same blood (recipient’s own blood) is used during surgery.

**Storage of Blood**

Blood is stored in the blood bank at 4°C. Stored blood for transfusion should ideally be used within 2 weeks of storage. However, blood should not be used if it is stored for more than 3 weeks, because gross hemolysis occurs after this period.

**Red Cell Changes during Storage**

Red cells undergo rapid changes during storage in simple citrate solutions even at 4° C. During cold storage, the changes that occur are mainly due to reduction of metabolism of cells. The changes are:

1. Increase in sodium and decrease in potassium concentration in the red cells. This occurs due to decreased active transport of ions across the cell membrane. At low temperature, Na⁺-K⁺ pump activity is grossly decreased. This results in net increase in the total base and water of the cell. The inhibition of Na⁺-K⁺ pump increases intracellular sodium concentration that causes water to enter the cell by endosmosis.
2. Cells swell and become more spherocytic. This results in spontaneous hemolysis. Leucocytes and platelets almost totally disappear within 24 to 48 hours of storage.
3. The ATP content in the cell decreases and inorganic phosphate concentration increases. This is due to imbalance between phosphorylation and dephosphorylation processes in the cell.

**Changes in Stored Blood after Transfusion**

1. Within 24 hours of transfusion, the cell metabolism greatly increases. Consequently, the sodium is extruded from the cells and the potassium is drawn back into the cells.
2. The volume, shape, and fragility of the red cells come back to normal within 24 to 48 hours.
3. Red cells show 80% of survival 24 hours after transfusion if the transfusion is given within 14 days of storage of the blood. But the survival rate greatly decreases if the blood is stored for more than 2 weeks.
4. Therefore, it is advisable to use blood ideally within 14 days of storage, though blood can be used up to 21 days.
5. Blood should never be used after 30 days of storage.

**Hazards of Blood Transfusion**

Blood transfusion, even in ideal condition carries risks of adverse reactions. Mostly, transfusion reactions occur due to human error:

1. **Due to Mismatched Transfusion:** When an incompatible blood is transfused, the mismatched transfusion reaction occurs immediately. The reaction is primarily due to agglutination of donor’s red cells followed by their hemolysis. This is called **acute hemolytic transfusion reactions.** Usually it occurs due to ABO incompatibility. The severity of the reaction depends on the degree of hemolysis. The complications of mismatched transfusion are:
   i. Shivering and fever (febrile reactions) occur usually
   2. Hemoglobinemia and *hemoglobinuria*
   3. Hemolytic jaundice
   4. **Acute renal failure.**

Renal failure occurs due to:

i. hemoglobin casts blocking the renal tubules and damaging the tubules,
ii. release of toxic substances from the lysed red cells cause renal vasoconstriction, and
iii. circulatory shock.
5. **Hyperkalemia** (due to release of potassium ions from red cells). This may cause cardiac arrest in diastole.

II. **Due to Faulty Techniques of Giving Blood**: Due to wrong method of transfusion, following complications may arise:

1. **Thrombophlebitis**: This is a common complication in those who receive repeated transfusions.
2. **Air Embolism**: Air enters the venous circulation and gets lodged at the outlet of the right ventricle and blocks the flow of blood to the lungs. Death may occur in severe cases. Use of plastic bags has reduced this complication.

III. **Due to Massive Transfusion**: This occurs when more than 10 units of blood are given within 24 hours or when the total blood volume is exchanged within 24 hours. This leads to **circulatory overload**. Cardiac arrhythmias and even sometimes cardiac arrest occur due to high potassium level in the stored blood.

IV. **Febrile Reaction**: The patient feels cold and may get rigor due to rise in body temperature. This occurs mainly due to presence of pyrogens in the transfusion apparatus.

V. **Allergic Reactions**: This is less frequent and is characterized by itching, erythema, nausea, vomiting, and in severe cases may cause anaphylactic reactions.

VI. **Transmission of Diseases**:

1. Hepatitis
2. Malaria
3. AIDS
4. Syphilis.

### CHAPTER SUMMARY

#### Key Concepts

1. Blood group of an individual depends on presence or absence of a specific blood group antigen on the surface of red cell (RBC membrane).
2. If a blood group antigen is present on the surface of red cell, the corresponding antibody must be absent in his plasma. However, if a blood group antigen is absent on the surface of red cell, the corresponding antibody may (or may not be) present in his plasma. This is called Landsteiner’s law.
3. In ABO system, the agglutinogens are highly antigenic. Therefore, for compatible blood transfusion, blood grouping and cross-matching must be done before the transfusion.
4. In major cross-matching, cells of the donor are matched against the plasma of the recipient.
5. Blood group AB positive is the universal recipient, and O negative is the universal donor.
6. For blood collection, disodium hydrogen citrate is the preferred anticoagulant, as it ensures low pH, which facilitates red cell survival.
7. Erythroblastosis fetalis occurs in Rh incompatibility when a mother with Rh negative blood group bears the fetus with positive blood group during pregnancy. It is treated by exchange transfusion and prevented by passive immunization with anti-D antibody.

#### Important to Know (Must Read)

1. In examinations, ‘Physiological basis of blood grouping of ABO system’ comes as a Long Question.
2. Landsteiner’s law, ABO agglutinogens, ABO agglutinins, inheritance of blood group, Rh incompatibility, erythroblastosis fetalis, cross matching, universal donor and recipient, changes in red cells following storage, and hazards of blood transfusion are usually asked as Short Questions in exams.
3. In Viva, examiners usually ask about types of blood groups, uses of blood groups, Landsteiner’s law, ABO agglutinogens, ABO agglutinins, H antigens, Bombay blood group, inheritance of blood group, Rh incompatibility, causes, features, treatment and prevention of erythroblastosis fetalis, types and importance cross matching, universal donor and recipient, method of blood collection, how to store blood in blood bank, changes in red cells following storage, and hazards of blood transfusion, and common diseases prevalent in various blood groups.
4. As blood groups have general and special interest in medicine, a student is expected to answer these questions.
White Blood Cells

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:

1. Classify leucocytes, and give the percentage of different leucocytes in blood.
2. Give the steps of leucopoiesis.
3. Give the general life history of leucocytes.
4. Describe the structure and functions of leucocytes, and list the common causes of decrease and increase of each type of leucocyte.
5. Explain the mechanism of phagocytosis and killing of organisms by neutrophil.
6. List the components of mononuclear-phagocyte system (MPS).
7. Understand the general role of leucocytes in defence mechanisms of the body.

The student **MAY** also be able to:

1. Describe the role of eosinophil in allergy.
2. Explain the role of MPS in defense of the body.
3. Briefly describe different types of leukemia.

**General Introduction**

Leucocytes or white blood cells perform the defense functions of the body. There are two series of leucocytes: **myeloid series** and **lymphoid series**. Each cell line has separate pathway of development from distinct primitive cells (Fig. 17.1):

1. The **myeloid series matures into granulocytes and monocytes**. The **granulocytes** are neutrophils, eosinophils and basophils.
2. The **lymphoid series matures into lymphocytes**.

Though monocytes and lymphocytes have some granules, they are not usually visible with commonly used stains. Therefore, monocytes and lymphocytes are traditionally classified under **agranulocytes** (Table 17.1). The leucocytes of granulocytic series develop from myeloblasts that are virtually agranular cells. During the process of development, the precursor cells synthesize proteins and store them in cytoplasmic granules. The enzymes of granules take part in killing organisms:

1. Granulocytes exhibit active motility and migrate to the site of inflammation by amoeboid movement to kill organisms by phagocytosis.
2. Neutrophils are highly amoeboid and phagocytic, and kill a variety of microorganisms, especially bacteria. Therefore, neutrophils are considered as **first line of defense** against acute bacterial infections.
3. Monocytes are also actively phagocytic and are considered as **second line of defense** against infections, especially in chronic and parasitic infections.
4. The eosinophils and basophils are specialized to participate in **allergic inflammatory responses**.
5. Lymphocytes are involved in **immunological responses**: **Life of leucocytes**: In general, leucocytes have **three phases** in their life: marrow phase, circulatory phase and tissue phase.

1. In the **marrow phase**, they develop from progenitor cells where they proliferate and grow into mature leucocytes and get released into circulation.
2. In the **circulatory phase**, they circulate for few hours before entering into tissues where they live a longer period of their life.
3. In the **tissue phase**, they enter the tissues. In the tissue, monocytes become macrophages that take part in nonspecific defenses of the body as a component of mononuclear phagocyte system.
Section 2: Blood and Immunity

LEUKOPOIESIS

Leukopoiesis is the development of leucocytes.

Stages of Leukopoiesis

The pluripotent stem cells in the bone marrow give rise to committed stem cells. The committed stem cells in the bone marrow are broadly of two types: The myeloid stem cells and lymphoid stem cells. The stem cells for lymphoid series form lymphocytes.

The stem cells for myeloid series are trilineage stem cells that form stem cells for three series of blood cells:

1. Erythroid series for red cells,
2. Megakaryocytic series for platelets and

Usually, life span is 6 to 10 days in the marrow phase, 6 to 8 hours in the circulatory phase and 4 to 5 days or more in tissue phase (Flowchart 17.1)
The stem cells for granulocyte-monocyte of myeloid series give rise to three categories of progenitor cells (colony forming units or CFUs): CFU-GM, CFU-Eo and CFU-Bas (Flowchart 17.2):

1. **CFU-GM** is the phagocytic series progenitor cell that on further differentiation from CFU-G (for neutrophils) and CFU-M (for monocytes).
2. The CFUs form blast cells.
3. CFU-G forms myeloblasts, which on further development form neutrophils.
4. CFU-M forms monoblast that develops into monocytes.
5. CFU-Eo forms eosinophil-myeloblast that develops into eosinophils.
6. CFU-Bas forms basophil-myeloblast that develops into basophils.

**Steps of Development**

The **myeloblasts** form promyelocytes. Promyelocytes form myelocyte, metamyelocytes that in turn develop into mature leucocytes (Fig. 17.2).

**Colony-forming Units**

Colony forming units (CFUs) are progenitor cells that develop from committed stem cells. There are different
CFUs for different cell lines (as described above). However, they possess the properties of stem cells and can not be distinguished morphologically.

**Blast Cells**

These are earliest precursor cells of leucocyte development that are **morphologically distinguishable**:
1. The blast cells for neutrophils are **myeloblasts**, for eosinophil are eosinophil-myeloblasts, and basophils are basophil-myeloblasts, for monocytes are **monoblasts** and for lymphocytes are **lymphoblasts**.
2. The blast cells are large cells (16–20 μm) with large nucleus containing multiple nucleoli.
3. The nucleoli are prominent features of blast cells and are the sites of assembly of ribosomal proteins and r-RNA.
4. The cytoplasm is scanty.
5. Cells are actively mitotic.

**Myeloblasts**: The earliest precursor cells for neutrophils are myeloblasts. They have scanty blue cytoplasm with 5–10 nucleoli in a large nucleus. There are separate myeloblasts for eosinophils (eosinophil-myeloblasts) and basophils (basophil-myeloblasts).

**Monoblasts**: These are the blast cells for monocytes. As they resemble myeloblasts morphologically, they are also called myelomonoblasts.

**Lymphoblasts**: These are blast cells for lymphocytes. They have fewer nucleoli. Nuclear chromatins are clumped.

**Promyelocytes and Promonocytes**

The promyelocytes and promonocytes develop from myeloblasts and monoblasts respectively:
1. The cells are also large and cytoplasm is granular.
2. Nucleus is round and condensed and contains less nucleoli.
3. Cells are mitotic.
4. **Promonocytes** are larger cells (larger than myeloblasts) that on further development form monocytes, the **largest cells** in peripheral blood.
5. The promyelocytes are also larger cells and contain large population of **peroxidase-positive granules**. The granules are large in size having diameter of about 500 nm.

**Neutrophilic Myelocytes**

Myelocytes have diameter of about 12–20 μm:
1. They contain round concentric nucleus. Nucleoli are absent.
2. Cells show some degree of mitosis. About three cell divisions occur in this stage of maturation.
3. The characteristic feature of this stage is appearance of **peroxidase negative specific granules**.
4. The granules are usually spherical (about 200 nm) or rod shaped.
5. The peroxidase positive granules are less than peroxidase negative granules. This is because, with each mitotic division, peroxidase positive granules are reduced whereas peroxidase negative granules continue to be formed.

**Metamyelocytes**

The diameter of metamyelocyte is 12–18 μm. The cells are nondividing (no mitosis) and have mixed granule populations.

**Neutrophils**

Neutrophils developed from metamyelocytes are **juvenile neutrophils** (band forms) that further grow into **matured neutrophils** (segmented neutrophils) (Fig. 17.2).

**Regulation of Leukopoiesis**

Leucopoiesis is mainly regulated by cytokines (for details of cytokines, refer ‘Immunity’), especially, colony stimulating factors (CSFs), interleukins and tumor necrosis factors (TNFs). T lymphocytes, monocytes, fibroblasts, endothelial cells, liver and kidney are the major sources of hemopoietic growth factors (HGFs) (Fig. 17.3). Types, sources and functions of HGFs are listed in Table 17.2.

**Interleukins**

IL-1, IL-6 and IL-3 promote maturation of stem cells. IL-5 helps in development of eosinophil, and therefore, IL-5 is also called eosinophilic growth factor. IL-3 and IL-4 facilitate development of basophils. IL-2 inhibits myelopoiesis.

**Colonystimulating Factors**

There are different colony stimulating factors (CSFs). The important CSFs that influence leucopoiesis are GM-CSF, G-CSF and M-CSF.

**GM-CSF**: This is the granulocyte-monocyte colony stimulating factor (GM-CSF), secreted by fibroblasts, vascular endothelial cells, monocytes and T lymphocytes. GM-CSF stimulates differentiation and proliferation of pluripotent stem cells into committed cells. GM-CSF also helps in differentiation of CFU into granulocyte and monocyte precursors and their further development into mature cells. It synergizes with IL4 to produce dendritic cells.

**G-CSF**: This is the granulocyte colony stimulating factor. It is produced by monocytes, endothelial cells and fibroblast. It helps in development and functions of granulocytes.

**M-CSF**: This is the monocyte colony stimulating factor. This is also called CSF-1. It is produced by fibroblasts, endothelial cells and macrophages. It promotes proliferation of monocytes and macrophages, and also stimulates functions of monocytes.

**Tumor Necrosis Factor**

Tumor necrosis factors (TNFs) help in proliferation and differentiation of stem cells.

Life History of Leukocytes

Leukocytes have mainly three phases in their life: The marrow phase, the circulation phase and the tissue phase (Fig. 17.4).

Marrow Phase

This is the phase of development in bone marrow, hence also called development phase. Marrow phase has two pools: mitotic pool and maturation pool.

Mitotic Pool

The development from myeloblasts to myelocytes is the phase of mitotic pool, as cells undergo mitosis in these stages.

Maturation Pool

This is the phase of maturation of metamyelocytes into mature cells. Cells do not undergo mitosis in these stages.

Duration of Leucopoiesis: From myeloblast to matured leukocytes, the process of development usually takes 10 days. About 5 days are spent in the mitotic pool (development up to myelocytes) and another five days are utilized in the maturation pool (development from metamyelocyte to the mature cells).

Circulation Phase

The matured cells are released into circulation and remain in circulation for few hours before they enter the tissues (circulation pool):
Chapter 17: White Blood Cells

1. At rest, many leucocytes especially neutrophils, adhere to the endothelial lining of blood vessels, which is called **margination pool** of leucocytes (Application Box 17.1).

2. In addition, leucocytes actually circulate in the blood (the **active circulation pool**).

**Application Box 17.1**

*Disruption of margination causes leucocytosis:* Leucocytes adhere to inner lining of blood vessel, called margination. In exercise and other conditions of increased hemodynamics, the leucocytosis occurs mainly due to disruption of margination of leucocytes.

**Tissue Phase**

After their activities in circulation, leucocytes enter the tissues. This is called **tissue pool** of leucocytes. Granulocytes live for few days in the tissues (Application Box 17.2), whereas monocytes remain for a longer period. In the tissues, monocytes are transformed into **tissue macrophages** that remain for many years.

**Application Box 17.2**

*Apoptosis of leucocytes:* Apoptosis is the programmed cell death. This is a physiologic phenomenon of elimination of mature cells from the body. Biochemically, apoptosis occurs due to internucleosomal DNA fragmentation, and morphologically, by nuclear and cytoplasmic condensation. The apoptotic cells are phagocytosed by macrophages. Senescent neutrophils and eosinophils undergo apoptosis.

---

**NEUTROPHILS**

Neutrophils are most prevalent leucocytes in blood. They provide the **major defense against acute pyogenic infections**. Neutrophils exhibit ameboid movements. In infections, they migrate to the site of microbial invasion in response to chemical factors. They ingest organisms and kill them. Thus, in neutropenia, body is vulnerable to bacterial infections.

**Structure**

Neutrophils are common granulocytes. The major identifying features of neutrophils are:

1. The average size of neutrophils varies between 10–14 μm.
2. The cytoplasm of neutrophils contains **fine pink colored granules**.
3. The nucleus is usually **multilobed** and the lobes are connected by thin strand (Fig. 17.5). Nucleus may contain **Barr body** (Application Box 17.3).

It is not known why the segmentation of nucleus of neutrophil occurs. The nucleus of **juvenile neutrophil** is single lobed (**band form**), whereas in mature neutrophils the number of lobes increases with age.

**Arneth count:** The oldest neutrophils may have 6 or 7 lobes in their nucleus. Based on the nuclear lobes
neutrophils are classified as N₁ to N₆/N₇. This is called Arneth count (Figs. 17.6A to F).

1. Normally, N₂ and N₃ constitute most of the neutrophils in peripheral blood.
2. Presence of younger neutrophils (mostly N₁ and N₂) indicates stimulation of bone marrow (shift to left).
3. Presence of older cells (mostly N₄ and N₅) indicates suppression of bone marrow (shift to right).
4. Hypersegmented nucleus of neutrophils is typically seen in megaloblastic anemia that occurs due to folate and vitamin B₁₂ deficiency (Figs. 17.7A and B).

**Granules of Neutrophils**

Neutrophils have four types of granules: primary or azurophilic granules, secondary or specific granules, tertiary granules and secretory granules. Primary granules are formed during granulopoiesis, whereas other granules are formed at later stages. The granular contents are determined by the time of their appearance in the leucopoiesis.

**Primary Granules**

These are peroxidase positive granules. They are also called azurophilic granules:

1. In addition to myeloperoxidase, they contain lysosomal enzymes and elastase, proteinase and α-1 antitrypsin.
2. They also contain antimicrobial proteins like cathepsin-G, defensins and bactericidal-permeability increasing proteins.
3. Contents of azurophil granules also cause tissue destruction during inflammation.

**Secondary Granules**

By definition, secondary granules do not contain peroxidase (peroxidase negative):

1. They are also called specific granules.
2. The secondary granules contain lactoferrin, gelatinase, lysozyme, vitamin B₁₂ binding protein and other proteins.
3. Lysozyme is microbicidal and lactoferrin is antibacterial.
4. About 16% granules contain only lactoferrin, 24% contain only gelatinase and 60% contain both.
5. In inflammatory responses, gelatinase containing granules are more readily released than the other granules.
6. The number of specific granules may be decreased in different conditions. The granules may disappear and nuclear lobes may become big giving spectacular appearance in Pelger-Huet anomaly. Morphologically, abnormalities of specific granules are Alder-Reilly anomaly and May-Hegglin anomaly (Fig. 17.8).

**Tertiary Granules**

Tertiary granules contain gelatinase, alkaline phosphatase and cytchrome-b. The alkaline phosphatase is located on the luminal side of the granule membrane. The low leucocyte alkaline phosphatase score is associated with chronic myeloid leukemia.

**Secretory Granules**

These are secretory vesicles and different from azurophilic and specific granules. They contain CD3, phospholipase and tyrosine kinase. Toxic granulations occur in severe infections (Clinical Box 17.2).
Figs. 17.7A and B: Hypersegmented neutrophil in megaloblastic anemia (in the inset), as shown in original peripheral blood smear (A) and drawn picture of the smear (B).

Toxic granulations of neutrophils: In severe infections, toxic granulations and Döhle bodies are seen in neutrophils in addition to nuclear pyknosis.

**Life History**

Neutrophils like other leucocytes have four stages in their life: marrow pool, circulation pool, margination pool and tissue pool.

**Marrow Pool**

This is the developmental stage of neutrophil. As soon as neutrophils are developed from metamyelocytes, they are released into circulation. However, large number of juvenile neutrophils are present in bone marrow, which constitutes marrow pool of the cell. This serves as the reservoir for peripheral neutrophils.

**Circulation Pool**

In peripheral blood, about 50% of neutrophils are present in circulation pool that actually circulate in the blood. Rest, 50% remains in the margination pool.

**Margination Pool**

About 50% of the neutrophils in the blood remain adhered (marginated) to endothelial lining of the blood vessels. This is called margination of leucocytes. Neutrophils present in the margination pool serve as the immediate source for circulation pool. In fact, any factor that causes disruption of margination increases neutrophil count and causes acute leucocytosis.

**Tissue Pool**

After their usual life in circulation for about 6–8 hours, neutrophils enter tissues where they live for about 4 days.

**Neutrophil Count**

Normally, neutrophils constitute 50–70% of the total leucocytes in the peripheral blood:

1. The neutrophil count in the blood is maintained due to the balance between neutrophilopoiesis that releases neutrophils into circulation and the shift of neutrophils into marginated and tissue pools.
2. In circulation, many neutrophils adhere to endothelium called margination.
3. Margination is due to firm attachment of neutrophils to endothelial lining, which is mediated by selectins, polypeptides that contain sugar binding site.
4. Temporary release of neutrophils from marginated pool also accounts for increase in count of neutrophils.
5. Neutrophil count alters in various conditions (Table 17.3).

**Table 17.3: Conditions that alter neutrophil count.**

**Functions**

Neutrophil is actively phagocytic. They contain many antimicrobial and bactericidal chemicals in their granules (see above). Therefore, neutrophils are capable of ingesting and killing microbial organisms. During inflammation due to acute bacterial infections, neutrophils soon migrate to the site of infection and kill the organisms. Hence, neutrophils are considered as the first line of defense against acute bacterial infections. Neutrophils provide major non-specific defense against invasion of pyogenic organisms. Consequently, neutropenia predisposes body to pyogenic infection.

**Neutrophil Phagocytosis**

Phagocytosis is the process of ingestion and killing of microbes or a foreign substance by a phagocyte. Actively phagocytic cells are neutrophils, monocytes and macrophages. Steps of phagocytosis include chemotaxis, diape-desis, adherence, ingestion and killing (Fig. 17.9).
Chemotaxis

Chemotaxis is the process of migration of neutrophils to the site of infection. The bacterial invasion triggers acute inflammatory response:

1. The chemical substances are released from the site of inflammation or infection by the infecting organisms or inflammatory cells.
2. These chemical factors attract neutrophils to the site of infection. Consequently, they are called chemotaxins (taxin means movement; chemical that produces movement is a chemotaxin) or chemoattractants or chemotactic factors.

3. Chemotaxins are usually the microbial products or chemicals secreted from leucocytes or chemicals released from damaged tissue.
4. Complement proteins, especially C5a and C3 also act as chemotaxins.
5. During chemotaxis, neutrophils change their shape and become highly ameboid.
6. Also, the bone marrow is stimulated in response to plasma factors and more neutrophils are produced.

Diapedesis

The neutrophils must enter the tissue from their circulation pool to kill organisms at the site of inflammation in the tissue. The process, by which neutrophils pass through the capillary endothelial cells to reach the invader in the tissue, is called diapedesis. The activated neutrophils first marginate (margination and pavementing) adhere tightly to endothelial lining (rolling and adhesion) with the help of L-selectins and then by their ameboid movement they squeeze through the space between endothelial cells (emigration and diapedesis) (Figs. 17.10A to D).

Opsonization and Adherence

The process by which the bacteria are made tasty to the phagocyte is called opsonization. In this process, antigen is coated by opsonins. The chemicals that facilitate the process of opsonization are called opsonins:

1. IgG antibody and complement proteins (C5a, C3b) are known high-quality opsonins.
2. Bacteria coated by opsonins bind to the receptor on the neutrophil membrane. The attachment of membrane of phagocyte to the membrane of microbe is called adherence.
3. Opsonization facilitates the process of adherence (Fig. 17.11A).

**Ingestion (Endocytosis)**
Adherence facilitates motor activity of neutrophils. The membrane of phagocyte extends projections from both the sides to encroach on to the microbe (Fig. 17.11B). These extensions are called pseudopodia. Pseudopodia finally surround the microbe and form phagocytic vesicle (Fig. 17.11C). The phagocytic vesicle fuses with the lysosome to form **phagolysosome** (Fig. 17.11D).

**Killing**
The bactericidal (killing of bacteria) mechanisms can broadly be divided into two types: nonoxidative and oxidative.

**Nonoxidative Mechanisms**
Neutrophil granules contain a wide variety of **antibacterial chemicals** such as degradative enzymes, proteases, defensins and cationic proteins:
1. Lysozyme that hydrolyzes the cell wall of bacteria and lactoferrin that sequesters iron (iron is required for bacterial growth) are nonoxidative components of bacterial killing.
2. Defensins (α and β defensins) released from azurophil granules have unusual cyclic structure and kill bacteria by disrupting their outer membrane and breaking single-strand DNA structure.

**Oxidative Mechanisms**
Activated neutrophils produce a number of oxygen metabolites that are antimicrobial.
1. The metabolites are superoxide anion (O$_2^-$), H$_2$O$_2$, free hydroxyl radicals (OH·), hypochlorous acid (HOCl) and singlet oxygen (¹O$_2$). These reactive metabolites are generated by a nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidase that reduces molecular oxygen to O$_2^-$. The oxidase is quiescent in resting neutrophils and is stimulated following neutrophil activation and promotes O$_2^-$ formation. O$_2^-$ is the most effective oxidant metabolite.
2. Activation of NADPH oxidase is associated with increased oxygen intake of neutrophil (Clinical Box 17.3). This is called **respiratory burst**. This leads to generation of O$_2^-$ by following mechanism:

   \[ \text{NADPH} + \text{H}^+ + 2\text{O}_2 \rightarrow \text{NADP}^+ + 2\text{H}^+ + 2\text{O}_2^- \]

   Two superoxide anions (O$_2^-$) react with two H$^+$ to form H$_2$O$_2$ by the action of **superoxide dismutase** (SOD) (Application Box 17.4). Both O$_2^-$ and H$_2$O$_2$ are active oxidants and are effective bactericidal agents. H$_2$O$_2$ is converted to H$_2$O and O$_2$ by the enzyme **catalase**. Hence, catalase is considered as an **antioxidant**.
3. Myeloperoxidase, the enzyme of primary granules facilitate conversion of Cl$^-$ to HOCl, which is also a potent oxidant.

**Clinical Box 17.3**
CGD occurs due to defective NADPH-oxidase: In chronic granulomatous disease (CGD), a genetic disorder, neutrophils fail to generate O$_2^-$ and related metabolites. Neutrophils and monocytes ingest catalase positive microorganisms but can not kill them due to lack of adequate active oxidants that result from decreased NADPH-oxidase activity. This leads to formation of chronic granulomas, the abnormal inflammatory tissue reactions.

**Application Box 17.4**
ALS occurs due to defective dismutase: Amyotrophic lateral sclerosis (ALS) is a motor system disease in which progressive degeneration of spinal motor neurons results in atrophy of skeletal muscles (amyotrophy). O$_2^-$ reacts with H$^+$ to form H$_2$O$_2$ with the help of cytoplasmic dismutase and H$_2$O$_2$ is converted to H$_2$O and O$_2$ by the enzymes catalase. Defective dismutase results in accumulation of O$_2^-$ in the motor neurons that damages the neurons. In ALS, genetic mutation of dismutase results in oxidative damage to the motor neurons in the spinal cord, which is progressively fatal.

**Interaction of Oxidative and Nonoxidative Mechanisms**
Nonoxidative mechanism facilitates the activity of oxidative mechanism for bacterial killing. The protease enzymes...
of primary granules and collagenase enzymes of secondary granules produce a killing zone around the activated neutrophil by locally damaging the inflammatory tissue, which helps the oxidant metabolites to promote their bactericidal properties. However, in diseases like rheumatoid arthritis, this becomes detrimental due to destruction of larger quantity of host tissue.

**Applied Aspects**

Chemotaxis and phagocytosis require active movements of neutrophil. When neutrophil is activated, its cytosolic calcium concentration increases that promotes contraction of microfilaments, microtubules and myosin-1 filaments. This increases the ameboid movement and activity of neutrophils. Neutrophil hypomotility, a primary phagocytic dysfunction of neutrophil, decreases phagocytic activity. There are about 15 primary disorders of neutrophil function.

**Eosinophils**

Eosinophils are known for their protective function against allergy including asthma, and helminthic parasite infections. Like neutrophils, eosinophils produce proinflammatory mediators:

1. Eosinophil-specific granule proteins are toxic for many mammalian cells and parasitic larvae.
2. In addition, cytokines produced by eosinophil such as leukotrienes and PAF, aid to their defense functions.
3. Eosinophils have short life span in circulation, whereas they live longer in tissue. They are primarily tissue dwelling cells. There are 100 eosinophils in tissue to 1 eosinophil in peripheral blood.
4. Eosinophils are present in the epithelia of respiratory, gastrointestinal and genitourinary tract.

5. Their production and function are mainly influenced by IL-5. IL-5 also stimulates production and function of basophils that are closely related to eosinophils.

**Structure**

Eosinophils are granular leucocytes having the size same as that of neutrophils. However, the granules are coarse and brick red in color in blood smear stained by Leishman stain. Moreover, the nucleus is usually bilobed and the lobes are separated by a thick strand. This gives eosinophil nucleus an appearance of a pair of spectacles (Fig. 17.12). The granules are plenty, and sometimes encroach upon the nucleus.

**Chemicals Secreted by Eosinophils**

Eosinophil secretes various chemicals that mediate many physiological activities. These chemicals may be divided into three categories: chemicals secreted from granules, cytokines, and lipid-derived chemicals (Table 17.4). The last two groups of chemicals are secreted from many other cells, whereas chemicals secreted from granules are eosinophil specific.

**Eosinophil Granular Contents**

The granules of eosinophil contain following major chemicals:
1. Major basic protein
2. Eosinophil cationic protein
3. Eosinophil-derived peroxidase
4. Eosinophil-derived neurotoxin
5. Cytokines
6. Other chemicals

**Major Basic Protein**

Major basic protein (MBP) is major toxic product of eosinophil. It is toxic against many intestinal parasites and their larvae such as:
1. Schistosomula (a larva of *S. mansoni*, which is an intestinal parasite, blood fluke) and the larva of *Ancylostoma duodenale* (hookworm)
2. *Ascaris lumbricoid* (roundworm)
3. *Toxocara canis*
4. *Wuchereria bancrofti* (filarial larva)
5. *Trichinella spiralis*

Eosinophil adheres with the IgG coated larva and this adherence results in secretion of MBP from eosinophil into the integument of the larva that causes damage to the larval tissue.
- MBP is also toxic to pneumocytes and epithelial cells of respiratory tract.
- MBP also makes the bronchial tree hyper-responsive to bronchoconstrictors.
- Therefore, these worm infestations are usually associated with respiratory symptoms like bronchial asthma (Clinical Box 17.4).
- Eosinophil peroxidase (EP) and MBP activate platelets, basophils and mast cells.
- Basophils also contain MBP, but the concentration is only 2% of eosinophils.

**Clinical Box 17.4**

**Asthma like symptoms occurs in worm infestations:** MBP released from eosinophil granules to kill worms, is also toxic to lungs. MBP makes the bronchial tree hyper-reactive to bronchoconstrictors. Therefore, these worm infestations are usually associated with respiratory symptoms like bronchial asthma.

**Eosinophil Cationic Protein**

Eosinophil cationic protein (ECP) is rich in arginine.
- Though ECP has 66% structural homology with eosinophil-derived neurotoxin (EDN) and 31% homology with pancreatic ribonuclease, its ribonuclease activity is less compared to the ribonuclease activity of EDN.
- ECP is toxic to helminthic parasites and tracheal epithelium.
- ECP along with EDN produces neurotoxicity.

**Eosinophil Peroxidase**

Eosinophil peroxidase (EP) is a heme containing protein.
- It has 68% homology with neutrophil myeloperoxidase and other peroxidases.
- EP is toxic to the adult parasites and pulmonary tissue.
- When combined with H₂O₂, its toxicity increases.

**Eosinophil-derived Neurotoxin**

Eosinophil-derived neurotoxin (EDN) is a glycosylated protein having striking ribonuclease activity. EDN is also secreted by mononuclear cells. It is toxic to the neural tissue. It is not toxic against nonneural tissue of parasites.

**Cytokines**

Cytokines are synthesized outside the granules but stored in granules. The important cytokines secreted from eosinophils are:
1. Interleukins (IL1-6, IL8 and IL12)
2. GM-CSF
3. Macrophage inhibition factor (MIF)
4. Transforming growth factors (TGF α and β)
5. Tumor necrosis factor-α.

TGF-α mediates the important role of eosinophil in wound healing. Many of the cytokines like interleukins such as IL5, IL3 and GM-CSF act in autocrine fashion as eosinophil growth factor. MIF plays a role in the genesis of adult respiratory distress syndrome.

**Other Chemicals**

Lysophospholipase constitutes 10% of eosinophil proteins. The enzymes secreted from eosinophils like phospholipase D, arylsulphatase-B, acid phosphatase, catalase and histaminase are other granular proteins that take part in eosinophil-mediated inflammatory reactions and killing of parasites.

**Functions**

Like neutrophils, eosinophils migrate into the tissues. There are selective chemoattractants for eosinophils such as eosinophil chemotactic factor of anaphylaxis (ECF-A). ECF-A in humans is a tetrapeptide that facilitates tissue accumulation of eosinophils. Eosinophils exhibit endothelial cell adhesion and chemotaxis to migrate into the tissues. Eosinophils participate in two important defense mechanisms of the body:
1. Against helminthic infections
2. Against allergy.

**In Helminthic Infections**

Eosinophils attack intestinal parasites especially the larva of *S. mansoni*, *Trichinella spiralis*, *Toxocara canis*, *N. brasiliensis*, *Fasciola hepatica*, roundworms and hook worms:
1. They attack the larva opsonized by IgG, IgE and complements. First, eosinophils attach themselves to the larva, which activates the eosinophils.
2. Within about 3 hours of this adherence, the activated eosinophils secrete proteins from their granules onto surface of the larva.
3. Once, the tegument is breached, eosinophils crawl under it and secrete toxic mediators that destroy the tissues of larva and phagocytose the larva or larval fragments.

4. In this process, degranulation of eosinophils occurs.

In Allergy

In allergic condition like bronchial asthma, eosinophils play a major role in pathogenesis:

1. Bronchial hyper-reactivity is correlated with eosinophilia and airway eosinophil content.
2. Inhibition of airway eosinophilia by glucocorticoid has been reported to cause improvement in bronchial hyper-responsiveness and asthmatic symptoms.

3. Though, glucocorticoid causes eosinopenia by eosinophil apoptosis, the main mechanism is the inhibition of production of IL5 and IL3 from type 2 helper cells (T4 lymphocytes).

4. It is not clear whether eosinophils prevent allergy and therefore eosinophilia occurs in allergy or eosinophilia in allergy aggravates the situation.

5. However, recruitment of eosinophil at the site of allergic inflammation is accompanied by increase in number of activated T cells and monocytes.

6. It has been proposed that asthma is an eosinophil-mediated disease driven by type-2 helper lymphocytes that secrete IL5 and IL3.

Alterations in Eosinophil Count

The normal eosinophil count is 2–4% in differential count (by examining blood smear), or 40–440 per μl of blood in absolute count (by hemocytometry). When eosinophil count is more than normal, called eosinophilia and less than normal, called eosinopenia (Table 17.5).

**Basophils and Mast Cells**

Basophils are least frequent granulocytes. They account for less than 0.5% of leucocytes in blood. Though they recruit into tissues in response to immunological and inflammatory reactions, unlike eosinophils they ordinarily do not reside in the tissue. Though basophils and mast cells resemble functionally, they are not identical (Table 17.6):

1. Mast cells are derived from blood precursors, but they mainly reside in the connective tissues, particularly beneath the epithelial surfaces and around the blood vessels, where they live a longer period.
2. Basophils and mast cells have high-affinity receptors for IgE on their surface.
3. As IgE is a reagin antibody, these cells mediate many allergic responses of the body.
4. Basophils and mast cells also contribute to protect host responses associated with IgE production.

**Structure**

**Basophils**

Identifying features of basophils are (Fig. 17.13):

1. They have the same diameter as of neutrophils (10–14 μm).
2. The nucleus is usually less segmented and often appear ‘S’ shaped.
3. Nuclear chromatin shows marked condensation.
4. The granules are large in size and oval or round in shape, and more in number. As cell is heavily studded with granules, nucleus is often not visible. Granules are surrounded by membranes and contain dense particles called Charcot-Lyden crystals.

5. Cytoplasm contains glycogen deposits, mitochondria, free-ribosomes and few lipid bodies. Basophil granules secrete histamine, chondroitin sulphate, tryptase, carboxypeptidase A, cathepsin G, leukotrienes, eosinophil chemotactic factor of anaphylaxis (ECF-A), neural protease and MBP.

Mast Cells

Mast cells that remain in the tissues are round or elongated cells with nonsegmented nucleus. Granules are numerous, but smaller in size. There are many cytoplasmic filaments, numerous lipid bodies and no glycogen deposits. Mast cell granules secrete histamine, heparin, chondroitin sulphate, carboxypeptidase, cathepsin, ECF-A and neural protease. There are two types of mast cells: mucosal mast cells (mast cell present in the mucosa) and connective tissue mast cell.

Differences between Basophils and Mast Cells

Though there are functional homology between basophils and mast cells, there are many differences between them (Table 17.6).

Functions

Basophils and mast cells are mainly involved in allergic reactions. During allergy, these cells release the content of their granules. Mediators such as histamine released by degranulation produce antimicrobial and anti-host effects. The usual stimulus for basophil and mast cell degranulation is an allergen, which should ideally cross-link IgE molecule bound to the surface of basophils or mast cells via its high affinity Fc receptor for IgE.

Role in Acute Allergic Reactions

Basophils and mast cells have receptors for Fc region of IgE:

1. IgE binds to membrane of these cells and initiate degranulation. This leads to release of histamine. Acute allergies such as acute rhinitis, urticaria, food allergy etc are mediated by this mechanism.

2. However, massive release of histamine produces immediate hypersensitivity reactions, also known as anaphylaxis. Anaphylaxis is acute systemic allergic reaction that occurs in conditions like injections of penicillin or xylocaine anesthesia in sensitive individuals.

3. In anaphylaxis, histamine released from basophils and mast cells cause vasodilation and inhibition of cardiac output that lead to acute hypotension.

Role in Chronic Allergic Reactions

Basophils and mast cells also contribute to late-phase reactions. In chronic allergic conditions such as bronchial asthma, basophils and mast cells are recruited to the site of allergy. Especially, mast cells secrete cytokines that attract leucocytes, eosinophils and basophils, which in turn mediate chronic allergy. This mechanism of pathogenesis of late-phase reaction is termed as mast cell-leucocyte cascade.

Role in T-cell Dependent Responses

Activation of mast cells in the affected tissues along with infiltration of basophils occurs in a variety of T-cell dependent immunological responses. T-cells secrete growth factors for basophils and mast cells.

Role in Host Defense

Basophils and mast cells play critical role in host resistance to some viral, bacterial and parasitic infections. These cells increase in conditions like chicken pox, small pox and tuberculosis.

Normal Count

Normal basophil count is 0–1%, and absolute count is 20–80 per μl of blood. Mast cells are normally not found in blood. Increase in basophil count is called basophilia and decrease in count is called basopenia (Table 17.7).

Mastocytosis

Secondary increase in mast cell count usually occurs in allergic conditions like asthma, and connective tissue disorders like rheumatoid arthritis. However, primary increase in mast cell number occurs in a group of systemic disorders called systemic mastocytosis. Depending on the degree of mastocytosis, the condition has been classified into 4 categories:

- Category I: Indolent mastocytosis as seen in urticaria pigmentosa.
- Category II: Mastocytosis with myeloproliferative disorder.
- Category III: Aggressive mastocytosis i.e., lymphadenopathic mastocytosis with eosinophilia.
- Category IV: Mast cell leukemia.
MONOCYTES AND MACROPHAGES

Monocyte is the largest leucocyte in the peripheral blood. After spending life in blood, monocytes enter the tissues, where they are transformed into macrophages:
1. Monocytes and macrophages are mononuclear phagocytes.
2. In the tissues, they play an important role in nonspecific defense against microbial invasion.
3. The tissue macrophage system was previously called as reticuloendothelial system (the term has become obsolete). Presently, this is known as mononuclear phagocyte system.
4. Monocyte is the second line of defense against microbial infections.

Monocytes

Morphology

Monocytes are the largest blood cells. The identifying features are:
1. The diameter of monocytes varies between 12–25 μm.
2. The nucleus occupies half of the cell and remains eccentrically. Cytoplasmic-nuclear ratio is 50:50.
3. Often the nucleus is reniform (kidney shaped), but may be horse-shoe shaped, round or irregular (Fig. 17.14).
4. There are characteristic fine nuclear chromatin net connecting small chromatin clumps. This gives the nucleus a non-homogenous or stringy appearance.
5. Cytoplasm is abundant and ground glass in appearance.
6. Though monocyte is traditionally classified as agranular leucocytes, fine pink-purple granules are present in about 40% of cells. Sometimes, large azurophil granules are also seen in monocytes. The monocyte granules contain hydrolytic enzymes such as acid phosphatase, lysozymes, etc. However, alkaline phosphatase is absent.

Monocytes have a number of receptors on its surface such as Fc receptors for IgG, IgA and IgE, receptors for complements, cytokines, and hormones like insulin, glucocorticoid and angiotensin. Monocytes and macrophages express HLA class II and their receptors on their surface that help in antigen presentation.

Functions

1. Phagocytosis and microbial killing: Monocyte is an active phagocyte:
   - It exhibits motility and chemotaxis.
   - The presence of various surface receptors enhances their phagocytic activity by facilitating the recognition of various host-derived factors including immunoglobulins, complements, cytokines, and hormones like insulin, glucocorticoid and angiotensin.
   - The receptors also identify various sugar units on microbial membranes.
   - The organisms once phagocytosed, are destroyed by oxidants produced by NADPH oxidase, nitric oxide synthase, and intracellular hydrolytic enzymes.
   - Monocyte also kills intracellular pathogens like viruses, and parasites.
   - Monocyte is the second line of defense against infections.

2. Antigen presentation: Monocyte is an important antigen presenting cell (APC):

**Fig. 17.14:** Structure of monocyte.
Partially digested product of the antigen (Ag) combines with the MHC II molecules produced by APC, and MHC + Ag complex expresses on the surface of APC.

Lymphocytes, especially T cells are activated when they come in contact with MHC + Ag present on the APC surface.

This is the first step in the activation of cellular immunity.

3. Release of cytokines: Monocyte secretes various chemokines that carry out different physiological functions:
- Monocyte produces IL-1 and IL-6 that are essential for coactivation of immunological responses.
- Monocyte secretes TNF-α and interferons that facilitate killing of viruses and other microbial organisms.
- Monocyte also secretes various growth factors like GM-CSF, M-CSF and erythroid colony potentiating factor that promote leucopoiesis and erythropoiesis, and transforming growth factors (TGF), PDGF and fibroblast growth factors (FGF).
- Monocytes by secreting complement factors augment the local tissue defense responses.
- Monocyte releases various enzymes like collagenase, elastase, plasminogen activator, etc. that participate in wound healing and tissue remodeling.

Life Span

Monocytes in circulation have a wide range of half life between 10–72 hours. Then, they enter the tissues where they live few weeks to months. The average life in tissues is three months. In tissue, they are transformed into tissue macrophages. If there is tissue infection or inflammation, within few hours monocytes migrate to the site of injury. However, initially the monocyte numbers are less than neutrophils. If inflammation persists for more than 12 hours, monocytes predominate over neutrophils.

Normal Count

Normal monocyte count is 2–8%, and the average absolute count is 400/μl of blood. Increase in count is called monocytosis and decrease in count is called monocytopenia (Table 17.8). The monocyte count is more in neonates and infants, which is about 1000/μl of blood. Men tend to have slightly higher monocyte count than women. However, in adults count more than 800/μl of blood is considered as monocytosis.

Macrophages

Monocytes after their life span in blood enter tissues and transform into tissue macrophages. They form mononuclear phagocyte system in various tissues (Table 17.9) (Also, refer Fig. 19.2, Chapter 19):

1. Macrophages are capable of cell division and resident or noninflammatory macrophages in the tissue are self-sustaining.
2. The exact mechanism of differentiation of monocyte to macrophages is not known. However, on becoming macrophage there is increase in cell size, number of cytoplasmic granules and vacuoles, and increase in heterogeneity of the cell shape.
3. The average diameter of macrophages varies from 25 to 50 μm.
4. The nucleus is fusiform or reniform and is eccentrically placed with one or two nucleoli in it.
5. Cytoplasm contains multiple large azurophil granules.
6. They contain all the surface receptors that are present in monocytes.
7. In chronic tissue inflammations, macrophages are converted into multinucleated giant cells that are highly phagocytic and microbicidal.

**Dendritic Cells**

Few monocytes are transformed into highly specialized mononuclear cells called dendritic cells:
1. They play important role in antigen processing and presentation to the T cells.
2. They are specialized in antigen capture, rather than in phagocytosis. Thus, they are specific antigen presenting cells.
3. However, unlike macrophages, dendritic cells lack receptors for immunoglobulins, complements and colony-stimulating factors, and specific granules in cytoplasm. Therefore, they are weakly phagocytic.
4. They are present in blood and bone marrow, where they account for about 0.1 to 1% of total mononuclear cells.
5. They are also present as Langerhans cells in skin, interdigitating cells in thymic medulla, and interstitial cells in the lung and heart.

**LYMPHOCYTES**

Lymphocytes are a heterogeneous group of cells with characteristic morphology. Lymphocyte is the only leucocyte that has different varieties of cells both morphologically and functionally. Structurally, lymphocytes are divided into two groups: small and large lymphocytes.

**Structure**

**Small Lymphocytes**

Small lymphocytes are same in size to that of red cells. They constitute 35% (20–50%) of total lymphocytes. The identifying features are:
1. The cells are 6–9 μm in diameter.
2. They have ovoid or kidney shaped nucleus with densely packed nuclear chromatin. Nucleus is usually eccentrically placed and occupies about 90% of the cell area (Fig. 17.15A).
3. There is a thin rim of bluish cytoplasm that does not contain granules.

**Large Lymphocytes**

Large lymphocytes constitute 65% (50–80%) of total lymphocytes. The identifying features are:
1. The cells are 10–15 μm in diameter (Fig. 17.15B).
2. The nucleus is homogenous and compact with dense nuclear chromatins. Nucleus is usually oval or kidney shaped and eccentrically placed.
3. The cytoplasm is navy blue in colour and usually does not contain granules. However, about 3% of large lymphocytes contain coarse pink granules (5 to 15 granules per cell). These granular lymphocytes are usually NK or T cells.

**Normal Count and Functions**

Normal lymphocyte count is 20–40% of total leucocytes. The absolute count is 500–8000 per cu mm of blood. Increase in count is called lymphocytosis and decrease in count is called lymphocytopenia (Table 17.10).

Functionally, lymphocytes are divided into three categories: B cells, T cells and NK cells. B cells on stimulation are transformed into plasma cells that secrete antibodies. B cells mediate humoral or antibody-mediated immunity. T cells mediate cellular or cell-mediated immunity. NK cells mediate natural and nonspecific immunity. Details of lymphocyte functions are discussed in the chapter “Immunity”.

**Summary of Blood Cells**

To summarize, blood cells are formed elements of blood. Erythrocytes are anuclear cells having diameter of 7 to 8 μm that are primarily meant for transport of oxygen from lungs to the tissues. Leucocytes are of various sizes and they mainly play role in defence mechanisms. Platelets are anuclear and smaller cells (cellular fragments) that principally participate in homeostasis (Table 17.11).

**LEUKEMIA**

**Definition and Concept**

Leukemia is defined as a malignant neoplasia of hemopoietic cells in which there is abnormal proliferation of leucocytes and their precursors resulting in appearance of abnormal and immature cells in the peripheral blood associated with very high leucocytosis, and infiltration of tissues by leukemic cells.

1. There is increased infiltration of bone marrow by the proliferating leukemic cells.
2. The total leucocyte count is usually very high, except in subleukemic or aleukemic form of leukemia.
3. Usually, the proliferation involves leucocytic series.
4. Occasionally, erythroid precursors or megakaryocytes may also be involved in the disease process.

**Types**

Leukemia is classified into two main categories: myeloid (myelocytic) and lymphocytic leukemia. These two varieties are subclassified into acute and chronic types.

**Acute Leukemias**

**Acute Lymphoblastic Leukemia**

Acute lymphoblastic leukemia (ALL) is primarily a disease of children and young adults:

1. This constitutes 80% of childhood acute leukemias. It rarely occurs in adults.

---

<td>Form platelet plug in hemostasis (temporary hemostatic plug).</td>
</tr>
</tbody>
</table>
2. The most common mode of presentation is with symptoms of anemia or hemorrhage, infective lesions of the mouth and pharynx, fever, prostration, headache and malaise.
3. Generalized **lymphadenopathy, splenomegaly and hepatomegaly** are common and occur due to infiltration of organs by leukemic cells.
4. The typical blood picture is of **anemia and thrombocytopenia**, with a moderate or marked increase in white cells, the majority of which are blast cells ‘lymphoblasts’ (Figs. 17.16A and B).

**Acute Myeloblastic Leukemia**

Acute myeloblastic leukemia (AML) primarily affects **adults between the ages of 15 and 40 years**. It constitutes only 20% of childhood leukemias:

1. The presentation is like that of ALL, but lymphadenopathy and hepatosplenomegaly is not common.
2. Blood picture presents anemia, thrombocytopenia, and moderate to high leucocytosis.
3. More than 60% of leucocytes in the peripheral blood are blast (myeloblast) cells (Figs. 17.17A and B).

**Chronic Leukemias**

**Chronic Myeloid Leukemia**

Chronic myeloid leukemia (CML) accounts for about 20% of all cases of leukemia. It is primarily a disease of **adults between the ages of 30 to 60 years** with the peak incidence in the 4th and 5th decades of life.

1. Onset is usually slow with nonspecific features like anemia, weight loss, weakness, and easy fatigability.
Section 2: Blood and Immunity

2. Splenomegaly is the outstanding physical sign. Hepatomegaly may be present, but lymph node enlargement is rare.
3. Markedly elevated total leucocyte count usually more than one lakh cells per cubic mm of blood is seen commonly.
4. Neutrophils, myelocytes and metamyelocytes constitute most of the circulating cells (Figs. 17.18A and B).
5. Blasts cells are present rarely except in the blastic crisis.

Chronic Lymphocytic Leukemia
Chronic lymphocytic leukemia (CLL) is the most indolent of all leukemias. It occurs typically in persons over 50 years:
1. Males are affected twice as frequently as females.
2. Patients present with nonspecific symptoms.
3. Lymphadenopathy is the outstanding physical sign.
4. Hepatosplenomegaly may be present.
5. Mild to severe increase in leucocyte count is seen.
6. More than 90% of leucocytes are mature lymphocytes (Figs. 17.19A and B).

CHAPTER SUMMARY

Key Concepts
1. In leucopoiesis, granulocytes and monocytes develop from myeloid stem cells and lymphocytes develop from lymphoid stem cells. Major hemopoietic growth factors are GM-SCF and interleukins.
2. Development of leucocytes in bone marrow occurs in 6 to 10 days (marrow phase), they spend 6 to 8 hours in peripheral blood (circulation phase), and then enter tissues (tissue phase).
3. Neutrophils are highly phagocytic cells, and are the first line of defense against acute pyogenic infection.
4. Eosinophils and basophils defend the body against allergy.
5. Monocytes are phagocytic, and defend the body against chronic infections. Monocytes enter the tissue to become tissue macrophages (Mononuclear phagocyte system).
6. Lymphocytes participate in immunity.
7. Leukemia is the malignancy of leucocyte precursor cells. ALL occurs in children, AML in young adults, CML in adults and CLL in elderly.

**Important to Know (Must Read)**

1. In examinations, ‘Steps and regulation of leucopoiesis’ and ‘Development, life history, structure and functions of neutrophils’ come as **Long Questions**.
2. Regulation of leucopoiesis, Life history of leucocytes, Types and fund functions of neutrophil granules, Phagocytosis by neutrophil, Oxidative mechanism of killing by neutrophils, Role of eosinophil in allergy, Functions of monocytes, and Leukemias, are usually asked as **Short Questions** in exams.
3. In **Viva**, examiners usually ask… the steps of leucopoiesis, hemopoietic growth factors controlling leucopoiesis, structure and function of each leucocyte, conditions that increase and decrease each leucocyte, role of neutrophil in acute defence, steps of phagocytosis, types of killing by neutrophil, definition and types of leukemia, and which leukemia is common in which age.
4. As TLC and DLC are routine and very useful hematologic investigations, questions on WBCs are very common in all exams (practical, theory and viva). Students are supposed to answer these questions well.
CHAPTER 18

Thymus, Lymphoid Tissues and Lymph

LEARNING OBJECTIVES

On completion of study of this chapter, the student **MUST** be able to:

1. Name the lymphatic tissues of the body.
2. Give the structure and functions of thymus.
3. Give the structure and functions of lymph node.
4. Give the structure and functions of spleen.
5. Give structure and functions of other lymphoid structures.
6. Composition, circulation and function of lymph.

The student **MAY** also be able to:

1. Describe the role of various lymphatic tissues in defence of the body.
2. Explain the development of lymphocytes in thymus.
3. Describe the lymphatic circulation.

THYMUS

The thymus is the organ usually not seen by most students and teachers as it is rudimentary in adults. The thymus is located in the superior mediastinum (Fig. 18.1). At birth, the thymus weighs 10–15 grams, which increases to 30–40 grams at puberty. Subsequently, much of the organ is replaced by fat and is atrophied in adults. The thymus is important as it produces T lymphocytes throughout life.

Structure

The thymus consists of right and left lobes that are joined together by fibrous tissue. Each lobe has a connective tissue capsule, which has septa passing inwards from the capsule that subdivide the lobe into a larger number of **lobules**.

1. Each lobule is about 2 mm in diameter. It has an outer **cortex** and an inner **medulla** (Figs. 18.2A to C).
2. Both the cortex and medulla contain cells of two distinct lineages. The medulla of adjoining lobule is continuous.
3. The thymus has a rich blood supply. It does not receive any lymph vessels, but gives off efferent vessels.

Epithelial Cells

Epithelial cells are called **epitheliocytes**. Seven types of epitheliocytes are recognized.

1. **Type 1** epitheliocytes line the inner aspect of the capsule, the septa, and blood vessels. These are the cells forming the partial haemotyphic barrier mentioned above.
2. **Type 2 and type 3** cells are present in the outer and inner parts of the cortex respectively.
3. **Type 4** cells lie in the deepest parts of the cortex, and also in the medulla. They form a network containing spaces that are occupied by lymphocytes.

4. **Type 5** cells are present around corpuscles of Hassall.

5. Cortical epitheliocytes are also described as **thymic nurse cells**. They destroy lymphocytes that react against self-antigens.

### Lymphocytes of the Thymus

Lymphocytes of thymus are called **thymocytes**.

1. In the medulla of each lobule also contains lymphocytes (medullary thymocytes), but these are less densely packed than the cortex (cortical thymocytes). Consequently, the epithelial reticulum is more obvious in the medulla than in the cortex.

2. As thymocytes divide they pass deeper into the medulla.

3. Thymocytes leave the thymus by passing into blood vessels and lymphatics.

### Macrophages

Apart from epithelial cells and lymphocytes the thymus contains a fair number of macrophages that are part of mononuclear phagocyte system (MPS). The **subcapsular macrophages** are highly phagocytic. Macrophages present more deeply are **dendritic cells**.

### Corpuscular Hassall

These are small rounded structures present in the medulla of the thymus.

1. Each corpuscle has a central core formed by epithelial cells that have undergone degeneration. These cells ultimately form a pink staining **hyaline mass**.

2. Around this mass there is a wall formed by concentrically arranged epithelial cells.

3. The central mass of the corpuscle may also contain degenerating macrophages.

### Functions of the Thymus

T cell develops from pre-T cell. The thymus is the site for T cell development. The **epithelial cells** play an important role in the development of bone marrow-derived pre-thymic cells into mature T cells (discussed below). Though thymus is reduced to a very small structure in adults, and in the atrophic adult thymus, cortex is mainly replaced by adipose tissue, the less cellular medulla remains apparently normal (Clinical Box 18.1).

#### Clinical Box 18.1

**Effects of thymectomy:** Thymectomy in young animals leads to lymphocytopenia, increased susceptibility to infections, atrophy of lymphatic tissues, failure to reject transplanted organs and suppression of delayed hypersensitivity reactions. Thymectomy in young animals leads to depletion of T cells and immunodeficiency within few months. These findings depict the importance of thymus in development of T cells in childhood and maintenance of T cells in adult life.

### Role in Lymphopoiesis

The role of the thymus in lymphopoiesis is significant.

1. Stem cells from bone marrow that reach the superficial part of the cortex divide repeatedly to form smaller lymphocytes.
2. It has been proposed that during these mitoses, the DNA of the lymphocytes undergoes numerous random mutations, as a result of which different lymphocytes acquire the ability to recognize a very large number of different proteins and to react to them.

3. As it is not desirable for lymphocytes to react against the body's own proteins, all lymphocytes that would react against them are destroyed. It is for this reason that 90% of lymphocytes formed in the thymus are destroyed within three to four days.

4. The remaining lymphocytes that react only against proteins foreign to the body are thrown into the circulation as circulating, immunologically competent T lymphocytes. They lodge themselves in secondary lymph organs like lymph nodes, spleen, etc. where they multiply to form further T lymphocytes of their own type when exposed to the appropriate antigen.

**Thymus as a Primary Lymphoid Organ**
Thymus is regarded as a primary lymphoid organ along with bone marrow.

1. It has been observed that, within the thymus, lymphocytes are not allowed to come into contact with foreign antigens, because of the presence of the **blood-thymic barrier**. It has also been stated that because of this thymocytes do not develop into large lymphocytes or into plasma cells, and do not form lymphatic nodules.

2. Recently, it has been postulated that the medulla of the thymus (or part of it) is a separate “compartment”. After thymocytes move into this compartment they probably come into contact with antigens presented to them through dendritic macrophages. Such contact may be necessary step in making T lymphocytes competent to distinguish between foreign antigens and proteins of the body itself.

3. The proliferation of T lymphocytes and their conversion into cells capable of reacting to antigens, probably takes place under the influence of hormones produced by epithelial cells of the thymus. T lymphocytes are also influenced by direct cell contact with epitheliocytes. **Hormones** produced by the thymus may also influence lymphopoiesis in peripheral lymphoid organs. This influence appears to be specially important in early life, as lymphoid tissues do not develop normally if the thymus is removed.

4. Thymectomy has much less influence after puberty as the lymphoid tissues have fully developed by then.

**Thymic Hormones**
A number of hormones produced by the thymus have now been identified as follows:

1. **Thymulin**: Thymulin enhances the function of various types of T cell, specially that of suppressor cells.

2. **Thymopoietin**: Thymopoietin stimulates the production of cytotoxic T cells. The combined action of thymulin and thymopoietin allows precise balance of the activity of cytotoxic and suppressor cells.

3. **Thymosin**: Thymosin α-1 stimulates lymphocyte production and also the production of antibodies. Thymosin β-4 is produced by mononuclear phagocytes.

4. **Thymic humoral factor** controls the multiplication of helper and suppressor T cells.

**Clinical Correlation**
Enlargement of thymus is often associated with a disease called **myasthenia gravis**. In this condition there is a great weakness of skeletal muscles. In many such cases the thymus is enlarged and there may be a tumor in it. **Removal of the thymus** results in considerable improvement in some cases. Thus, myasthenia gravis is now considered to be a disturbance of the immune system, in which, antibodies are produced against these proteins rendering them ineffective (autoimmune disease).

**LYMPHATIC TISSUES**
Lymphatic system consists of lymphatic vessels and lymphatic tissues.

**Lymphatic Vessels**
When circulating blood reaches the capillaries, part of its fluid content passes into the surrounding tissues as tissue fluid. Most of this fluid reenters the capillaries at their venous ends. Some of it is, however, returns to the circulation through a separate system of lymphatic vessels (usually called lymphatics). The fluid passing through the lymphatic vessel is called **lymph**.

1. The smallest lymphatic (or lymph) vessels are lymphatic capillaries that join together to form larger lymphatic vessels.

2. The largest lymphatic vessel in the body is the thoracic duct, which drains lymph from the greater part of the body.

3. The thoracic duct ends by joining the left subclavian vein at its junction with the internal jugular vein (Fig. 18.3).

**Fig. 18.3**: Origin, course and termination of thoracic duct.
4. On the right side there is the right lymphatic duct that has a similar termination.

**Lymphoid Tissues**

Lymphoid tissue may be broadly classified as: Diffused lymphoid tissue and dense lymphoid tissue.

**Diffused Lymphoid Tissue**

Diffused lymphoid tissue consists of diffusely arranged lymphocytes and plasma cells in the mucosa of large intestine, trachea, bronchi and urinary tract.

**Dense Lymphoid Tissue**

It consists of an aggregation of lymphocytes arranged in the form of nodules. These nodules are found either as discrete encapsulated organs or in close association to the lining epithelium of the gut. Dense lymphoid tissue can therefore be further divide as:

1. **Discrete lymphoid organs**: these include thymus, lymph nodes, spleen, and tonsils.
2. **Mucosa associated lymphoid tissue (MALT)**: small numbers of lymphocytes may be present almost anywhere in the body, but significant aggregations are seen in relation to the mucosa of the respiratory, alimentary and urogenital tracts. These aggregations are referred to as MALT.

**Mucosa associated lymphoid tissue in the respiratory system**: in the respiratory system the aggregations are relatively small and are present in the walls of the trachea and large bronchi. The term bronchial associated lymphoid tissue (BALT) is applied to these aggregations.

**Mucosa associated lymphoid tissue in the alimentary system**: This is also called gut associated lymphoid tissue (GALT) and includes Payer’s patches of ileum, adenoids (located in the roof of pharynx), lingual tonsils in posterior 1/3rd of tongue, palatine tonsils and lymphoid nodules in vermiform appendix.

*Note*: Thymus and bone marrow are primary lymphoid organ while others are secondary lymphoid organ.

**Lymph Node**

Lymph nodes are small encapsulated organs present in the pathway of lymphatics. They are found usually in groups, especially in neck, submandibular region, axilla and inguinal regions.

1. They have afferent and efferent lymphatics. **Afferent lymphatics** penetrate the capsule and join the sinus inside.
2. **Trabeculae** extend from capsule into the stroma in the node.
3. **Stroma** is made up of reticular lymphoid tissue arranged in outer cortex and inner medulla (Fig. 18.2A and B).
4. **Cortex** has lymphatic nodules or follicles with definite germinal centers.
5. **Each follicle has central pale area that represent germinal center and surrounding little darker area representing B cell area of the node.**
6. The **T cell area** is present in the paracortex, the junction between cortex and medulla (Fig. 18.4).
7. **Medulla** has lymphoid cells arranged in strands forming medullary cords.
8. Lymph flows from afferent lymphatics to subcapsular sinus, and then along trabeculae to the cortical and medullary sinuses, and exits via efferent lymphatics at the hilus.
9. Thus, lymph nodes filter the lymph that flows through it (Clinical Box 18.2). Lymph nodes also assist in processing of lymphocytes that takes place in the germinal centers.
Clinical Box 18.2

Lymphadenopathy indicates infection in the area: Lymph nodes draining a particular area get enlarged in response to infection or inflammation in the area. For example, axillary lymphadenopathy indicates infection, tumor or malignancy in the mammary gland, especially in females, and submandibular lymphadenopathy in throat infections. Thus, clinically it helps in detecting the area of pathology.

Spleen

Spleen is the largest lymphoid organ in the body.
1. It is surrounded by a capsule made up of elastic and smooth muscle fibers.
2. A number of trabeculae extend from capsule into the organ.
3. Stroma contains network of reticular fibers and cells and many venous sinuses.
4. Parenchyma contains splenic pulps made up of white pulp and red pulp. Red pulps are present around the white pulps (Figs. 18.5A and B).
5. The white pulp appears as circular patches. It consists of lymphoid nodule containing B cells, central artery and germinal center. The periarteriolar lymphocytes are mainly T cells. However, B cells slightly predominate T cells in spleen.
6. The red pulp is made up of diffuse lymphoid tissue organized as splenic cords separated by venous sinuses. Red pulp contains red cells, lymphocyte, other white cells and macrophages.
7. The cords contain fine network of reticular fibers and cells. This fine reticular network in the splenic red pulp filters the blood cells that pass through it. The arrangement of splenic circulation (open and closed circulation) in the red pulp and location of the sinusoids help in filtering senescent and abnormal cells (Fig. 18.6).
8. The aged and defective cells are easily detected and destroyed in the pulp. Otherwise also blood cells are trapped in the splenic pulp (Clinical Box 18.3).

Figs. 18.5A and B: Histological picture of spleen, in low magnification (A), and in photomicrograph (B). (1: Red pulp; 2: White pulp; 3: Germinal center; 4: Arteriole; Ca: Capsule; T: Trabeculus).

Fig. 18.6: The splenic circulation. Note the location of sinusoids that filter cells.
Functions of Spleen

1. Spleen plays important role in immunity (Clinical Box 18.4). Macrophages in spleen help in phagocytosis of pathogens or antigens. Spleen is the site for production of B and T cells. Germinal centers in the spleen helps in development of lymphocytes. Spleen also helps in production of antibodies.
2. Spleen removes old and abnormal red cells, white cells and platelets. Cells of MPS detect these senescent and abnormal cells and remove them from blood.
3. Spleen helps in hepatic stage of hemopoiesis during intrauterine life. Extramedullary hemopoiesis takes place in spleen in postnatal life in pathological conditions.
4. Spleen acts as an important reservoir of blood in mammals.
5. Macrophages in spleen recycle iron, which has been released from destroyed red cells. This iron is reutilized for synthesis of hemoglobin.

Mucosa-associated Lymphoid Tissue

As discussed significant aggregation of lymphocytes seen in relation to the mucosa of the respiratory, alimentary and urogenital tracts are refereed as mucosa-associated lymphoid tissue (MALT). The total volume of MALT is more or less equal to that of the lymphoid tissue present in lymph nodes and spleen. Mucosa associated aggregations of lymphoid tissue have some features in common as follows:

- These aggregations are in the form of one or more lymphatic follicles (nodules) having a structure similar to nodules of lymph nodes. Germinal centers may be present. Diffuse lymphoid tissue (termed the parafollicular zone) is present in the intervals between the nodules. The significance of the nodules and of the diffuse aggregations of lymphocytes is the same as already described in the case of lymph nodes. The nodules consist predominantly of B, while the diffuse area consists of T lymphocytes.
- These masses of lymphoid tissue are present in very close relationship to the lining epithelium of the mucosa in the region concerned, and lie in the submucosa. Larger aggregations extend into the submucosa. Individual lymphocytes may infiltrate the epithelium and may pass through it into the mucosa.
- The aggregations are not surrounded by a capsule, nor do they have connective tissue septa. A supporting network of reticular fibers is present.
- As a rule these masses of lymphoid tissue do not receive afferent lymph vessels, and have no lymph sinuses. They do not therefore, serve as filters of lymph. However, they are centers of lymphocyte production. Lymphocytes produced here pass into lymph nodes of the region through efferent lymphatic vessels. Some lymphocytes pass through the overlying epithelium into the lumen.

Mucosa-associated Lymphoid Tissue in Respiratory System

In the respiratory system the aggregations are relatively small and are present in the walls of the trachea and large bronchi. The term bronchial associated lymphoid tissue (BALT) is applied to these aggregations.

Mucosa-associated Lymphoid Tissue in Alimentary System

This is also called gut associated lymphoid tissue (GALT). In the alimentary system examples of aggregations of lymphoid tissue are tonsils, Peyer’s patches and lymphoid nodules in vermiform appendix.

LYMPH AND LYMPHATIC CIRCULATION

Lymph is a transudate from blood and contains the same proteins, but in smaller amounts and in different proportions. Suspended in lymph there are cells that are chiefly lymphocytes. Most of these lymphocytes are added to lymph as it passes through lymph nodes, but some are derived from tissues drained by the nodes. Large molecules of fat (chylomicrons) that are absorbed from the intestines enter lymph vessels. After a fatty meal these fat globules may be so numerous that lymph become milky (is called chyle). Under these conditions the lymph vessels can be seen easily as they pass through mesentery.

Functional Anatomy

Lymphatics drain lymph from different tissues of the body and empty the same into the subclavian veins at their junctions with internal jugular veins.

1. Lymphatic vessels typically begin as blind tubular bulbs (lymphatic bulbs) that drain into meshwork of interconnected lymph vessels. For example, in the intestine, villous lacteals are lymphatic bulbs.
Section 2: Blood and Immunity

2. **Blood and Immunity**

![Diagram: The lymphatic drainage system. Note, there is no valve in initial lymphatics, but the valves are present in collecting lymphatics. Black arrows indicate the direction of flow of fluid movement into lymphatic bulb.](image)

**Fig. 18.7:** The lymphatic drainage system. Note, there is no valve in initial lymphatics, but the valves are present in collecting lymphatics. Black arrows indicate the direction of flow of fluid movement into lymphatic bulb.

2. Tissue fluid enters into the bulbs that in turn drain to interconnected lymph vessels and then from these vessels into tubular lymphatic vessels and the larger lymphatic vessels (Fig. 18.7).

3. Lymphatic vessels coalesce into increasingly larger vessels.

4. Larger vessels are surrounded by contractile cells similar to that of smooth muscles of blood vessels.

5. Lymph nodes are interposed in the path of lymphatics.

**Important Note**

Organs with no lymphatics: Lymphatics are absent in bone, teeth, cartilage, placenta and CNS.

**Types of Lymphatics**

Lymphatics are of two types: Initial lymphatics and collecting lymphatics.

**Initial Lymphatics**

Initial lymphatics are lymphatic bulbs and interconnected vessels (lymphatic capillaries).

Lymphatic capillaries differ from vascular capillaries in several ways:

1. No basal lamina (or scanty basal lamia) under the endothelium.

2. Junctions between endothelial cells are open.

3. No fenestrations in endothelium (non-fenestrated)

4. Tight junctions (tight intercellular connections) are absent

Initial lymphatics lack valves and smooth muscles in their walls. Tissue fluid enters into them through gaps or loose junctions between the endothelial cells present in their linings. Movement of fluid in them is facilitated by contraction of organs in which they are present and the contraction of arterioles and venules with which they are often associated. They drain into collecting lymphatics.

**Collecting Lymphatics**

Collecting lymphatics are tubular and larger lymphatics.

1. They have valves and smooth muscles in their walls.

2. They exhibit peristaltic contraction that propels lymph in forward direction.

3. Lymph flow is further facilitated by skeletal muscle contraction, negative intrathoracic pressure (during inspiration), and suction effect created by higher velocity of flow in veins into which the lymphatics drain.

4. Unidirectional flow of lymph is maintained by presence of valves in the larger lymphatic ducts.

5. Substances that increase lymph flow are called lymphagogues. Usually, agents that increase capillary permeability also act as lymphagogues.

**Formation and Composition of Lymph**

Lymph is formed from tissue fluid. Therefore, essentially it is a modified tissue fluid (Table 18.1). It is formed by transcapillary exchange and exchange between tissue fluid and lymphatic ducts. Lymph flow is much slower (1 mL/min in thoracic duct) than blood. Its colloidal osmotic pressure is less than that of plasma. Presence of more lipid gives milky color to the lymph, hence called chyle.

**Functions of Lymphatic Circulation**

1. Extra amount of fluid left in the tissue space by capillary filtration is taken up by lymphatics and returned back to circulation. Thus, lymphatics prevent accumulation of excess free fluid in the interstitial space (prevent edema formation), and at the same time contribute to water content of plasma to some extent.

2. In liver and intestine, a significant quantity of protein enters into interstitial space. This protein is returned to circulation via lymphatics. This accounts for 25 to 50% of circulating protein in the blood. Thus, lymphatics maintain protein content of plasma.

<table>

</tr>
<tr>
<td>6. Ions: Sodium, potassium, calcium, chloride, sulfates, phosphate</td>
</tr>
<tr>
<td>7. Water</td>
</tr>
</tbody>
</table>
3. Long-chain fatty acids, cholesterol and fat-soluble vitamins absorbed from intestine are transported to circulation via lymphatics.
4. Mononuclear phagocytes in lymph nodes remove bacteria and pathogenic organisms from lymph draining from the organ. Thus, they play protective function (Clinical Box 18.5).

Clinical Box 18.5

Lymphadenopathy: Specific lymph nodes draining from the site of infection and inflammation are usually enlarged during the active phase of the disease process. Enlarged lymph nodes (lymphadenopathy) in a particular part of the body provide clinical clue to the physician to locate the site of infection. For example, enlarged submandibular lymph glands indicate infection in the throat.

CHAPTER SUMMARY

Key Concepts
1. Thymus is a primary lymphoid organ involved in T cell development.
2. Lymph node, spleen and associated lymphatic tissue are secondary lymphoid organs where the lymphocytes reside and mature.
3. Spleen is the site of destruction of old and abnormal blood cells.
4. Splenomegaly and lymphadenopathy indicates infection or proliferation of abnormal cells in general.

Important to Know (Must Read)
1. In examinations, Long Questions do not come from this chapter.
2. Functions of thymus, functions of spleen, composition and functions of lymph, & lymphatic circulation may come as Short Questions in exams.
3. In Viva, examiners may ask… hormones secreted from thymus, how T cells are developed in thymus, functions of thymus, spleen and lymph node, composition of lymph, and design of lymphatic circulation.
The process of defense of the body against harmful elements that threaten our normal health is the immunity. Our environment is rich in varieties of infectious microbes, such as bacteria, viruses, fungi, protozoa and multicellular parasites. When these organisms enter the body they multiply, and if their growth and multiplication are unchecked, they produce disease in the host and eventually they may even kill the host. Therefore, the living beings require quick and continuous mechanisms to kill and remove the pathogens from their body.

1. Adequacy of the defense systems mainly depends on the activities of immune mechanisms.
2. Mammalians are endowed with various defense mechanisms that can broadly be divided into specific and non-specific defenses.
3. The specific defense mechanisms of the body are collectively known as immunity.
4. The immune responses greatly depend on the site of infection and the type of infecting organism (pathogen).

**CLASSIFICATION OF IMMUNITY**

The ability of the body to defend against invading agents is called immunity. The invader may be a living organism or a nonliving substance.

Immune responses broadly involve two steps:

1. Recognition of pathogen or the foreign material,
2. Reactions or responses to eliminate it. The responses are called immune responses (Table 19.1).
Chapter 19: Physiology of Immunity

159

Largely, immune responses are of two types:
1. Innate or nonadaptive response (Innate immunity).
2. Acquired or adaptive response (Acquired immunity).

Scientist contributed

Paul Ehrlich a German physician and scientist worked in the fields of immunology, and antimicrobial chemotherapy. He invented the precursor technique to Gram staining bacteria. The methods he developed for staining tissue made it possible to distinguish between different types of blood cells, which led to the capability to diagnose numerous blood diseases. He was awarded Nobel Prize in Physiology or Medicine in 1908 for his pioneering work on humoral immunity.

Paul Ehrlich (1854–1915)

Innate immunity: Innate immunity is mostly nonspecific:
1. It include phagocytosis, inflammation, release of cytokine and antibacterial peptides from phagocytes and inflammatory cells, activation of complement system, etc.

Scientists contributed

Bruce A Beutler Jules A Hoffmann Ralph M Steinman

The Nobel Prize in Physiology or Medicine 2011 was divided, with one half jointly to Bruce A Beutler and Jules A Hoffmann for their discoveries concerning the activation of innate immunity, and the other half of the prize was given to Ralph M Steinman, for his discovery of the dendritic cell and its role in adaptive immunity.

2. Though, highly developed in mammals, this is also the major mechanism of immunity in invertebrates and plants.

Acquired immunity: Vertebrates, especially mammals are gifted with acquired immunity in which specific set of lymphocytes are activated with specific antigens and eliminate antigens by specific mechanisms (specific immunity).

NONSPECIFIC DEFENSE SYSTEM
(Innate Immunity)

Non-specific defense systems include the skin and mucous membrane (mechanical factors and chemical factors), antimicrobial mechanisms (interferons and complements), natural killer cells, phagocytosis, inflammation and fever. Thus, nonspecific defence mechanisms are:
1. Mechanical defense
2. Chemical defense
3. Defense by NK cells
4. Defense by phagocytic cells
5. Defense by inflammation and fever

Mechanical Defense

Skin and epidermis: Skin and epidermis are the most important and natural defense barriers of the body. They form the partition between the body and the external environment that immediately checks the entry of organisms into the body. Therefore, loss of skin as occurs in burns leads to infection and septicemia.

Mucous membranes: Mucous membrane also forms the physical barrier for the organisms and prevents their entry into the body. Wherever there is no skin on the body surface, mucous membrane covers the body, especially the surface of body cavities such as oral cavity, nasal cavity etc. Mucous membrane mechanically traps the organisms and secretes chemicals that inhibit the organisms.

Mucus: Mucus is secreted from glands located in the mucosal epithelium. Mucus, by virtue of its physical property traps microorganisms, especially in the respiratory, gastrointestinal and genitourinary tracts.

Hairs: Almost all openings (entry points) of the body such as nostrils, ears, eyes, anus, urethra and vagina (in females) are guarded by hairs. They filter microorganisms and prevent their entry into the body.

Cilia: Cilia also filter microorganisms. They are present in mucous membranes. They remove dust and microbes from upper respiratory tract. Along with mucus they also trap microbes.

Tear: Tear is secreted from lacrimal apparatus. It washes the microbes and dilutes the chemical substances produced by microbes.

Saliva: Saliva washes microbes from the oral cavity and keeps the mouth and teeth clean. It also contains antimicrobial chemicals.
Urine: During micturition, urine comes out of the urinary tract forcefully. Therefore, urine flow washes microbes from urinary tract.

Defecation: During the act of defecation, fecal matter is forcefully evacuated from the rectum and anal canal. Thus, along with fecal matters microbes are washed from lower GI tract.

Chemical Defense

Acidic pH of Skin: Acidic pH of skin inhibits growth of micro-organisms.

Bactericidal Substance of Sebum: Sebum is the secretion of the glands in the skin. It contains bactericidal substances like unsaturated fatty acids that kill microbes.

Chemicals in Body Secretions: Antimicrobial substances like lysozyme secreted in saliva, tear, sweat and other body secretions inhibit growth of micro-organisms.

Acidic pH of Stomach and Vagina: Strongly acidic pH of gastric secretion kills many micro-organisms and also destroys toxins in the stomach. Low pH of vaginal secretion also prevents entry of microbes into the body.

Complement Proteins: There are different complement proteins in plasma that are activated in response to entry of microorganisms into the body. They help in destroying the organisms by facilitating opsonization and phagocytosis. They also participate in immunity (refer 'complement system').

Interferons: These are chemicals secreted from activated lymphocytes, etc., These are usually antiviral substances that kill viruses.

Defense by NK Cells

NK Cells or natural killer cells are third category of lymphocytes that are neither B nor T cells:

1. They have the ability to kill a wide variety of micro-organisms and tumor cells.
2. They do not mature in thymus.
3. Unlike B and T cells, they lack surface antigen receptors.
4. They carry surface molecules CD2, CD16, and CD56, but negative for T cell marker CD3.
5. These are large granular lymphocytes (Fig. 19.1).
6. They constitute about 15% of total lymphocytes in the body.
7. They are present in the spleen, lymph nodes, bone marrow and blood.
8. They take part in natural or innate immunity.
9. They recognize antibody coated target cells and kill them by antibody-dependent cell-mediated cytotoxicity (ADCC), which works more effective against viruses and tumour cells.

Mechanism of Killing

NK cells kill microbes by following mechanisms:

1. Osmotic lysis by incorporating perforins into the surface of the microbes.
2. They release interferons that activate phagocytosis and immunity.
3. They possess Fc receptors that allow them to kill antibody coated viruses.
4. Kill by antibody-dependent cell-mediated cytotoxicity (ADCC), especially the viruses and tumour cells.

Special Features: NK cells differ from other lymphocytes by following characteristics:

1. They do not require prior sensitization to kill microbes.
2. They do not involve major histocompatibility complex (MHC) antigen for killing micro-organisms.
3. They are the first line of defense against viral infections.
4. They are also active against tumor cells, especially malignant cells.
5. They usually attack cells that do not display proper markers.

Defense by Phagocytic Cells

Role of Granulocytes and Mononuclear Cells

Granulocytes (neutrophils, eosinophil and basophil), monocytes and macrophages kill micro-organisms by phagocytosis:

1. Phagocytosis is the process of ingestion of microbes or foreign cells or solid materials by a phagocyte. Phagocytes are neutrophils, monocytes and macrophages (scavenger cells). Monocytes transform themselves into macrophages in the tissue.
2. There are two types of macrophages: the wandering macrophages and fixed macrophages. The macrophages that are mobile in the tissues are called wandering macrophages.
3. The fixed macrophages are present in specific tissue sites in the body. These macrophages are mononuclear cells, and therefore this system of phagocytes is called as mononuclear phagocyte system (MPS). Previously, this system of cells was known as reticuloendothelial system, but they neither are reticular in appearance nor have endothelial origin. Therefore,
Chapter 19: Physiology of Immunity

the term reticuloendothelial system is obsolete. The important examples of MPS include the following (Fig. 19.2):

a. Kupffer cells of the liver
b. Alveolar macrophages in the lungs
c. Microglia of brain
d. Tissue macrophages in the spleen and lymph nodes
e. Osteoclasts in bone
f. Mesangial cells in kidney
g. Histiocytes in connective tissues
h. Langerhans cells in the skin

Scientist contributed

Élie Metchnikoff was a Russian zoologist best known for his pioneering research in immunology. In particular, he is credited with the discovery of phagocytes (macrophages) in 1882. This discovery turned out to be the major defence mechanism in innate immunity. He and Paul Ehrlich were jointly awarded the 1908 Nobel Prize in Physiology or Medicine “in recognition of their work on immunity”. He established the concept of cell-mediated immunity, while Ehrlich described humoral immunity. Their works are regarded as the foundation of the science of immunology. In immunology, Élie Metchnikoff is given an epithet the “Father of natural immunity.”

Inflammation

In the process of inflammation, microorganisms are killed by the chemicals released from the inflammatory cells, and also by phagocytes.

Defense by Inflammation and Fever

In the process of inflammation, microorganisms are killed by the chemicals released from the inflammatory cells, and also by phagocytes.

Inflammation

The response of the tissue to injury is known as inflammation. This is a defensive response of the body against the tissue injury. It is characterized by appearance of four features in sequence at the site of injury:

1. Rubor (redness)
2. Dolor (pain)
3. Calor (increased temperature)
4. Tumor (swelling).

The fifth component of inflammation is the functiolesia, the loss of function of the injured part of the body. Inflammation helps in killing the organisms and disposing them off. It also destroys toxins released by microbes, and helps in tissue repair. Thus, inflammation restores tissue homeostasis.

Stages of Inflammation

There are three stages of inflammation: vasodilation and increased permeability, phagocyte migration and phagocytosis, and tissue repair (Fig. 19.3).
Vasodilation and Increased Permeability
Vasodilation occurs immediately following injury, which allows more blood to flow to the site of injury. This causes redness of the area. This is followed by increased permeability which allows fluid to escape into the tissue that causes local swelling (wheal), and also permits antibodies and phagocytes to enter the injured area (Figs. 19.4A and B):

1. Vasodilation and increased capillary permeability are produced by histamine released from mast cells, basophils, and platelets, bradykinin formed in the blood and in tissues from plasma kininogen and tissue kininogen respectively, prostaglandins released from damaged cells, and complement proteins formed by activation of complement system.
2. Contraction of vascular endothelial cells at the site of injury increases the gap between the cells that facilitates vascular permeability (Fig. 19.5).
3. The arteriolar dilation increases further blood flow that causes increased local temperature (calor) and flare i.e., spread of redness to the surrounding area, the phenomenon called triple response (Figs. 19.4A and B).

Phagocyte Migration and Phagocytosis
Within minutes to hours of inflammation, phagocytes appear at the site of injury. The first to appear is neutrophil, followed by monocyte and macrophage (Application Box 19.1):

1. Phagocytes reach the site of injury by diapedesis and chemotaxis (for details, refer Figs. 17.12 and 17.13, Chapter 17).
2. As the inflammatory response continues, phagocytes die in the process of killing the microbes.
3. Within few days, the dead phagocytes and damaged tissue cells form viscous fluid called pus. Usually, over a period of days pus is absorbed.
4. The pus that cannot be drained out from the region of inflammation slowly forms abscess (localized accumulation of pus).

**Application Box 19.1**

Alteration in cell count indicates nature of inflammation: As neutrophils first participate in inflammation, neutrophilia indicates acute inflammation or infection. As inflammation continues, monocytes and macrophages take part in phagocytosis. Therefore, monocytosis is the feature of chronic inflammation.

**Tissue Repair**

Tissue repair is the healing stage in inflammation. This is facilitated by migration of fibroblasts, macrophage and epithelial cells to the site of injury that repair and restore the epithelium by secreting growth factors. Tissue plasmin promotes migration of keratinocytes that aid to the healing process. Proliferation of collagen produces scar.

**Role of NF-κB**

Recent evidences suggest that a transcription factor, called nuclear factor kappa B (NF-κB), plays an important role in inflammation:

1. Normally, NF-κB is bound to another cytoplasmic protein called IκBα, and this binding keeps NF-κB in an inactive state.
2. Viruses and cytokines that induce inflammation separate NF-κB from IκBα. NF-κB then migrates to nucleus and attaches with the DNA.
3. This induces the transcription of genes for formation of various chemicals that participate in inflammation.
4. Thus, NF-κB stimulates synthesis and secretion of mediators of inflammation (Application Box 19.2).

**Systemic Response to Inflammation**

Cytokines produced during inflammation induce systemic responses. The major change is the increase in acute phase reactants (APRs) in plasma. APRs are plasma proteins whose concentration increases at least by 25% in response to acute inflammations.

These acute phase proteins are mainly synthesized by liver. The important APRs are:

1. C-reactive protein (CRP)
2. Orosomucoid protein
3. Fibrinogen
4. Haptoglobin
5. Serum amyloid protein A
6. C3 complement protein

The first to appear in acute inflammation is CRP. In many acute conditions, the plasma level of high-sensitive CRP (hsCRP) is an important marker of inflammation (Clinical Box 19.1). However, CRP concentration decreases rapidly within first week of the onset of the disease. The fibrinogen concentration increases slowly and remains elevated for 2 to 3 weeks. Increase in ESR in acute inflammation is due to increased level of fibrinogen that neutralizes the negative charges on the red cell surface.

**Clinical Box 19.1**

hsCRP is a prognostic marker: Estimation of ultrasensitive-CRP (us-CRP) has recently been used for diagnosis, and assessing the prognosis of inflammatory diseases and coronary artery disease.

**Inflammatory Cells and Cytokines**

Cells for acute inflammation: Neutrophils, eosinophils and basophils.

Cells for chronic inflammation: Monocytes, macrophages, lymphocytes and plasma cells.

These cells kill organisms by phagocytosis and also by secreting cytokines. Many of the mediators of inflammation are secreted by the inflammatory cells.

**Fever**

Fever is one of the protective phenomena of the body against infections:

1. Increased body temperature as occurs in acute infections and inflammations, prevents growth of microorganisms.
2. Fever also facilitates the actions of interferon and different body enzymes that inhibit the growth of many microorganisms.
3. Therefore, unless very high and deleterious, fever should not be brought down immediately by antipyretics.

**Contribution of Toll-like Receptors**

Innate immunity in Drosophila is mainly due to the presence of a receptor protein called ‘Toll’. The toll binds with fungal antigens that activates of genes coding for antifungal proteins. A large number of toll like receptors (TLRs) are found in mammals including human beings. TLR4, one of these proteins, binds to bacterial polysaccharides and to CD14. It is proposed that this binding initiates intracellular events that activate transcription of genes for a variety of proteins required for innate immune responses (Application Box 19.3).
Pattern Recognition Receptors: TLRs are referred to as pattern recognition receptors (PRRs) as they organize and respond to the molecular patterns expressed by pathogens. Few PRRs such as nucleotide-binding oligomerization protein domain (NOD proteins) may be intracellular. NOD 2 has recently been identified as the product of a candidate gene involved in inflammatory bowel disease and Croh'n disease.

**SPECIFIC DEFENSE MECHANISMS**

(ACQUIRED IMMUNITY)

Acquired immunity is broadly divided into two categories: the cellular (cell mediated) immunity, and humoral (antibody mediated) immunity.

**Cellular Immunity:** Cell mediated immunity is due to the presence of **cytotoxic T cells** (killer cells) in the body:
1. These cells develop and proliferate in response to a particular antigen (or a specific organism) and kill that organism (or destroy that antigen).
2. This immunity is particularly effective against **intra-cellular organisms** like viruses, parasites and fungi, cancer cells, tumor cells, and transplanted tissues.

**Humoral Immunity:** Humoral immunity is due to the presence of **antibodies** in the body:
1. Antibodies are formed by plasma cells. Plasma cells are developed from activated B cells in response to antigen.
2. This immunity works mainly against **extracellular organisms** such as bacteria and the antigens dissolved in the body fluids.

Though pathogens stimulate activation of a particular immune mechanism predominantly, often they provoke both cellular and humoral immunity simultaneously.

**Development of Immunity**

Development of immunity is the development of lymphocytes. Immunity develops naturally in the body, but is activated in response to an antigen, which is generally an infective organism or a nonliving substance:
1. A specific antigen stimulates the development of a specific set of lymphocyte.
2. Functionally, lymphocytes are of three types: **B cell**, **T cell**, and **NK cell**.
3. NK cell (described earlier) is mostly involved in relatively nonspecific defenses of the body.
4. The major sites of lymphocyte development are the **primary lymphoid organs**. In these organs, lymphocytes differentiate from their precursors that originate from the bone marrow, and proliferate and mature into functionally potent cells. In mammals, **T cells mature in the thymus**, and **B cells mature in the bone marrow and bursal equivalent**. Thus, **thymus, bone marrow and bursal equivalent** are the primary lymphoid organs.
5. After their maturity, they circulate in blood and migrate to **secondary lymphoid organ** where they reside.

Flowchart 19.1: General outline of the development of immunity. T4 cells induce development of both cellular and humoral immunity.

Secondary lymphoid organs are **lymph nodes**, **spleen** and **gut associated lymphoid organs**.

T cells develop in thymus, and B cells in bursal equivalents. The general outlines of development of immunity are summarized in Flowchart 19.1. For details of lymphoid tissues (thymus, lymph node, spleen, and other lymphoid tissues), and their functions, especially their role in immunity, refer the previous chapter. Distribution of T and B cells in different lymphoid tissues is depicted in Table 19.2.

**Development of Bursa:** B cells develop in bursa. In the birds, lymphoid tissue is present in bursa of Fabricius, which is located near the cloaca:
1. This bursa helps in development and processing of **B lymphocytes**, where pre-B cells develop into B cells. Therefore, these cells are called bursa-dependant cells or B cells.
2. However, in mammals there is no such bursa, but they have **bursa equivalents**. The bursal equivalent issues are **bone marrow and fetal liver**.

**Development of Gut-Associated Lymphoid Organs:**

Lymphatic tissues are present at many places in GI tract starting from oral cavity to colon:
1. **Tonsils** (palatine, lingual and nasopharyngeal) that are present in the oral cavity and pharynx contain lymphatic follicles.
2. Lymphoid tissues are present extensively in the form of **Payer's patches** along the entire wall of intestine in the submucosal layer.
3. Vermiform appendix is rich in lymphatic tissue.
4. Lymphatic tissues are also present in colon.
5. These lymphatic structures in GI tract provide immunity to body by killing organisms, parasites and larvae that try to enter blood from intestinal lumen.

**Development of T Cells**

**Mechanism of Development**

Development of T cells takes place in thymus. Hence, they are called thymus-dependent or T cells:

1. The stem cells or precursor cells that migrate to thymus before they mature into competent lymphocytes in the thymic environment are called pre-T cells. The lymphocytes that develop from pre-T cells are called T cells.
2. It is not clearly known whether the migration of prethymic (pre-T) cells is selective or random, and whether they are multipotent or destined to from only T cells.
3. Experimental evidences suggest that migration of stem cells into thymus is not a random process, but results from chemotactic signals that are periodically emitted from the thymus. β2-microglobulin, a component of MHC-I molecule is putative chemoattractant for pre-T cells.
4. Though experimental evidences suggest that stem cells destined for thymus express CD7, a marker of T cells, they are multipotent in nature. However, in the thymic environment they develop only into T cells.
5. In the thymus, epithelial cells, macrophages and interdigitating cells are rich in MHC class II antigens. These cells are important in the differentiation of pre-T cells into T cells.
6. The most important among them is the epithelial cell. Specialized epithelial cells in the peripheral areas of cortex are called thymic nurse cells. The thymic nurse cells contain pockets of thymocytes (cortical and medullary) that secrete IL-7, which supports differentiation and proliferation of pre-T cells.

**Steps of Development**

Stem cells (pre-T cells) first colonize in the subcapsular cortical region of the thymus. Then, they develop into large actively proliferating lymphoblasts that possess the property of self-renewal:

1. Lymphoblasts differentiate and proliferate into pre-T cells.
2. Pre-T cells develop into T cells.
3. Pre T cells become Naïve T cells, that further proliferate to form T immunoblasts (Fig. 19.6).
4. There are 2 types of T immunoblasts. One set expresses CD8+ on the surface that develops into CD8+ cells (Tcells, or cytotoxic T cell) and the other set expresses CD4+ on the surface that develops into CD4+ cells (T helper T cell).
5. As cells mature, they migrate to the medulla, and mature T cells leave thymus via postcapillary venules located at the corticomedullary junction, and also via lymphatic vessels.
6. After processing and development in the thymus, the mature T cells migrate into the lymph nodes, spleen, bone marrow, other tissues and blood.
7. T cells participate in cell-mediated or cellular immunity.

**Changes during Development**

During their processing (differentiation and proliferation) in the thymus, they undergo two morphological and chemical changes that confer on them the ability to recognize and kill the antigens. These changes are formation of specific receptors and synthesis of chemokines:

1. **Formation of specific receptors on T cells**
   - The receptors to recognize the particular antigen are formed on T cell surface (Fig. 19.7), and are called T cell receptors (TCR). There are four types of polypeptides for TCR: α, β, γ and δ. However, only two sets are present in TCR. The combinations are either αβ or γδ. Accordingly, TCR are either αβ TCR or γδ TCR. The T cells with αβ TCR are called αβ T cells, and T cells with γδ TCR are called γδ T cells. 95% of circulating T cells are αβ T cells and only 5% are γδ T cells.

2. **Synthesis of chemokines to kill antigens**
   - The cells acquire capacities to from various chemokines that are capable of killing invading organisms. Important chemokines are lymphotxin and interferons.

**Types of T Cells**

There are three types of T cells: the helper T cells (T4 cells), cytotoxic T cells (T8 cells), and memory T cells.

**Helper T Cells (T4 Cells)**

The helper T cells are called T4 cells as they contain CD4 protein on their cell surface. They are known as helper or inducer cells as they assist in induction of both cellular and humoral immunity. There are two sets of helper T cells: **Type 1 helper cells** (TH1 cells) that assist in cellular immunity and **type 2 helper cells** (TH2 cells) that assist in humoral immunity.
immunity. Activated T_{H1} cells secrete IL-2 and γ-interferon, and T_{H2} cells secrete IL-4, IL-5, IL-6 and IL-10 (Fig. 19.7).

**Cytotoxic T Cells**

These are called T_{8} cells as they contain CD8 protein on their cell membrane. They are called cytotoxic or killer cells as they kill invading organisms by producing cytotoxicity. They are sometimes also referred to as suppressor T cells (T_{S}).

**Memory T Cells**

A small subset of T cells remains in the tissue as memory T cells. These cells remember the initial immunologic insult,
and on subsequent exposure to same challenges they are activated immediately without presentation of antigen by antigen presenting cells (see below) and proliferate to millions of T cells that instantaneously fight to eliminate the antigens. Memory T cells live a very long life, may be the entire life of the individual. Therefore, similar antigenic exposure at any time during the life of the person induces prompt and focused cell-mediated immune response.

**T Cell Receptor**

The T cell receptor (TCR) complex consists of seven polypeptide chains:
1. In the majority of (95%) of T cells, δ and β chains form the antigen-binding site of TCR (δβ TCR).
2. Each of these chains has a variable and a constant region similar to immunoglobulins.
3. The δ and β chains are linked together by a disulfide bond to form δ-β complex which is composed of five polypeptide chains.
4. The variable regions of δ and β chains bind antigen while CD3 converts this antigen recognition into intracellular activating signals.
5. In a minority of T cells, γ and δ polypeptide chains are present instead of δ and β chains (γδ TCR).

**TCR Gene Arrangement**

The genetic structure of TCR bears resemblance to that of immunoglobulin. The TCR β chain gene is located on chromosome 7 and TCR α chain gene is on chromosome 14:
1. Although all somatic cells contain T cell receptor gene in germ line configuration, rearrangement occurs only in T cells.
2. The TCR β gene consists of variable (V), diversity (D), joining (J) and constant (C) regions.
3. One segment each from V, D and J regions join together with deletion of intervening sequences. The rearranged gene is transcribed into mRNA. Rearrangement of other peptide chain occurs similarly.
4. As there are a number of V, D and J segments which code for amino acid sequences in variable region, it is possible to generate T cell receptor with different antigen specificities by various combinations during rearrangements.
5. Rearrangement of TCR β gene precedes the rearrangement of TCR α gene.

**T Cell Ontogeny**

Progenitor T cells from the bone marrow are transported to thymus where they undergo maturation. During maturation,
there is rearrangement of TCR genes, expression of some cell surface proteins, and acquisition of ability to distinguish self antigen from foreign antigens:

1. Initially immature cortical thymocytes express CD7, TdT and cytoplasmic CD3 (cCD3).
2. Those T cells which subsequently are going to form δ and β polypeptides (δβ TCR), first rearrange TCR β gene followed by TCR α gene.
3. Expression of δβ TCR occurs in association with expression of CD3 on surface of cells.
4. Initially both CD4 and CD8 antigens are acquired, but with further maturation cell retains either CD4 or CD8 antigen.
5. CD4⁺ cells are called as helper or inducer T cells whereas CD8⁺ cells are called cytotoxic T cells.
6. The mature T cells are released from thymus, circulate in peripheral blood and are transported to peripheral lymphoid organs.

Development of B Cells

The lymphocyte precursors that enter the bursa equivalents like fetal liver and bone marrow in mammals form B cells. They are called B cells as they develop in the bursa equivalent tissues (hence, bursa-dependent cells or B cells):

1. In the birds, a lymphoid tissue is present near the cloaca (the bursa of Fabricius) help in development and processing of B lymphocytes, where pre-B cells develop into B cells. However, in mammals there is no such bursa, but they have bursa equivalents.
2. During their development in bursa equivalent structures, B cells acquire characteristic surface molecules. They acquire receptors to recognize antigen and receptors for various cytokines, and most importantly the genes for immunoglobulin synthesis. First, the gene rearrangement occurs for heavy chain and then the gene rearrangement occurs for light chain of immunoglobulins.
3. Pre B cells become Naive B cell, that transform into Mantle Cell, Centroblast and Centrocyte. Centrcytes mature into plasma cell or transform to memory B cells (see Fig. 19.6)
4. Each B cell lineage is committed for making only one specific antibody against a specific antigen. This is the central theme of clonal selection theory of antibody production.
5. Pre B cells once mature in bursa equivalents migrate to lymph nodes, bone marrow, blood and other tissues like lymph nodes and lymphoid follicles.
6. In these structures (bone marrow, lymph nodes and lymphoid follicles), they further process to become B immunoblasts or centroblasts, those under on specific immunologic stimulation undergo further transformation to form plasma cells (Fig. 19.8).
7. Plasma cells produce large quantities of antibodies. Plasma cells are not normally found in blood. Antibodies formed by plasma cells kill or neutralize antigens.
8. A small set of B cells form memory B cells that on subsequent exposure to an antigen get readily converted into effective B cells (plasma cells) to carry out immuno-

![Fig. 19.8: Development of B cells. Note pre B cells migrate to lymph node or lymphoid follicles to become B immunoblasts or centroblasts, which further transform to form plasma cell.](image-url)
Antigens

Definition
Antigens are living organisms or substances that on entry into the body induce specific immunological reactions. Antigens have two important properties: immunogenicity and reactivity:

1. **Immunogenicity** is the ability to provoke an immune response i.e., to stimulate the production of specific antibody or proliferation of specific T cells or both.
2. **Reactivity** is the ability of the antigen to react specifically with an antibody or a cell or both.
3. An antigen that possesses both the properties is defined as a complete antigen.
4. An antigen that has the reactivity but lack immunogenicity is called partial antigen or a hapten.

Nature of Antigen
Antigens may be the entire micro-organism like a bacterium or a virus, or a part of the organism like capsule of the virus, flagella of bacteria or the cell wall of the organism. The antigen may also be a nonmicrobial substance, such as pollen, egg white, transplanted tissue or incompatible blood cells.

Chemical Nature: Antigens are large complex molecules. Usually, they are protein in nature. However, nucleoproteins, glycoproteins, or large polysaccharides also behave as antigens. Usually T cells respond to protein antigens, whereas B cells respond to proteins and non-protein antigens.

Antigenic Determinant
Specific portion of an antigen that triggers the immunological reaction is called antigenic determinant or epitope. Usually an antigen possesses many antigenic determinants, each of which induces production of a specific antibody or proliferation of a specific set of T lymphocytes.

MHC Antigens
Major histocompatibility complex or MHC antigens are self-antigens that help in identifying and rejecting the foreign antigens:

1. They are also called HLA antigens (human leucocyte associated antigens), as they were first identified on the membrane of leucocytes. However, afterward they were found to be present on the surface of all the body cells except in red cells (remember, red cells contain blood group antigens).
2. Like blood group antigens they are chemically glycoproteins. They are made up of α and β subunits.
3. Though MHC antigens are responsible for rejection of transplanted tissues, their normal function is to identify the foreign antigens and present them to the T cell for induction of cellular immunity.
4. The recognition of an antigen is the first and foremost step in the process of activation of immunological responses, especially for initiation of cellular immunity.

Types of MHC Antigens
There are two types of MHC antigens: type 1 or MHC I, and type 2 or MHC II antigens.

- **MHC I antigen**: MHC I antigens are present on the cell membranes of all body cells except red cells. MHC I is made up of three α and one β subunits.
- **MHC II antigen**: MHC II antigens are present on the surface of antigen presenting cells (APCs), thymus cells and activated T cells. MHC II is made up of two α and two β subunits.

Mechanism of Action of MHC Antigens
The proteins in the cells are continuously broken down to their peptide fragments. MHC I molecules pick up the peptide fragments containing 8–10 amino acids, whereas MHC II molecules pick up peptides containing 13–17 amino acids:

1. When a peptide fragment of a self protein is picked up by the MHC antigen and expressed on the surface of the APC along with MHC proteins, T cells ignore it.
2. However, when the peptide fragment is of a foreign protein, T cells recognize it and get activated that induce cell-mediated immunological responses.

Significance of HLA Antigens
1. They are important as histocompatibility antigens in organ transplantation.
2. HLA antigens play a major role in recognition of foreign antigens and in immunity.
3. In transfusion medicine, they are responsible for autoimmunization against platelet antigens and refractoriness to platelet transfusion, febrile transfusion reactions and graft versus host disease.
4. A relationship exists between presence of some HLA antigen and susceptibility to certain diseases.
5. HLA antigen typing can also be used for paternity testing.

Recognition of MHC-Ag Complex by TCR
The MHC protein-Antigen complex on the surface of the APCs binds to appropriate receptor on T cells. Therefore, receptors on the T cell should recognize a wide variety of protein complexes (Figs. 19.9A and B). As discussed above, TCR is made up of α and β subunits that form heterodimers to recognize the MHC proteins and the antigen fragments with which they are combined. These cells are called αβ T cells. Details of TCR recognition of antigen presented by APCs are discussed below. About 10% of
circulating T cells are αδ T cells. These T cells are prominent in the mucosa of the gastrointestinal tract. The αδ T cells form a link between the innate and acquired immune systems, and help in secretion of cytokines.

**CELLULAR IMMUNITY**

Cell mediated immunity is mediated by T cells. Cellular immunity is particularly effective against *intra-cellular organisms* like viruses, parasites and fungi, cancer cells, tumor cells, and transplanted tissues. This immunity is induced following entry of an antigen into the body. However, antigen directly does not induce cellular immunity unless presented appropriately to the T cells. The antigen is recognized and processed by the antigen presenting cells (APCs) and then presented to the immunocompetent lymphocytes that are activated and proliferated to destroy the antigen.

**Steps of Cellular Immunity**

Mechanism of cellular immunity includes following steps:
1. Antigen recognition, processing and presentation
2. Activation and proliferation of T cells
3. Elimination of the invader

**Antigen Recognition, Processing and Presentation**

There are different varieties of antigens but human body has the ability to recognize each of them. This recognition ability is innate, which develops without prior exposure to the antigen. The precursor stem cells of lymphocytes differentiate into millions of different T and B cells. Each T or B cell type has the ability to respond to a particular antigen. On entry into the body, antigens bind with an appropriate receptor present on the B cell surface and activate the B cells:
1. However, for activation of T cell to occur the antigen should be processed and presented by the APCs to the appropriate receptors on the T cell.
2. The cells that process and present antigens to the T cells are called antigen presenting cells (APCs).
3. APCs include macrophages, dendritic cells and B cells.
4. APCs are present in more numbers specifically at locations that are the usual sites for antigen entry into the body like skin, and mucous membrane of respiratory, gastrointestinal and genitourinary tracts.

**Steps of Antigen Presentation**

There are five major steps in antigen presentation: ingestion of antigens, digestion of antigen, fusion of vesicles, binding of peptide fragments to MHC molecule, and incorporation of antigen-MHC complex into the cell membrane of APC (Fig.19.10):

1. **Ingestion of the antigen:** Antigens are *ingested by APCs* by the process of endocytosis.
2. **Digestion of the antigen and formation of vesicles:** Following phagocytosis, antigen is digested partially by the lysosomal enzymes and form *phagosome* within the cytoplasm of APCs. The phagosomal vesicles contain peptide fragments of antigens. Simultaneously, MHC II molecules are formed in the cell (*MHC vesicles*).
3. **Fusion of vesicles:** The phagosomal vesicles containing peptide fragments of antigen combine with the vesicles containing MHC II molecules. These two vesicles merge to form single vesicle.
4. **Binding of peptide fragments with MHC II molecules:** Following fusion of vesicles, antigen fragments bind with MHC II molecules. The fused vesicles containing MHC II and peptide fragments (MHC-Ag complex) undergo exocytosis.

5. **Incorporation of antigen-MHC complex into the cell membrane of APC:** During the process of exocytosis, the peptide fragments (antigens)–MHC-II complex get incorporated into the cell membrane of APC:
   - An APC containing the MHC-antigen complex migrate into the lymphatic tissue or circulate in the blood.
   - When APC containing this MHC-Ag complex comes in contact with a particular T cell, the complex attaches with T-cell receptor (Fig. 19.11).
   - Consequently, the T cell gets activated that triggers cell mediated immunity.

### Immunologic Synapse

For antigen recognition, antigen presenting cell (APC) presents the antigen to T cell. T cell receptors are surrounded by adhesion molecules. Proteins bind to complementary proteins in the APC when the two cells transiently join. The junction between T cell and APC is called immunologic synapse. The activity at this synapse permits the T cell activation to occur. It is now generally accepted that two signals are necessary to produce activation. One is produced by the binding of the digested antigen to the T cell receptor. The other is produced by the joining of the surrounding proteins in the synapse. If the first signal occurs but the second does not, the T cell is inactivated and becomes unresponsive.

### Activation and Proliferation of T Cells

The cell-mediated immunity depends on the activation of T cells by a particular antigen. An activated T cell undergoes differentiation and proliferation into the **effector T cells**, which eliminates the antigen. Activation of cellular immunity involves **two steps**: activation of T cells and proliferation and differentiation of T cells (Fig. 19.12).
Activation of T Cells
There are receptors on the T cell surface, known as TCR. When TCRs come in contact with MHC-antigen complex located on the surface of the APCs, T cells are activated (see Fig. 19.11). This is the first step in induction of cellular immunity.

Proliferation and Differentiation of T Cells
The activated T cells with proper costimulation by inducer cells (type 1 Helper Cells), undergo proliferation and differentiation into two sets of T cells: the cytotoxic T cells, and the memory T cells:
1. **The cytotoxic T cells** are also called T₈ cells, as they display CD8 proteins on their cell membrane. They are also known as **killer T cells** as they kill the microbes.
2. The **memory T cells** are programmed to recognize the original invading antigen in future, when the body is reexposed to the similar antigens. Therefore, when the same antigen invades the body at a later date, thousands of T cells are formed immediately and the invader is killed promptly.

Elimination of the Invader
The cytotoxic T cells kill the invading microbes by following three major mechanisms:
1. **Cytolysis**: Killer cells synthesize and secrete **perforins**, and incorporate them into the membranes of the invading organisms. Perforins are water channels that freely allow water to enter the microorganism along the osmotic gradient. The invading cell swells and finally undergoes **osmotic lysis**.
2. **Lymphotoxin**: Activated T cells secrete **lymphotoxins** that kill the microbes. Tumor necrosis factor (TNF)-β is an important known lymphotoxin.
3. **Interferons**: Cytotoxic T cells secrete gamma-interferons that are mainly **antiviral**. They also increase the phagocytic activity of neutrophils and macrophages by promoting opsonization.

Cellular immunity is activated mainly against intracellular pathogens and tumor cells, as in:
1. Viral infections
2. Fungal infections
3. Tumor cells, especially cancer cells
4. Transplanted cells
5. Chronic bacterial infections like tuberculosis, brucellosis, etc.
6. Parasitic infections

Humoral Immunity
Humoral immunity is the immunity mediated by antibodies. Antibodies are produced by plasma cells. Plasma cells are normally not present in the blood, but are formed from B cells on specific antigenic stimulation:
1. In response to an antigen, the B cells are activated and are differentiated into plasma cells.
2. Normally, B cell activation does not depend on presentation of antibody by APCs.
3. Antigens can directly stimulate B cells. However, antigens on the surface of APCs also activate B cells.

Steps of Humoral Immunity
Activation of humoral immunity involves **six steps** (Fig. 19.13):
Chapter 19: Physiology of Immunity

1. Presentation of antigen
2. Activation of B cells
3. Differentiation of B cells into plasma cells
4. Proliferation of plasma cells and antibody production
5. Killing of the invaders by antibodies that include activation of complement system
6. Formation of memory B cells and subsequent immunological responses

**Presentation of Antigen**
Antigen presenting cells in humoral immunity include B cells themselves. Therefore, antigen presentation through APCs is **not a must** for induction of humoral immunity. However, antigen combined with MHC II molecules on the surface of APC (Ag-MHC complex) may also be presented to B cells.

**Activation of B Cells**
When an antigen binds directly to the receptors present on the surface of the B cells, the B cells are activated. B cells are also activated when they come in contact with MHC-antigen complex presented by the APCs:
1. This process of activation is accentuated by the **costimulation from type 2 helper cells**.
2. T_{H,2} cells stimulate B cell by secreting IL-2, IL-4, and IL-5.
3. Activated B cells form plasma cells and memory B cells.

**Differentiation of B Cells into Plasma Cells**
The activated B cell enlarges in size that undergoes complete transformation to become plasma cell. This is not a simple differentiation as occurs for T cells in cellular immunity:
1. The cell is transformed completely in structure and function.
2. Plasma cell has larger cytoplasm containing numerous rough endoplasmic reticulums.
3. The enlarged B cell appears almost like a **lymphoblast**, called **B immunoblasts** (see Figs. 19.6 and 19.8). Therefore, sometimes this differentiation is called as **blast transformation**. Co-stimulation by T helper cells (T_{H,2} cells) facilitates the process of transformation.

**Proliferation of Plasma Cells and Antibody Production**
Activated B cells are differentiated into plasma cells. Plasma cells then undergo proliferation to form millions of plasma cells. Plasma cells secrete a large quantity of antibodies:
1. A specific antigen stimulates activation of specific B cells that undergo proliferation of a selective clone of plasma cell.
2. This is called **clonal selection** of plasma cell.
3. Specific clone of plasma cells produce specific antibodies.

**Killing of the Invaders**
Antibodies attack antigens and kill organisms (destroy antigens) by following mechanisms:
1. **Neutralizing antigen**: Antibodies neutralize the antigens. For example, antigens detoxify the bacterial toxins and prevent them to induce immunological reactions.
2. **Immobilization of microbes**: Antibodies prevent the motility of bacteria thereby inhibit their spread to the surrounding tissue.
3. **Activation of complement system**: Antibodies (antigen-antibody complex) activate the classical pathway of complement system by activating C1 (for details, see below) and complements kill organisms.
4. **Precipitation of antigens**: Antibodies cause agglutination and precipitation of antigens. By this mechanism, soluble antigens become insoluble. Insoluble antigens are easily phagocytosed by phagocytic cells.
5. **Facilitation of phagocytosis**: Antibodies enhance phagocytosis by opsonizing the antigen. Opsonization is the process by which microbes or antigens are made tasty to phagocytes for ingestion by coating antigen with opsonins like antibody, complement proteins, etc.
6. **Providing immunity to newborns**: IgG antibody can easily cross placenta and enter fetal circulation from the maternal blood. Thus, it provides immunity in newborns. IgA antibody from the maternal milk also provides immunity to the newborn.

**Formation of Memory B Cells and Subsequent Immunological Responses**
A small subset of activated B cells differentiates into memory B cells. However, this differentiation is not like blast transformation. Memory B cells normally remain inactive, unless stimulated by the similar antigens. They respond quickly and vigorously to the same antigens on subsequent exposures. The immunological responses on second and subsequent exposures to antigen are much more in intensity and duration than on first exposure. This is called **secondary immunological response** (see below). These memory B cells live a longer life, may be the life of the individual.

**Types of Humoral Immune Responses**
There are two types of immune responses: the primary response, and the secondary response.

**Primary Response**
When antigen enters into the body for the first time, the immune response induced is called primary response:
1. The antibodies are formed slowly with a latent period of about four days to four weeks.
2. The concentration of antibodies rises gradually and attains a smaller peak (Fig. 19.14).
Fig. 19.14: Primary and secondary immunological responses.

3. Though IgM and IgG antibodies contribute to the primary response, the response is **mainly due to IgM**.
4. Also, antibody titer in primary response returns back to normal within few days to weeks.

**Secondary Response**

When the same antigen enters the body for the second time, the immune response triggered is the secondary response:
1. It occurs speedily and intensely, which is due to the **immunological memory**.
2. Persistence of memory B and T cells help in carrying out the secondary response.
3. Antibodies are formed rapidly. Therefore, concentration of antibody rises fast (fast rising slope) and reaches a greater peak (see Fig. 19.14).
4. Antibody titer falls very slowly and never returns to normal, rather remains elevated for a longer duration. The antibodies in the secondary response are primarily of IgG type.

**Complement System**

There is a group of plasma proteins designated as complement proteins as they complement the effects of antibodies in destroying antigen. These proteins constitute the complement system:
1. Though there are more than 30 complement proteins, eleven are categorized in this system and are designated as C1–C9. C1 is further divided into C1q, C1r, and C1s (thus, total is 11).
2. These are a system of plasma enzymes that are normally present in the inactive form.
3. Once activated, they exert their immunological and inflammatory actions and boost the humoral immune mechanism.

**Mechanisms of Activation of Complement System**

There are **three mechanisms** of complement activation: classical pathway, alternative pathway and mannose-binding lectin pathway.

**Classical Pathway**

In this process, C1 binds with immunoglobulin attached to an antigen. This binding triggers a sequence of events that activates other complement proteins:
1. The mechanism of activation of complements is similar with the activation of intrinsic pathway of blood coagulation (the enzyme cascade theory), in which one activated protein activates the other protein (see Fig. 19.15).
2. Once, antigen-antibody complex activates C1, activated C1 (C1a) activates C2 and C4. Activated C2 and C4 (C4b, and C2a) activates C5, which (C5a) in turn activates C6, C7, C8, and C9.
3. These activated complement proteins kill microorganisms and facilitate inflammation by **following mechanisms:**
   - C3a, C4a, and C5a: Promote **phagocytosis** by facilitating chemotaxis, releasing histamine from mast cells, and causing arteriolar dilation.
   - C3b: Promote **opsonization** (makes the bacteria tasty to the phagocytes).
   - C5b, C6, C7, C8, and C9: Cause **cytolysis** of the microbes.

   The activated complements incorporate perforins (pore-forming molecules) into the membranes of microbes. This results in transport of ions and water into the microbes through the pores, which finally result in **osmotic lysis** of microbes.

**Alternative Pathway**

This is also called **properdin pathway** as the key protein in the plasma for this pathway is the **properdin**. In this system, a circulating protein called **factor-1**, recognizes the polysaccharide unit present on the surface of microorganisms (but not in the normal mammalian cells). The interaction of factor-1 with the polysaccharide on microbes triggers a reaction that activates C3 and C5. Once C3 is activated, it activates other complement proteins (see Fig. 19.15).
Chapter 19: Physiology of Immunity

Mannose-binding Lectin Pathway

The plasma protein lectin binds with mannose group on the surface of bacteria, which activates complement proteins.

The complement system activates B cell, and thus serves as the link between innate and acquired immunity. Following apoptosis, complement proteins help in disposing the debris.

Antibodies

Antibodies are immunoglobulins (Ig). Ig binds specifically with the antigenic determinant of the antigen. This binding triggers the production of further antibodies. Binding of antigen with Ig is like the key fitting into the lock. There are specific antigen receptors on B cells. Binding of specific antigen with the specific receptor on B cell, results in production of specific antibody.

**Types of Antibodies**

There are five types of antibodies: IgG, IgA, IgM, IgD, and IgE (Table 19.3). They are produced in response to specific stimuli (specific antigens). A specific clone of B cells that are activated by specific antigenic stimulus produce specific antibody, i.e. monoclonal antibody (details, given below). The concentration of IgG in plasma is maximum (1000 mg%), followed by IgA (200 mg%), IgM (120 mg%), IgD (3 mg%), and IgE (0.05 mg%).
Structure of Antibodies

Most antibodies have four polypeptide-chains. The two of them are heavy (H) chains and the other two are light (L) chains (Fig. 19.16):

1. The two H chains are identical to each other and contain about 450 amino acids, which may be either of α, γ, µ, δ and ε chains. The two L chains consist of about 220 amino acids. The polypeptides in L chain are κ and λ chains that are same in all antibodies. L chains are also identical to each other.
2. There may be some additional polypeptide chains in certain antibodies.
3. Antibodies are glycoproteins and their carbohydrate residue is attached to the heavy chains.
4. Disulfide bonds bridge the L and H chains. H chains are attached to each other at the middle by disulfide bonds. At this point, H chains display flexibility. Therefore, this region of H chain is called hinge region.
5. The tip of H and L chains is called variable region, as this region is different for each type of antibody. The variable region contains antigen binding site. This part of antibody recognizes and specifically attaches to a particular antigen.
6. The flexibility at hinge region allows the antibody to bind to two antigenic determinants (of antigens).
7. The rest of the H and L chain is called constant region, as this part of antibody is same in all types of antibodies.

Functions of Antibodies

Different antibodies play different role in immunological responses:

- **IgG**: Complement fixation by classical pathway
- **IgA**: Localized protection in body secretions like tear, salivary and intestinal secretions, etc.; complement fixation by alternate pathway
- **IgM**: Complement fixation by classical pathway
- **IgD**: Antigen recognition by B cells
- **IgE**: Histamine releases from mast cells and basophils; also has reagin activity

MECHANISMS OF SELF-RECOGNITION (Immunological Tolerance)

Self recognition is the process by which own MHC proteins do not recognize self antigens (identify only foreign antigens). This is due to the mechanism of immunological tolerance (Application Box 19.4). Immunological tolerance is defined as unresponsiveness of the individual to an antigen. Immunological tolerance to self antigen provides the physiological basis for self recognition. Development of immunological tolerance is based on the process of negative and positive selections.

**Scientists contributed**

The Nobel Prize in Physiology or Medicine for the year 1960 was awarded to Australian scientist Sir Frank Macfarlane Burnet and Brazilian scientist Sir Peter Brian Medawar for their discovery of the mechanism of acquired immunological tolerance.

**Negative Selection**

During the process of development of T cells in thymus, cells with TCR that recognize peptide fragments of self proteins are eliminated while cells with TCR that do not recognize peptide fragments of self proteins are retained. This occurs either due to deletion (the self-reactive T cells undergo apoptosis) or anergy (the self-reactive T cells remain unresponsive to immunologic stimulation).

**Clonal Deletion**

During embryonic life, the clone of T cell and B cells containing receptors that react against self antigens are selectively removed from the body during their thymic and bursal development, so that they are not available in post-natal life to react against self antigens. These self reactive lymphocytes undergo apoptosis.

**Clonal Anergy**

The self-reactive clone of T and B cells those remain alive during post-natal life loose the capacity to be activated in
response to self antigens. This is because they lose the activity of their receptors and lymphokine systems to react against self antigens, which may be due to the immune suppression of these cells by body’s self regulating systems. This state of idleness is called clonal anergy.

Positive Selection

Immunological tolerance is also achieved by positive selection in which the T cells that are capable of recognizing self-MHC molecules during their thymic development survive and those that do not recognize undergo apoptosis. The T cells recognize MHC - self antigen complex as the self antigens and do not react against them.

Application Box 19.4

Fetal tolerance: Though fetus that grows in the mother’s uterus is genetically a different organ (fetal graft) and foreign tissue immunologically, is not rejected during pregnancy like rejection of a transplanted organ. This is an example of immunological tolerance, called as fetal tolerance. Fetal tolerance is due to four mechanisms:

1. During the formation of placenta, trophoblast cells that separate the mother and fetus do not express MHC I and II antigens, and therefore, lose their immunogenicity. Instead, placenta expresses, HLA-G a nonpolymorphic antigen. Therefore, antibodies against fetal tissue do not develop.
2. Placenta has Fas ligand on its surface which attaches to the T cells. This attachment causes apoptosis of T cells that are supposed to react against fetal tissue.
3. Alpha fetoprotein (AFP) that is formed during fetal development causes suppression of T and B cells that react against fetal graft.
4. High level of progesterone during pregnancy is believed to suppress immunity against fetal tissue.

APPLIED PHYSIOLOGY

Organ Transplantation

Tissue or organ transplantation involves replacement of an injured or diseased tissue or organ by a new tissue or organ. Sometimes, it is required for the treatment of debilitating diseases like renal failure, liver failure, etc. Commonly transplanted organs are skin, kidney, bone and liver. However, the transplanted tissue is rejected as the recipient develops an immune response against the transplanted organ, which is a foreign tissue to him:

Scientists contributed

The Nobel Prize in Physiology or Medicine for the year 1990 was awarded to American transplant surgeon Joseph E Murray and E Donnall Thomas for their discoveries concerning organ and cell transplantation in the treatment of human disease.

1. Transplant rejection is due to the activation of cellular immunity.
2. The immune system recognizes the transplanted tissue as a foreign organ and initiates a series of immunological reactions that finally rejects the tissue.
3. The rapidity at which the transplanted tissue is rejected depends on degree of matching of MHC antigen (HLA antigen) of donor with the HLA antigen of the recipients.

Types of Transplants

1. Autograft: Transplantation of a tissue from one part of the body to another part of the same individual is called autograft. The best example is the skin graft on a burnt or scarred surface of the patient by taking a flap of skin from other part of his body. Autografts are never rejected.
2. Isograft: Transplantation of organs between the genetically identical individuals. The best example is the transplantation of tissues from the identical twin. Isograft is also not rejected.
3. Allograft: This is the transplantation of organs between individuals of the same species, but with different genetic background. The example is transplantation from an individual other than identical twin. Allograft is rejected. If the graft is taken from the very close relations, rejection occurs slowly.
4. Xenograft: This is a transplant from or between different species. For example, transplantation of organ between animal and man. Commonly used xenograft is the physiological dressing using animal skin over severe burn surfaces. Xenograft is rejected fast.

Prevention of Transplant Rejection

A number of treatments are available to prevent rejection of a transplanted organ. These are:

1. Immunosuppressive drugs: The commonly used drug is azathioprine. This is a purine antimetabolite that kills T lymphocytes. However, the individual on azathioprine is susceptible to severe infection because of immunosuppression.
2. Glucocorticoid therapy: Glucocorticoids have strong immunosuppressive activity. They inhibit proliferation of cytotoxic T cells by inhibiting the production of interleukin 2 (IL-2) from T cells.
3. Antilymphocyte globulins: These are monoclonal antibodies produced against T lymphocytes. They inhibit T cell activity.
4. Antibiotics: Antibiotics usually used for the prevention of transplant rejection are cyclosporine, tacrolimus and rapamycin. Cyclosporine is a fungal extract and tacrolimus is an antibiotic of fungal origin. They prevent T cells from transcribing the IL-2 gene by preventing dephosphorylation of NF-AT, a transcription factor.
**Section 2: Blood and Immunity**

*Rapamycin* prevents activation of IL-2 receptor from producing T cell differentiation and proliferation.

5. **Monoclonal antibodies**: They prevent activation and proliferation of T cells.

**Monoclonal Antibodies**

Monoclonal antibodies are antibodies prepared from a single clone of B or plasma cells. They are used for immunotherapy of different diseases or to prevent rejection of transplanted tissue. They are obtained by fusing a B cell with a tumor cell that produces antibodies in large quantity.

**Method of Production**

An animal is immunized by injecting a particular antigen. The animal is then sacrificed and the antibody producing **cells** are extracted from the spleen of the animal:

1. The antibody producing cells are fused to the myeloma cells that are obtained from B lymphocyte tumor in a patient suffering from multiple myeloma.
2. Fusion of myeloma cell with antibody producing cell results in formation of a hybridoma which grows to become an antibody producing tumor.
3. The fused cells (hybridoma cells) are separated and every single cell is allowed to form a clone of cells.
4. The single clone of hybridoma cells produce specific antibody consisting of heavy or light chains of spleen cell or of myeloma cells. These are called monoclonal antibodies.

**Uses of Monoclonal Antibody**

Monoclonal antibodies are used in a wide variety clinical spectrum:

1. For measurement of drug level in patient’s blood.
2. Diagnosis of allergic diseases, hepatitis, sexually transmitted diseases, etc.
3. Detection of cancer in the early stage.
4. Preparation of vaccines.
6. Treatment of autoimmune diseases.

---

**Immunotherapy**

Immunotherapy is the treatment that aims at induction of the immune system of an individual. This is called **immunostimulation** or **immune enhancement**. This is especially helpful for the treatment of different malignant diseases. There are different types of immunotherapies: cellular immunotherapy, cytokine therapy, antibody therapy and adjuvant therapy.

**Cellular Immunotherapy**

Cells that have anti-tumor activity are injected into the blood of the cancer patient. These cells destroy the malignant tumor cells:

1. Patient’s own inactive cytotoxic T cells or NK cells are used for this purpose.
2. In practice, these cells are removed from the blood of the patient and cultured with IL-2, which activates them.
3. These activated cells are called lymphokine-activated killer cells (**LAK cells**). LAK cells are then transfused into the patient’s blood.

**Cytokine Therapy**

Different cytokines (see below) can be used in the treatment of different diseases. The best example is **interferon**. Interferons are especially used for the treatment of viral infections or malignancies. **Interleukin-2** is also used for the treatment of cancer.

**Antibody Therapy**

Monoclonal antibodies are extensively used for the treatment of malignancies or for preventing transplant rejection.

**Adjuvant Therapy**

Adjuvant is a compound, which is introduced with an antigen to enhance immune responses nonspecifically against the antigen. This was first discovered by Freund, hence called **Freund’s adjuvant**:

1. Adjuvants may be complete adjuvants like tubercular bacilli and gram negative bacilli or incomplete adjuvants like aluminum hydroxide, aluminum phosphate, mineral oil, etc.
2. Adjuvants nonspecifically stimulate lymphocytes and macrophages.
3. However, adjuvants may cause delayed hypersensitivity reactions.

**Immunological Disorders**

**Allergy**

This is a hyper-reactive response of the body to an antigen which is usually tolerated by others. There are two types of allergies: the **local allergy** and the **systemic allergy** (anaphylaxis).
Local Allergy
When allergic reactions are limited to an area of the body, are called localized allergy. Examples are swelling of the lips, eczema, hives, urticaria, etc.

Systemic Allergy
When allergic reaction is generalized (affects systemic functions), is called systemic allergy or anaphylaxis. For example, anaphylactic reaction that occurs due to injection of penicillin or xylocaine in sensitive individuals. Anaphylaxis is an acute medical emergency, which may results in shock, called anaphylactic shock.

Hypersensitivity Reactions
There are four types of hypersensitivity reactions:

Type I Reaction or Anaphylaxis
In this reaction, the individual over-reacts to a sensitized allergen. Usually it occurs on re-exposure. But in highly sensitive individual, it occurs on first exposure:
1. The antigen-antibody complexes release histamine and slow-releasing substance A from mast cells and basophils.
2. Histamine produces bradycardia and rapid vasodilation leading to acute hypotension.
3. Myocardial contractility is also inhibited resulting in reduced cardiac output. It is an acute medical emergency, which requires prompt medical support.

Type II Reaction or Cytotoxic Reaction
This reaction is caused by IgG or IgM antibody, which is directed against antigen present on person’s red cells. Incompatible blood transfusions, hemolytic diseases of newborn and autoimmune hemolytic anemias are examples. This causes acute hemolysis and requires early medical intervention.

Type III Reaction or Immune Complex Disease
In this reaction, the antigen and antibodies form complexes that escape phagocytosis. These immune complexes are deposited on the basement membrane of the blood vessels. They activate complements and induce inflammation. Examples are glomerulonephritis, systemic lupus erythematosus (SLE) and rheumatoid arthritis.

Type IV Reaction or Cell Mediated Reaction or Delayed Hypersensitivity Reactions
These reactions are mediated by macrophages that are activated by T cells.
1. Allergens (antigens) are taken up by APCs and presented to T cell.
2. This causes proliferation of T cells, some of which migrate to the location of allergen entry into the body. There, they secrete cytokines that activate macrophages and induce inflammatory reactions.
3. The appropriate example is the skin test for tuberculosis.

Autoimmune Diseases
Normally, the immune system does not react against self proteins. However, in some conditions, immune system fails to neglect self antigens and triggers immune reaction against body’s own antigens. This results in autoimmune diseases:
1. This may be due to the persistence of T cells or B cells that are active against self antigens. Especially, failure of the process that removes antibodies against self antigens leads to formation of autoantibodies (Clinical Box 19.2). Thus, B cells produce antibodies against self antigens.
2. The common examples are SLE, rheumatoid arthritis, insulin-dependent diabetes mellitus, myasthenia gravis, Grave’s disease, etc.
3. Autoantibodies may eliminate the receptors or activate the receptors. For example, in myasthenia gravis, antibodies are formed against nicotinic cholinergic receptors that destroy the receptors, whereas in Grave’s disease, antibodies formed against TSH receptors activate the receptors.

Immunodeficiency States
Immunodeficiency diseases may be broadly classified into two categories: congenital or primary and acquired or secondary.

Congenital Immunodeficiency Syndromes
There are list of diseases in which severe combined immunodeficiency (SCID) occurs due to defects in development in either cellular or humoral immunity:
1. **Autosomal recessive SCID:** In this syndrome, stem cells (pre-T cells) in thymus fail to develop into mature T cells. Therefore, severe deficiency occurs in the cellular immunity.

2. **X-linked SCID:** In this disease, pluripotent stem cells fail to develop into progenitor cells of lymphoid series. Therefore, severe deficiency occurs in the development of both humoral and cellular immunity.

3. **X-linked agammaglobulinemia:** In this defect, pre-B cells fail to develop into B cells. Therefore, severe deficiency of humoral system of immunity ensues.

4. **MHC class II deficiency:** Deficiency of MHC II antigen leads to deficiency of CD4 cells. Thus, both cellular and humoral immunities fail to develop.

**Acquired Immunodeficiency Syndrome (AIDS)**

AIDS occurs due to infection by human immunodeficiency virus (HIV). HIV is a retrovirus that binds to CD4 protein on the surface of helper cells and decreases number of circulating T4 cells:

1. As helper cells are required for induction of both cellular and humoral immunity, HIV infection causes severe immunodeficiency state that predisposes the individual to all type of serious infections and malignancies. Consequently, the disease becomes a dangerous as cancer.

2. The usual clinical features are fever, lymphadenopathy, sore throat, diarrhea and weight loss.

3. Oral candidiasis, anogenital herpes simplex infection, Pneumocystis carinii pneumonia, cryptococcus meningitis and cytomegalovirus infections are common.

4. Finally, the patient dies due to secondary infection or cancer.

5. The commonest malignancy is Kaposi’s sarcoma.

6. The disease is transmitted by blood, semen, or vaginal secretions or through breast feeding. The usual mode of transmission is sexual contact.

7. Though there is no definite treatment, interferon, azathioprine and protease inhibitors are used to reduce the severity. Efforts have been made recently to develop vaccines to prevent AIDS.

**Cytokines**

Cytokines are a group of hormone like substances that usually act in a paracrine fashion to control immunological responses. They are secreted from activated lymphocytes, macrophages, endothelial cells, glial cells, etc. They are classified into: interleukins, tumor necrosis factors (TNF), interferons, transforming growth factors (TGF) and GM-CSF (Table 19.4).

**Interleukins**

There are different types of interleukins. However, physiologically important interleukins are **IL-1 to IL-13:**

1. They are produced by macrophages, activated T cells, APCs, NK cells, mast cells and other somatic cells.

2. They assist in proliferation of B and T cells, activation of leucocytes, lymphopoiesis, erythropoiesis, thrombopoiesis and leucopoiesis.

3. The specific interleukins have specific functions. For example IL-1 produces fever, induces anorexia, increases neutrophil count and decreases lymphocyte count. Though it increases capillary permeability, it produces hypertension.

**Tumor Necrosis Factors (TNFs)**

There are two types of TNFs, TNF-α, and TNF-β. TNF-α is produced by activated macrophages. It acts like interleukin-1. It produces vascular thrombosis and tumor necrosis. TNF-β is produced by activated type 1 helper cells. The physiological effects are same as TNF-α.

**Interferons (IFN)**

There are three types of IFNs: IFN-α, IFN-β, and IFN-γ.

**IFN-α:** This is produced by macrophages, neutrophils, and other somatic cells. It prevents growth of viruses (antiviral). It also activates macrophages and NK cells, and induces the expression of type I MHC on all somatic cells.

**IFN-β:** Same as IFN-α.

**IFN-γ:** Secreted by activated type 1 helper cells and NK cells. It induces expression of MHC I on all somatic cells and MHC II on APCs. It activates macrophages, neutrophils and NK cells. It stimulates cellular immunity. It is also antiviral.

**GM-CSF**

Functions of GM-CSF have been discussed in detail in ‘leucopoiesis’.

#### Chapter Summary

**Key Concepts**

1. Nonspecific immune mechanism (innate immunity) is mainly due to NK cells, phagocytosis by mononuclear phagocyte system, inflammatory cells, and chemicals present in skin and mucous membrane.
2. T cell (T<sub>8</sub> cell or cytotoxic T cell) is for cellular immunity, which is mainly targeted against intracellular pathogens like viruses, parasites and fungi, cancer cells, tumor cells, and transplanted tissues.
3. B cell is for humoral immunity mediated by antibodies, which is mainly targeted against extracellular pathogens like bacteria.
4. Type 1 helper cell induces cellular immunity and type 2 helper cell induces humoral immunity.
5. Complement system activates B cells, and also helps in nonspecific immunity.
6. Monoclonal antibodies help in transplant rejection and used in immunotherapy.
Important to Know (Must Read)

2. NK cells, Inflammation, Phagocytosis, Mononuclear phagocyte system, Development of T cell, Development of B cell, Types and functions of T cells, T cell receptor, MHC antigens, Immunoglobulins, Cellular immunity, Humoral immunity, Immune responses, Antigen presenting cells, Mechanism of antigen presentation by APCs, Complement system, Monoclonal antibodies, Immunological tolerance, Immunotherapy, Prevention of transplant rejection, Immunodeficiency states, AIDS, Autoimmunity, and Cytokines are usual Short Questions in exams.

3. In Viva, examiners may ask any questions from the topics listed as short notes. In addition, classification of immunity, types of antibodies and their functions, and all immunological disorders, may be asked.
Platelets and Their Role in Hemostasis

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:
1. Define hemostasis and list the major steps of hemostasis.
2. Give the steps of thrombopoiesis and briefly describe its regulation.
3. Describe the structure (cytoskeletal systems and granules) of platelet and correlate the structure with platelet functions.
4. Appreciate the properties of platelet, especially platelet adhesion, aggregation and release reaction.
5. Explain the role of platelet in hemostasis, with special reference to the role in temporary hemostatic plug formation.
6. List the causes of thrombocytosis and thrombocytopenia.
7. List the platelet function tests.
8. Understand common platelet dysfunctions.

Student **MAY** also be able to:
1. Describe the role of platelets in hemostasis.
2. Describe platelet function test.
3. Describe the physiological basis of common platelet dysfunctions, especially ITP.

**Definition and Concept**

Hemostasis is defined as the process of **arrest of bleeding** while maintaining blood in a fluid state within the vascular system.

Hemostasis is the mechanism by which loss of blood from vascular system is prevented by a complex interaction of vessel wall, platelets and plasma proteins. This happens broadly in two stages: primary and secondary.

**Primary hemostasis:** This is the initial stage during which vascular wall and platelet interact to limit the blood loss from damaged vessel. This is also called temporary hemostasis, as platelet plug alone cannot stop bleeding for a longer duration.

**Secondary hemostasis:** A stable fibrin clot is formed from clotting factors by enzymatic reactions. This is also called definitive hemostasis, as formation of clot in the vicinity of platelet plug finally stops bleeding.

Although formation of blood clot is needed to arrest blood loss, ultimately blood clot needs to be dissolved to resume the normal blood flow, and the process of dissolution of clot is called fibrinolysis.

Bleeding occurs when blood vessels are damaged. The vascular injury initiates a series of events in sequence that finally forms clot at the site of injury and prevents loss of blood from the body. Thus, hemostasis is a life-saving process that maintains homeostasis of blood volume.

**Steps of Hemostasis**

Hemostasis occurs in **three stages**: vasoconstriction, temporary hemostatic plug formation, and blood coagulation (Flowchart 20.1).

**Vasoconstriction**

Immediate response of blood vessel to injury is vasoconstriction.
1. This occurs due to the contraction of vascular smooth muscle in response to injury.
2. It instantaneously decreases loss of blood and also helps in platelet plug formation (see below).
3. Contraction of vascular smooth muscle to injury is initially a mechanical response (**stretch-induced contraction**).
4. However, later vasoconstriction is maintained and potentiated by secretion of vasoconstrictor substances like serotonin from the activated platelets.

**Temporary Hemostatic Plug Formation**

Formation of platelet plug at the site of injury is called temporary hemostatic plug. This occurs due to three properties of platelets: adhesion, aggregation, and release reaction (secretion) (Fig. 20.1).

1. The initial response of platelet to vascular injury is the change in shape of platelets and its increased surface adhesiveness to the injured vascular endothelium. This is called adhesion.
2. Platelets also stick to each other (aggregate) at the site of the injury. This is called aggregation.
3. Simultaneously, platelets are also activated to release a number of chemicals (release reaction or secretion) that further facilitate vasoconstriction, adhesion and aggregation.

The whole process finally results in formation of a platelet plug that arrests bleeding temporarily. As platelet plug is not a stable one, the plug is called temporary hemostatic plug (or primary hemostatic plug), and the process is called temporary hemostasis. This is also called primary hemostasis as this is the first step in hemostasis that occurs very quickly and stops bleeding instantaneously.

**Blood Coagulation**

Immediately following injury, the clotting mechanism of blood is initiated. This results in formation of blood clot at the site of injury that stops bleeding.

1. The formation of blood clot occurs in and around the platelet plug and the plug formed is a stable one. Therefore, this plug is called a definitive hemostatic plug (or secondary hemostatic plug).
2. This process is also called secondary hemostasis as this step follows the primary hemostasis.
3. Blood coagulation is initiated by the vessel injury that releases tissue factors and exposes collagen of the vessel wall (for details, see the next chapter).

**THROMBOPOIESIS**

The development of platelets is called thrombopoiesis or thrombocytopenia. Platelets are the smallest formed elements of blood. They are anuclear fragments of mega-karyocytes. Megakaryocytes are the giant cells in the bone marrow: The major steps of thrombopoiesis are summarized in Flowchart 20.2.

### Stages of Development

Thrombopoiesis occurs in three broad steps (Figs. 20.2):

1. **Formation of megakaryoblast** from hemopoietic stem cells (Pluripotent stem cells, Committed stem cells and CFU-Mega).
2. **Megakaryopoiesis**: This is formation of megakaryocyte (Promegakaryocyte, basophil megakaryocyte, granular megakaryocyte and mature megakaryocyte) from megakaryoblast.
3. **Formation of platelets** from megakaryocytes

### Stem Cells

Platelets develop from myeloid stem cells that form CFU-Mega, which in turn develop into megakaryoblast (for details, refer ‘Hemopoiesis’).

### Megakaryoblasts

Megakaryoblasts are the first identifiable cells of the thrombopoietic series in the bone marrow. Their size is more than 15 µm. The cytoplasm is basophilic and nucleus is multilobed.

### Megakaryocytes

Megakaryocytes grow in three stages: promegakaryocyte, granular megakaryocyte, and mature megakaryocyte.

#### Promegakaryocytes

The cells are bigger than megakaryoblast (size more than 20 µm).

1. Cytoplasm is basophilic and contains few azurophilic granules around the centrosome.
2. The nucleus is horse-shoe shaped.
3. This is also called basophil megakaryocyte.

#### Granular Megakaryocytes

The cells are very big having the size between 25 and 50 µm.

1. Cytoplasm is acidophilic and contains numerous azurophilic granules around the centrosome.
2. The nucleus is irregular or horse-shoe shaped.

#### Mature Megakaryocytes

These are the largest cells in bone marrow. The characteristic features are:

1. These are polyploid bone marrow cells (ploidy means DNA content; diploidy means double amount of DNA; polyploidy means increased amount of DNA in the nucleus). Megakaryocyte has large nucleus, which is polyploid.
2. The cells are still bigger in size (more than 25 to 50 µm).
3. Cytoplasm contains numerous granules of different kinds. Four types of granules have been described in megakaryocyte:  
   - α-granules, dense granules, lysosomal granules, and myeloperoxidase granules.
4. Most of the proteins and granules of megakaryocyte determine the characteristic of platelets. When the need for platelet increases, the megakaryocytes increase in size, number and ploidy, and the opposite effects occur when the demand decreases.
5. Granules are present around the centrosome.
6. The nucleus is reduced in size.

### Platelets

Megakaryocytes form platelets by pinching off bits of cytoplasm and extruding them into the circulation (Figs. 20.2). On average, each megakaryocyte produces about 1,000 to 3,000 platelets. Normally, platelet production per day is about 35,000 to 45,000 per microliter of blood.
Regulation of Thrombopoiesis

The production and release of platelets from bone marrow remains normally constant. The production of platelets is enhanced by removal of platelets from blood (thrombocytopenia) and decreased by transfusion of platelets. This indicates that a feedback regulatory mechanism exists for platelet production. Thrombopoietin, interleukins, and GM-CSF control thrombopoiesis.

Thrombopoietin

The endogenous thrombopoietin is a short-lived polypeptide, produced mainly from liver parenchymal cells. To some extent, it is also formed in kidney. However, the naturally occurring thrombopoietin for medical uses is very less. Therefore, commercial thrombopoietin have been synthesized by recombinant technology for use in thrombocytopenic conditions. Recombinant thrombopoietins have half-life of 20–40 hours. They are produced by E. coli. Thrombopoietin stimulates differentiation and proliferation of megakaryocytes.

Interleukins

Interleukin-1, interleukin-3, interleukin-6, and interleukin-11 stimulate platelet production. They do not stimulate thrombopoietin release.

GM-CSF

GM-CSF is produced by monocytes, T lymphocytes, fibroblasts, and endothelial cells. It stimulates erythropoiesis, granulopoiesis, and thrombopoiesis.

Life History

Platelets have the half-life of about 4 days. They survive in circulation for about 8–12 days. The aged platelets are removed from circulation by reticuloendothelial systems. Spleen plays an important role in destruction of platelets. Therefore, platelet count increases after splenectomy and decreases in splenomegaly.

Structure and Functions

Structure

Platelets are small, anucleate cell fragments adapted to participate in hemostasis. By their membrane properties they adhere to damaged blood vessels and aggregate with each other. Though the cells are small, platelets have developed cellular structures (Fig. 20.3)

1. They have highly developed cytoskeletal system suited for their functions.
2. They have specialized canalicular system.
3. They have developed membrane systems. When activated, they change their shape due to change in activity of membrane structure and cytoskeleton. This helps in release of chemicals from its granules.

4. They contain extensive microtubules and microfilaments and numerous granules. Frequently, they change their shape with very long and thin processes extending out from their body called as **filopodia**.

**Dimensions**

Platelets are small, granulated, spherical, or oval bodies having diameter ranging from 1.5 to 3.0 µm. The size of platelets is approximately one-third to one-fourth of red cells. However, there is considerable variation in size of platelets even in the same individual. Few platelets may have diameter more than half the diameter of red cells (> 4 µm).

**Cell Membrane**

Cell membrane is covered by an **exterior glyocalix coat** that consists of **glycoproteins** including glycoprotein receptors, glycolipids, and mucopolysaccharides.

1. Platelets have negative charge on their surface due to presence of sialic acid residues attached to the exterior coat. This **prevents the resting platelets to attach to each other** or to the negatively charged endothelial cells.

2. The cell membrane is a **trilaminar unit** consisting of a bilayer of phospholipids in which cholesterol, glycolipids, and glycoproteins are embedded.

3. **Glycoproteins** aid to prevent adherence of platelets to the normal vascular endothelium.

4. However, **glycoprotein receptors** help in adhesion and aggregation of platelets.

5. Platelets have **receptors** on their cell membrane for collagen, ADP, von Willebrand factor (vWF), and fibrinogen.

**Membrane Glycoproteins**

The cell membrane contains integral membrane glycoproteins (Gp) (Fig. 20.4), which play an important role in hemostasis. Important platelet membrane glycoproteins and their functions are as follows:

- **Gp Ib-IX-V**: This is a constitutively active receptor that mediates vWF dependent adhesion of platelets to subendothelial collagen.

- **Gp IIb/IIIa**: On activation, serves to bind fibrinogen and thus mediates aggregation. Also, this is the receptor for vWF, fibronectin, and thrombospondin.

- **Gp Ia-IIa**: Constitutively active receptor for collagen and mediates platelet adhesion independent of vWF.

**Cytoskeletal Systems**

Cytoskeletal system of platelets can be broadly divided into membrane and cytoplasmic cytoskeletal systems.

**Membrane Cytoskeleton**

An elongated tetramer of **spectrin molecule** is present in the cell membrane, which is connected to the ends of actin filaments that are situated close to the cell membrane and membrane of open canalicular system.

1. **Filamin 1** (actin binding protein) **interacts with membrane glycoprotein and actin** present below the membrane. Filamin 1 also connects these proteins (membrane glycoprotein and submembrane actin filaments) to the transmembrane spectrin network, and this **provides stability** to the membrane and discoid shape of the platelets.

2. Other membrane proteins include **talin, vinculin, and vimentin**. Membrane cytoskeleton plays important role in **platelet spreading** following their adhesion to the vascular endothelium.

**Cytoplasmic Cytoskeleton**

Cytoplasm contains a well-developed contractile system, which consists of an **extensive network of microtubules** and **microfilaments**.

**Microtubules**

There is a sub-membrane microtubular system consisting of many microtubules that are arranged beneath the membrane.

1. Microtubules are made up of **α and β tubulins**.

2. Cytosolic motors like **dynein and kinesin filaments** are also associated with microtubules.

3. Microtubules **provide stability to the membrane and support the discoid shape** of the cell.
### Microfilaments

Platelet microfilaments consist mainly of actin molecules that polymerize into microfilamentous bundles. There are also few myosin filaments attached to actin filaments.

1. Actin and myosin filaments constitute contractile system in platelets.
2. The microfilament system is not prominent in the resting cells. However, when platelets are activated and they change their shape, microfilament bundles become more extensive.
3. They form the major contractile system of the cell that helps to change the shape of platelets and discharge their granular content to the exterior through canaliculi (cell release).

### Cellular Systems

There are two developed cellular systems in platelets that help in platelet functions: open canalicular system and dense tubular systems (see Fig. 20.3).

#### Open Canalicular System

There are many canaliculi in the platelets that open to the exterior.

1. The open canaliculi are extensive invaginations of cell membrane deep into the cytoplasm that form the conduits for discharge of contents of granules.
2. Presence of numerous canaliculi in platelet eliminates the dependence of the cell for its chemical release solely on the migration of granules to the periphery for their fusion with cell membrane for exocytosis, as the granule-movement toward the interior of the cell and fusion of the granules with the canalicular membrane facilitates the process of release of chemicals from platelet granules.
3. Thus, open canalicular system enhances the degree and rate of platelet release (see below).

#### Dense Tubular System

This a closed system of channels formed by residual endoplasmic reticulum that are less extensive than canalicular system.

1. This system is found close to the open canalicular system.
2. They sequester the ionized calcium.
3. The membrane of tubular system contains peroxidase activity, and the interior contains calreticulin, a calcium binding protein that helps in calcium accumulation.
4. Release of calcium from dense tubular system facilitates platelet release.

### Cytoplasmic Organelles

Cytoplasmic matrix contains microfilaments, structured filaments, and microtubules. Interspersed in the matrix are various types of granules and electron dense bodies. Organelles are mainly mitochondria. Sometimes Golgi apparatus is found.

### Platelet Granules

Platelet contains numerous peroxisomes, mitochondria, lysosomes, and granules. Activation of platelet leads to discharge of content of granules that facilitate the process of hemostasis. The granules of platelets are of two types: the alpha granules and dense granules (Fig. 20.4).

#### Alpha granules:

The alpha granules are abundant in platelets. About 50–80 granules are present per platelet. They are about 200 nm in diameter. They contain various chemicals (Table 20.1).

#### Dense granules:

There are about 3–8 dense granules per platelet. They are also called dense bodies. They have diameter of about 20–30 nm. They contain chemicals like serotonin, ADP, calcium, ATP, etc.
Chapter 20: Platelets and Their Role in Hemostasis

Properties of Platelets

Platelets have three unique properties: adhesion, aggregation, and activation and release.

Adhesion

Platelets easily adhere to the damaged vascular endothelium. This is called platelet adhesion. Platelets have the tendency to stick to the exposed collagen of the injured vessel wall. Adhesion is facilitated by von Willebrand factor. However, platelets do not adhere to the normal vessel wall.

Role of membrane proteins: This means binding of platelets to non-endothelial surfaces, particularly subendothelium which is uncovered following vascular injury. von Willebrand factor mediates adhesion of platelets to subendothelium via GpIb on the surface of platelets (Clinical Box 20.1).

Clinical Box 20.1

Deficiency of membrane proteins causes bleeding disorder: Congenital absence of glycoprotein receptor GpIb (Bernard-Soulier syndrome) or of von Willebrand factor in plasma (von Willebrand’s disease) causes defective platelet adhesion and bleeding disorder.

Aggregation

Platelets not only stick to the injured vessel wall but also to each other. The property of platelets to stick to each other is called platelet aggregation. Fibrinogen and GpIb-IIIa mainly promote aggregation of platelet to each other (Fig. 20.5). Also, thrombin, ADP and PAF promote platelet aggregation.

Activation and Release (Secretion)

Platelets are activated when they bind to collagens or to each other.

1. The activation is facilitated by thrombin and ADP.
2. Platelets normally circulate as round to oval disc like structures. With the activation platelets undergo shape change, i.e. they become more spherical and form pseudopodia. This shape change is due to recognition of microtubules and contraction of actomyosin of microfilaments.
3. The activated platelets change their shape and discharge their granular contents (Fig. 20.6). The discharge of the granular content to the exterior through open canalicular system is called platelet release (see below).
4. The release reaction (secretion) is facilitated by chemicals released from platelet granules.

Functions of Platelets

In addition to their important role in hemostasis (described below), platelets serve many other functions of the body. Important functions of platelets are as follows:

1. Temporary hemostasis: Platelets prevent bleeding by forming plugs at the site of injury (temporary hemostatic plug). Platelets also promote vasoconstriction by producing serotonin that helps in hemostasis.
2. Blood coagulation: Platelets contribute to blood coagulation by releasing platelet factor 4, and synthesizing clotting factors V and XI.
3. Clot retraction: Platelets promote clot retraction, which is essential for stabilization of clot.
Section 2: Blood and Immunity

5. **Phagocytosis**: Platelets phagocyte smaller molecules like immune complexes and viruses.

6. **Storage and transport**: Platelets synthesize, secrete, and transport many chemical substances (as listed in Table 20.1).

7. **Vascular growth**: Platelets help in growth of vascular endothelium by secreting platelet-derived growth factor (PDGF). PDGF is also produced by macrophages and endothelial cells. PDGF is synthesized in three forms: PDGF-AA, PDGF-BB, and PDGF-AB (containing either of the two polypeptide chains A or B).

### Normal Count and Variations

**Normal count of platelet** is 1.5–4 lakhs/mm$^3$ of blood.

**Thrombocytopenia**

Thrombocytopenia is defined as the platelet count less than 1.5 lakhs/mm$^3$ of blood.

1. However, significant bleeding occurs when platelet count decreases below 50,000/mm$^3$ of blood. Therefore, platelet count below 50,000/mm$^3$ of blood is called **critical count**.

2. Thrombocytopenia occurs in idiopathic thrombocytopenic purpura (ITP), aplastic anemia, hypersplenism, acute leukemia, cytotoxic chemotherapy and radiation (Table 20.2).

3. About 70% of platelets released from bone marrow are present in circulation and 30% are sequestered in spleen.

4. Therefore, splenectomy usually causes thrombocytosis and hypersplenism invariably causes thrombocytopenia.

**Thrombocytosis**

Thrombocytosis commonly occurs in polycythemia vera, chronic myeloid leukemia, iron deficiency anemia, splenectomy, chronic infection, surgery, and following acute hemorrhage.

---

**Table 20.2**: Variations in platelet count.

**A. Thrombocytosis**

1. Essential thrombocythemia

2. Other myeloproliferative diseases like polycythemia rubra vera, CML, etc.

3. Familial thrombocytosis

4. Acute blood loss

5. Iron deficiency

6. After splenectomy

7. Malignancies

8. Drugs: vincristine, epinephrine

9. After surgery

10. Chronic infection

**B. Thrombocytopenia**

1. Hereditary thrombocytopenias like Fanconi anemia, Alport syndrome, May-Hegglin anomaly, etc.

2. Hypersplenism

3. Idiopathic thrombocytopenic purpura (ITP)

4. HIV infection

5. Aplastic anemia

6. Massive transfusion of stored blood

7. Drugs: Heparin, quinidine, quinine, rifampicin, etc.

8. Acute leukemia

9. Cytotoxic chemotherapy

10. Irradiation of bone marrow

---

**ROLE OF PLATELET IN HEMOSTASIS**

Hemostasis is the **arrest of bleeding**. Hemostasis occurs in two major steps: temporary hemostasis and definitive hemostasis. Following injury to blood vessels, platelets aggregate at the site of injury and seal the opening in the vascular tree. This is the first and important step in prevention of bleeding, which is called **temporary hemostasis**. Simultaneously, mechanisms of coagulation of blood are also activated that form blood clot, the processes combine known as **definitive hemostasis** (refer Flowchart 20.1).

Though platelet is essential for temporary hemostasis, it also contributes to **blood coagulation and clot retraction**. Platelet also controls **thrombolysis**.

**Role in Temporary Hemostasis**

Immediate hemostasis following vascular injury is achieved by formation of platelet plug (also called, **platelet thrombus**) at the site of injury. As platelet thrombus can be washed away, unless supported by a clot, this is called **temporary hemostatic plug**. Temporary hemostatic plug formation depends on adhesion, platelet aggregation, and release reaction.
Platelet Adhesion

The damage to blood vessel exposes underlying portion of the vessel wall that are normally concealed from the circulatory platelets by intact lining of the endothelium. Platelets have high affinity to adhere to the exposed vascular wall, which is called platelet adhesion (Fig. 20.7A). Especially, exposed collagen and von Willebrand factor in the injured vessel wall attract platelets for them on their cell membrane. However, platelet adhesion is also controlled by following factors:

1. **Depth and degree of injury:** Deeper and extensive the injury more is the platelet aggregation. This occurs due to release of more quantity of platelet activating factors from the tissue.
2. **Site of injury:** Injury in mucocutaneous vascular bed depends more on platelet for hemostasis, whereas injury of vascular beds in muscles and joints rely more on coagulation mechanism. Platelet aggregation is more in mucocutaneous tissue.
3. **Age of the individual:** As composition of vessel wall changes with age, platelet aggregation alters with age of the individual. In elderly individuals, the aggregation is less.

Platelet Aggregation

Platelet adhesion is immediately followed by platelet aggregation at the site of injury (Fig. 20.7B). Fibrinogen, GpIIb-IIIa, and thrombin promote platelet aggregation. Simultaneously, platelets are activated, and activated platelets release chemicals from their granules (refer Fig. 20.5). These chemicals, especially ADP and platelet activating factor (PAF) further facilitate platelet aggregation (Clinical Box 20.2). Thus, accumulation of more platelets at the site of vascular injury facilitates the process of temporary hemostatic plug (platelet thrombus) formation. Then, formation of clot is initiated (Fig. 20.7C).

Clinical Box 20.2

**Use of ADP inhibitors:** ADP facilitates platelet thrombus formation. There are ADP receptors on the surface of platelets. In human beings, three types of ADP receptors have been identified on platelet membrane: P2Y1, P2Y2, and P2X1. ADP released from dense granules during platelet activation binds with ADP receptors on platelet membrane and facilitates platelet aggregation that promotes platelet thrombus formation. Therefore, inhibitors of ADP (ADP receptor antagonists that prevent platelet aggregation) have been clinically tried in the prevention of myocardial infarction and stroke that occur due to platelet thrombus obstructing blood flow to the concerned tissues.

Important Note

**Use of antiplatelet drugs such as aspirin:** Aspirin inhibits platelet aggregation by inhibiting the membrane enzyme cyclooxygenase (Flowchart 20.3). Cyclooxygenase facilitates thromboxane A2 formation that facilitates platelet aggregation and causes vasoconstriction. Therefore, dispirin (soluble aspirin) is used in treatment and prevention of myocardial infarction and stroke. Steroids inhibit phospholipase.

Platelet Activation and Release

Adhesion of platelets to damaged vascular endothelium activates the platelets. Polymerization of microfibrillar actin occurs in activated platelets that results in pseudopodia or spicules formation. Platelets are also activated by tissue factors and chemicals released from granules of the platelets, especially PAF. Thrombin and ADP also promote activation.
The activated platelets release various chemicals from their granules to the exterior via canalicular system; the process is called release reaction or platelet release (secretion). Following are the possible mechanisms of platelet release.

**Through Platelet Activating Factor**
Platelet adhesion activates platelets. Activation of platelet is facilitated by PAF, a cytokine secreted from neutrophils, monocytes and platelets.
- PAF is a phospholipid produced from membrane lipids. PAF acts via G-proteins and activates phospholipase-C and diacylglycerol (DAG).
- DAG increases cytoplasmic calcium by promoting calcium release from dense tubular systems that are present close to open canaluli.
- Calcium causes contraction of microfilaments that helps in movement of granules to the open canalicular system.
- Membranes of granules fuse with the membranes of canaluli and the contents of granules are released into the canalici by exocytosis.
- From canalici, chemicals are transferred to the exterior of the cell. During this process, platelets change their shape and exhibit movement.

**Through Thromboxane and Serotonin**
Formation of DAG (as described above) activates the enzyme phospholipase A_2, which converts membrane phospholipid into arachidonic acid.

- Arachidonic acid is converted to endoperoxides by cyclooxygenase. Endoperoxides in turn form thromboxane A_2 (TX-A_2).
- TX-A_2 is a potent vasoconstrictor and also promotes platelet aggregation (Flowchart 20.3).
- Serotonin released from platelet produces vasoconstriction and promotes hemostasis.

**Through Thrombospondin and Thrombonectin**
Thrombospondin and thrombomectin released from platelet granules facilitate the activity of contractile system and further promote exocytosis of granules and release of their content to the exterior.

Normally, platelet thrombus formation is prevented due to the balance between the factors that promote and inhibit platelet adhesion, aggregation and activation (Table 20.3). Alteration in this balance, even without vascular injury leads to intravascular platelet thrombus formation resulting in tissue infarction.

**Other Hemostatic Functions**

**Role in Blood Coagulation**
Activation of platelet leads to increased platelet coagulant activity.
1. Platelet factor 4 (PF4) acts as a cofactor for blood coagulation (see next chapter).
2. Platelet synthesizes coagulation factors V and XI.
3. Platelet phospholipids present on the platelet surface accelerate the formation of Va, VIIIa, and Xa. Va is essential for conversion of prothrombin to thrombin.
Chapter 20: Platelets and Their Role in Hemostasis

Flowchart 20.4: Procoagulant activity of platelet. Platelets provides surface for activation of few clotting factors.

Fig. 20.8: Role of blood vessel in hemostasis. Note the factors produced by endothelial cells that promote and inhibit hemostasis.

4. They also facilitate the conversion of X to Xa and prothrombin to thrombin (Flowchart 20.4). Thus, platelets accelerate thrombin formation.

Role in Clot Retraction

If platelets are present in the clot in a test tube, within minutes to hours, the clot contracts, extruding a very large fraction of serum. This is called clot retraction.

1. The platelet filopodia extends into fibrin clot and fibrin strands tug with filopodia. Thus, shrinkage of platelet with contraction of filopodia causes internalization of fibrin that causes clot retraction.
2. In vivo, the phenomenon akin to clot retraction is the consolidation of the thrombus, which not only firmly seals the opening in the injured vessel, but also facilitates wound healing.
3. Clot retraction also prevents the process of thrombolysis.
4. Platelet deficiency prolongs the clot retraction time.

Role in Thrombolysis

Role of platelet in fibrinolysis is complex. Both profibrinolytic and antifibrinolytic actions of platelets have been demonstrated.

1. Thrombospondin, tPA, and plasmin that are profibrinolytic are synthesized and released by platelets.
2. However, antifibrinolytics like plasminogen activator inhibitor-1 and a2-antiplasmin are also secreted from platelets.
3. Platelets by causing clot retraction decrease the efficiency of thrombolysis.
4. It appears that antifibrinolytic effects of platelets predominate over their profibrinolytic effects in vivo as platelet rich thrombus is known to resist thrombolysis.

Role of Vascular Wall in Hemostasis

Vascular endothelium plays an important role in hemostasis. Endothelial cells of blood vessel synthesize certain substances that are inhibitory and substances that have facilitatory influence on hemostasis (Fig. 20.8).

Inhibitors of Hemostasis

Endothelial cells synthesise certain substances which have inhibitory influence on hemostasis. These include;

- Thrombomodulin
- Protein S
- Heparin-related substances
- Prostacyclin (PGI2)
- Tissue plasminogen activator (tPA).

Thrombomodulin: Binding of thrombomodulin to thrombin causes activation of protein C. Protein C inactivates factors V and VIII and is a potent inhibitor of coagulation.

Protein S: Protein S is a cofactor for protein C. deficiency of protein C or protein S is associated with tendency toward thrombosis.

Heparin: Heparin-like substances on the surface of endothelial cells potentiates the action of antithrombin.

Prostacyclin: Prostacyclin, a prostaglandin synthesized by endothelial cells, induces vasodilation and also inhibits platelet aggregation. Endothelial cells also synthesize tissue plasminogen activator, which converts plasminogen to plasm, and activates fibrinolytic system.

Promoters of Hemostasis

Certain factors synthesized by endothelial cells promote hemostasis. These are tissue factor, von Willebrand factor and platelet activating factor.

1. Tissue factor or thromboplastin activates extrinsic system of coagulation.
2. von Willebrand factor mediates adhesion of platelets to subendothelium.
3. Platelet activating factor induces aggregation of platelets.
4. Another vascular factor promoting hemostasis is vasoconstriction of small vessels following injury.
5. Subendothelial collagen promotes platelet adhesion and also activates factor XIII (intrinsic pathway).

PLATELET FUNCTION TESTS

1. Platelet count: Decreased platelet count is associated with prolongation of bleeding time. Though, normal count of platelet is 1.5–4 lakhs/mm$^3$ of blood, significant prolongation of bleeding time occurs when platelet count is less than 50,000/mm$^3$ of blood (critical count). Platelet count is not routinely ordered in clinical practice. However, for assessing integrity of hemostatic mechanisms, especially in the diagnosis of a bleeding disorder, platelet count is a must.
2. Bleeding time: Bleeding time assesses integrity of platelets. Bleeding time is routinely assessed before any surgery or dental procedures. It is prolonged in thrombocytopenia and thrombasthenia. Thrombosthenia is a condition in which platelet count is normal but functionally platelets are abnormal.
3. Platelet aggregation tests: Ability of platelets to aggregate is assessed with the help of aggregometer. In this test, an aggregating agent is added to a suspension of platelets in plasma and the response is measured turbidometrically as a change in transmission of light through the suspension.
4. Platelet adhesiveness test: Platelet’s ability to adhere to glass surface is measured in this test. Anticoagulated blood is allowed to pass at a constant rate through a plastic tube containing glass beads, during which platelets stick to the beads. Platelet adherence is measured by estimating the platelet retention in the tube.
5. Clot retraction time: When blood is collected without anticoagulant, clotted blood retracts and 50% retraction occurs by the end of one hour. Clot retraction completes at the end of 18 to 24 hours. When retraction is less than 50% in one hour, thrombocytopenia or platelet malfunction is reported.

COMMON PLATELET DYSFUNCTIONS

Idiopathic Thrombocytopenic Purpura

Idiopathic thrombocytopenic purpura (ITP) is a primary autoimmune purpura characterized by thrombocytopenia which usually occurs due to formation of antibody against platelets. Antiplatelet antibodies get attached to platelet membrane glycoproteins, and these platelets are phagocytosed in spleen resulting in thrombocytopenia (Fig. 20.9).

It occurs in two forms: childhood ITP and adult ITP.

Childhood ITP: Childhood ITP is common but less severe and occurs equally in both genders that usually resolves spontaneously in six months.

Adult ITP: Adult ITP is less common and occurs predominantly in females.

1. The common feature of the disease is bleeding that usually occurs spontaneously. Skin is the commonest site of hemorrhage, exhibiting petechiae or ecchymoses. Bleeding occurs from mucus membranes in the form of epistaxis (bleeding from the nose), or bleeding-gums.
2. Diagnosis is made by demonstrating thrombocytopenia, anemia, and anti-platelet antibodies in the patient.

Fig. 20.9: Pathogenesis of ITP. Note that platelets having antiplatelet antibodies on their surface are destroyed in spleen. Courtesy: Figure 35.1, Essentials in Hematology and Clinical Pathology by Ramadas Nayak et al., 1st edition, 2012; Jaypee Brothers Medical Publishers (P) Ltd.
Increased numbers of megakaryocytes are seen in bone marrow smear (Fig. 20.10).

The treatment consists of administration of corticosteroids, and splenectomy.

Thrombocytopenia in Pregnancy

Thrombocytopenia is common during pregnancy and usually asymptomatic.

1. A form, called as gestational thrombocytopenia that occurs during late gestation (count may be less than 70,000/cu mm of blood in last trimester) and resolves following delivery, but causes excessive bleeding during parturition.

2. Another form is associated with preeclampsia.

3. Pregnancy-induced hypertension (PIH) and thrombocytopenia (platelet count less than 50,000/cu mm of blood) have lower prognostic value.

Neonatal Autoimmune Thrombocytopenia

Sometimes, neonatal autoimmune thrombocytopenia (NATP) occurs in newborns and platelet count is less than 50,000/cu mm of blood in this condition. It may be associated with autoimmune hemolytic anemia. Antibodies are demonstrated against platelet specific alloantigens. It is more severe when the mother has ITP. NATP is treated by platelet transfusion, steroid and immunoglobulins.

CHAPTER SUMMARY

Key Concepts

1. Platelets are subcellular elements produced by pinching off from megakaryocytes.

2. Though platelets are small in size, they have highly developed membrane and cellular cytoskeletal system, open canalicular system, alpha and dense granules, and membrane glycoproteins. All these cellular specializations help in platelet functions: adhesion, aggregation, activation, and secretion.

3. Primary hemostasis (temporary hemostatic plug formation) is the first and important step in hemostasis, which mainly depends on platelets. Therefore, platelet deficiency leads to bleeding.

4. Platelet also play role in clotting by activating few clotting factors and promoting clot retraction.

5. Splenomegaly causes thrombocytopenia as platelets are destroyed in spleen.

6. Platelet count less than 50,000 per cu mm of blood is called critical count, as bleeding is significant below this count.

Important to Know (Must Read)

1. In theory examination, “Role of platelets in hemostasis”, “Steps and regulation of thrombopoiesis”, and “Structure, properties and functions of platelets” may come as Long Questions.

2. Temporary hemostatic plug, properties of platelets, thrombopoiesis, platelet granules, cytoskeletal and canalicular systems of platelets, functions of platelets, and platelet function tests may come as Short Questions in exams.

3. In Viva, examiners may ask… platelet count, functions of platelets, causes of thrombocytopenia and thrombocytosis, mechanism of temporary hemostatic plug formation, specialities of platelet structure, properties of platelets, steps of thrombopoiesis, regulation of thrombopoiesis, chemicals secreted from platelet granules, mechanism of platelet adhesion, mechanism of aggregation, mechanism of platelet release, causes and features of ITP, and platelet function tests.
Blood Coagulation

Chapter 21

Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Name the clotting factors.
2. Describe the mechanisms (intrinsic and extrinsic) of blood coagulation.
3. Understand the importance of clot retraction.
4. Explain the anticoagulant mechanism (process of fibrinolysis).
5. Appreciate the physiological basis of use of fibrinolytic agents in coronary artery disease and stroke.
6. List the anticoagulants.
7. List the investigations for detection of defects in temporary and definitive hemostatic plug formation.
8. Enumerate the common abnormalities of coagulation.

The student MAY also be able to:
1. Describe various clotting factors.
2. Describe the mechanism of action and uses of anticoagulants.
3. Understand the pathophysiology of common abnormalities of coagulation, such as DIC, hemophilia and von Willebrand disease.
4. Describe the physiological basis of investigations of bleeding disorders.

Introduction

Coagulation of blood is a vital physiological process, as hemorrhage is detrimental to life. Blood is maintained in a fluid state in the vascular compartment, yet swiftly coagulates to seal a vascular injury. Failure to form clot results in hemorrhage or thromboembolic phenomenon. Immediately following vascular damage, platelet plug (temporary hemostatic plug) formation occurs at the site of injury that immediately stops bleeding. However, unless associated with definitive hemostatic plug, hemorrhage continues as platelet thrombus is not a stable plug. The definitive hemostasis is the coagulation of blood, the process which is simultaneously activated along with the activation of platelets. Coagulation of blood occurs due to activation of clotting factors (coagulation proteins) that are normally present in their inactive form in plasma.

Clotting Factors

Coagulation of blood depends on a series of chemical reactions involving clotting factors. There are known 12 clotting factors (Table 21.1) that were depicted earlier as factors I to XIII (factor VI absent). Later, few more were added to the list.

Scientist contributed

In 1905, Paul Morawitz was the first scientist who systematically assembled coagulation factors into the scheme of coagulation and demonstrated that, in the presence of calcium and thromboplastin, prothrombin (II) was converted to thrombin, which, in turn, converted fibrinogen (I) into a fibrin clot. This theory persisted for 40 years until the discovery of factor V.

Factor I

Factor I is the fibrinogen.
1. It is a dimeric glycoprotein with molecular weight of 340,000. Each of the two subunits consists of three chains: Aα, Bβ and γ. The A and B fibrinopeptides are separated by action of thrombin.
2. The genes for three chains of fibrinogen are found in the chromosome 4 at q23–q32.
3. Fibrinogen is present in plasma and α-granules of platelet.
4. Its plasma concentration is \(2000-4000\ \mu\text{g/ml}\).
5. Its half-life in plasma is 3–5 days.
6. **Fibrinogen is converted to fibrin** by IIa (thrombin) and is stabilized by physical contact with XIIIa (activated fibrin-stabilizing factor).
7. Fibrin forms the *structural meshwork that transforms the loose platelet plug into a solid hemostatic plug*.
8. Fibrinogen is an **acute phase reactant** and is synthesized by liver.
9. Its concentration is greatly increased in **acute inflammations**.
10. IL-6 stimulates fibrinogen synthesis.

### Factor II

Factor II is **prothrombin**, a vitamin K-dependent coagulation protein primarily synthesized in liver.
1. It is a single chain zymogen with molecular weight 72,000 and plasma half-life of about 60 h.
2. Its plasma concentration is \(100–150\ \mu\text{g/ml}\).
3. The gene for human prothrombin is located on **chromosome 11** close to the centromere.
4. **Prothrombin is activated to thrombin** by Xa (activated Stuart-Prower factor).
   
   In clotting mechanism, **thrombin has many functions**, such as:
   1. It converts fibrinogen to fibrin monomers by removing fibrinopeptides A and B from fibrinogen. Fibrin monomers then form fibrin polymers (clot).
   2. It is a potent activator of platelets.
   3. It activates procarboxypeptidase B that inhibits plasmin-mediated fibrinolysis.
   4. It has also anticoagulation activity. It binds to cofactor thrombomodulin on endothelial cells that allows protein C to be activated.
   5. It has growth factor and cytokine like activities that play a role in inflammation, wound healing and atherosclerosis.

   **Inhibitors of thrombin**: The primary inhibitor of thrombin in plasma is **antithrombin III**. Heparin cofactor II also inhibits thrombin.

#### Factor III

Factor III is a tissue factor, known as **tissue thromboplastin** (TPL).
1. It is a membrane protein containing 263 amino acids.
2. The gene for factor III is located on **chromosome 1**.
3. Though TPL is not expressed normally in the cells in close contact with flowing blood, it is expressed in many extravascular tissues and in the adventitia of blood vessels.
4. It is an important physiological **initiator of extrinsic pathway for blood coagulation**.
5. When blood comes in contact with TPL following extravasation of blood from the injured vessel, circulating factor VII binds with TPL and gets rapidly converted to VIIa, an active protease that converts X to Xa. This initiates the process of coagulation.

#### Factor IV

Factor IV is **calcium**. Calcium acts as a cofactor in many steps of intrinsic and extrinsic pathways of blood coagulation, especially for **conversion of X to Xa** and **prothrombin to thrombin**.

#### Factor V

Factor V is **proaccelerin**.
1. This is a large glycoprotein with molecular weight 333,000 and plasma half-life of about 12h.
2. The gene for factor V is located in chromosome 1 at q21–q25.
3. The primary function of factor V is to **activate prothrombin to thrombin**, though it also participates in activation of Xa.
4. The acidic regions of factor V contain high aspartic and glutamic acid residues that are important in activating factor II. Sulfation of factor V potentiates its activity.

#### Table 21.1: Clotting factors.

| Factor I | Fibrinogen |
| Factor II | Prothrombin (α2-globulin) |
| Factor III | Tissue thromboplastin |
| Factor IV | Calcium ion |
| Factor V | Preaccelerin |
| Factor VI | Factor VI does not exist |
| Factor VII | Proconvertin |
| Factor VIII | Antihemophilic factor (antihemophilic globulin (AHG) or antihemophilic factor A) |
| Factor IX | Christmas factor (antihemophilic factor B) |
| Factor X | Stuart-Prower factor |
| Factor XI | Plasma thromboplastin antecedent (antihemophilic factor C) |
| Factor XII | Hageman factor, contact factor |
| Factor XIII | Fibrin stabilizing factor (Laki-Lorand factor) |
| HMW-K | High-molecular weight kininogen (Fitzgerald factor) |
| Pre-K | Prekallikrein (Fletcher factor) |
| Ka | Kallikrein |
| PL | Platelet phospholipid |

**Inhibitors**

| Protein C |
| Protein Z |
| Thrombomodulin |
| Antithrombin III |
| Tissue factor pathway inhibitor |
| Protein Z-dependent protease inhibitor |
**Factor VII**
Factor VII is also called proconvertin. It is among the vitamin-K-dependent clotting factors.
1. It consists of single chain polypeptide.
2. It has the half-life of about 3.5 h, which is shortest amongst procoagulant factors.
3. The gene for factor VII is located on chromosome 13.
4. It is activated by the tissue factor and inhibited by tissue factor pathway inhibitor (TFPI).
5. The primary function is to activate X to Xa. It also activates IX to IXa.

**Important Note**

Naming of Stuart-Prower Factor: Factor X deficiency was described in 1957 in a woman named Prower and a man Stuart, in whose blood the defects in blood clotting were observed. Later the clotting factor was identified and named after the patients.

**Factor VIII**
Factor VIII is antihemophilic factor.
1. The gene for factor VIII is located on the X chromosome at q28. It is synthesized in liver.
2. Its half-life is 8 to 12 h when it is associated with vWF. The half-life is reduced when concentration of vWF is reduced in plasma. Therefore, deficiency of vWF also reduces the level of VIII.
3. Factor VIII is activated by thrombin or Xa and the activation results in its release from vWF.
4. The main function of VIIIa is to activate X to Xa.

**Factor IX**
Factor IX is also called Christmas factor or anti-hemophilic factor B.
1. It is synthesized in liver dependent on vitamin K.
2. It has the half-life of 18–24 h.
3. The gene for factor IX is located on the tip of long arm of X chromosome. Therefore, hemophilia B is a sex-linked disorder.
4. Factor IX is activated by Xla or VIIa-TF complex.
5. Along with cofactor VIIIa, it activates factor X. This activity is physiologically expressed on the surface of platelets and evidences suggest that platelets have receptors for IXa.

**Factor X**
Factor X is known as Stuart-Prower factor.
1. It is a vitamin K-dependent polypeptide synthesized by liver.
2. It has molecular weight of 59,000 and plasma half-life of 34 to 40 hours.
3. The gene for factor X is located on chromosome 13 in close proximity to factor VII gene.
4. Activation of factor X is the target of both intrinsic and extrinsic pathways of coagulation.
5. It is activated by IXa of intrinsic pathway and VIIa of extrinsic pathway.
6. The primary function of factor Xa is the conversion of prothrombin to thrombin. It has also mitogenic activity for smooth muscle cells. It possesses receptor mediated proinflammatory activity.
7. Factor Xa is inhibited by antithrombin III (AT-III), which is accelerated by heparin. TFPI also inhibits Xa.

**Scientists contributed**

Oscar D Ratnoff and Joan E Colopy worked in the field of blood coagulation. In 1955, Ratnoff and Colopy identified a patient named John Hageman with a Factor XII deficiency that died from a thrombotic event and not a bleeding disorder. The factor was named as Hageman’s factor.

**Factor XI**
Factor XI is known as Hageman’s factor.
1. This is also called glass factor or contact factor.
2. The gene for factor XII was located on chromosome 5.
3. Factor XII is activated when it comes in contact with negatively charged surface. This is called contact activation. HMW kininogen and prekallikrein facilitate the process.
4. Xla promotes the conversion XI to Xla.

**Factor XII**
Factor XII is known as Hageman’s factor.
1. It is a glycoprotein consisting of A and B subunits.
2. It has molecular weight of 320,000 and half-life of about 10 days.
3. The B chain is not active enzymatically. The A chain (XIII-A) is a member of transglutaminase family, which contains 731 amino acids with molecular weight of 83,000.
4. In addition to its presence in plasma, it is also found in platelets, monocytes and macrophages.
5. The plasma XIII contains both A and B chains, and the cellular XIII contains only A chain.
6. The gene for A chain is located on chromosome 6 and the gene for B chain is located on chromosome 1.
7. Thrombin causes cleavage of A and B subunits of XIII that causes exposure of active site on A chain. This activates XIII to XIIIa. The XIIIa cross-links α and β chains of fibrin to stabilize the fibrin plug. In XIIIa deficiency, though clot formation occurs, hemostasis becomes inadequate.
8. It also promotes wound healing and tissue repair. It helps in maintenance of pregnancy.

**HMW Kininogen**

High molecular weight kininogen is also called *Fitzgerald factor*.
1. It is a nonenzymatic cofactor that circulates in complex with factor XI and prekallikrein. It is a contact factor for coagulation.
2. The gene for HMW kininogen is located on chromosome 3.
3. Its plasma half-life is 150 h.
4. It is synthesized by liver.
5. In addition to its nonenzymatic function in contact activation, it acts as a thiol protease inhibitor.
6. It is cleaved by *prekallikrein to bradykinin*, a potent vasodilator.

**Prekallikrein**

Prekallikrein is also called *Fletcher factor*. It is a contact factor for coagulation.
1. The gene for prekallikrein is located on chromosome 4.
2. It has half-life of 35 h in plasma. It is synthesized by liver.
3. It circulates as a complex with factor XI and HMW kininogen.
4. It causes contact activation of blood coagulation.
5. Along with HMW kininogen and factor XII, it participates in inflammatory response.

**Protein C**

Protein C is a vitamin K-dependent protein. However, unlike other vitamin K-dependent proteins (factors II, VII, IX and X), it is *not a procoagulant*.
1. It regulates clotting by inactivating Va and VIIIa.
2. The gene for protein C is located on chromosome 2.
3. It has molecular weight of 59,000 and half-life of about 6 h.
4. It is activated by thrombomodulin.

**Protein S**

Protein S is a single-chain glycoprotein cofactor synthesized primarily in liver. It is also synthesized by endothelial cells, megakaryocytes, Leydig cells and osteoblasts.
1. It has molecular weight of 75,000 and half-life of about 42 hours.
2. The gene for protein S is located on chromosome 3.
3. Protein S acts as a cofactor for protein C. It forms a complex with protein C that inactivates Va and VIIIa. Thus, it is an important component of anticoagulation mechanisms. However, it does not require proteolytic activation for its activity.
4. It has also its independent anticoagulant activity by virtue of its ability to compete with factor Xa for binding with factor Va.

**Protein Z**

Protein Z is synthesized in liver. It has half-life of about 60 hours. The gene for protein Z is located on chromosome 3. Function of protein Z is similar to that of protein S.

**Tissue Factor Pathway Inhibitor (TFPI)**

TFPI is a single chain polypeptide with molecular weight of about 35,000.
1. It is mainly synthesized by endothelial cells of blood vessels.
2. The gene for TFPI is located on chromosome 2.
3. It has three protease inhibitor domains. It inhibits factors Xa and VIIa.
Antithrombin III (AT-III)

AT-III is member of a large family of serine protease inhibitors, known as serpins.
1. The gene for AT-III is located on chromosome 1.
2. It inhibits thrombin, Xa and IXa, which is facilitated by heparin.
3. Factor VIIa is normally resistant to the action of AT-III. However, VIIa complexed with tissue factor is inhibited by AT-III in the presence of heparin.

MECHANISMS OF BLOOD COAGULATION

Blood coagulation occurs in three major stages (Fig. 21.1):

**Stage 1:** Activation of Stuart-Prower factor (formation of prothrombin activator)

**Stage 2:** Formation of thrombin from prothrombin

**Stage 3:** Formation of fibrin from fibrinogen

**Activation of Stuart-Prower Factor (Factor X)**

Activation of Stuart-Prower factor or factor X is the key to blood coagulation. Factor Xa is called prothrombin activator as it activates prothrombin to form thrombin. Therefore, this process is also called prothrombin activation.

This is achieved by two pathways: the intrinsic pathway and the extrinsic pathway (Fig. 21.1).

**Intrinsic Pathway**

Intrinsic mechanism of prothrombin activation occurs in four steps:

**Step 1 (Activation of XII)**

Activation of intrinsic pathway starts with contact of Hageman factor with a negatively charged surface or exposed collagen of the injured vessel wall.
1. High molecular weight (HMW) kininogen and kallikrein act as cofactors to facilitate the activation of factor XII.
2. Exposed collagen stimulates platelet adhesion and aggregation before initiating blood coagulation.

**Step 2 (Activation of XI)**

Activated XII (XIIa) converts XI to its active form (XIIa). This step is accelerated in the presence of HMW kininogen.

**Step 3 (Activation of IX)**

XIIa then converts IX to IXa, which is accentuated by VIIa. Calcium accelerates this process.
Step 4 (Activation of X)

Final step in activation of prothrombin activator is activation of X. IXa causes activation of X to Xa, the activated Stuart-Prower factor. The membrane phospholipid, calcium and activated factor VIII act as cofactors for the activation of Stuart-Prower factor.

Formation of VIIIa is crucial in Stage 1

Formation of VIIIa is the key to the process of activation of X. Factor VIII circulates as a complex with vWF.
1. Separation of VIII from vWF activates VIII.
2. Activation of VIII is facilitated by Xa and thrombin, the factors that are the consequences of formation of VIIIa.
3. Thus, activation of factor VIII and further activation of clotting mechanism become a vicious cycle.

Enzyme Cascade Hypothesis

In the intrinsic system of blood coagulation, activation of one clotting factor acts as an enzyme for the activation of next factor that leads to sequential activation of subsequent factors in a series of steps. Therefore, the intrinsic process of blood coagulation is called enzyme cascade hypothesis.

Extrinsic Pathway

Extrinsic pathway of blood coagulation occurs in three steps.

Step 1 (Release of TPL)

Key to the clotting mechanism is the release of tissue thromboplastin (TPL) from the injured tissue. As TPL is the tissue factor which is viewed as extrinsic to circulating blood, this system of blood coagulation is called extrinsic system of clotting.

Step 2 (Activation of VII)

TPL converts factor VII to its active form (VIIa). This is the key step in extrinsic mechanism. VIIa directly activates not only X (Stuart-Prower factor), but also IX (Christmas factor). Thus, it also influences intrinsic mechanism of activation of factor X.

Step 3 (Activation of X)

VIIa converts X to Xa. This process is accelerated in the presence of calcium, platelet phospholipid and TPL.

Note: Though there are intrinsic and extrinsic systems of blood coagulation, recently it is believed that these two systems do not operate independently, and all the clotting factors are interrelated for homeostasis.

Formation of Thrombin from Prothrombin

This is the second stage of blood coagulation in which activated Stuart-Prower factor (Xa) converts prothrombin to thrombin, in the presence of platelet phospholipid, calcium and activated factor V (Va). Factor Va acts as cofactor for acceleration of this process. Therefore, it is also called proaccelerin or accelerator globulin.

Important Note

Thrombin formation occurs rapidly: Factor II is prothrombin, a vitamin K-dependent protein formed in liver. Prothrombin forms thrombin, which is basically a proteolytic enzyme having molecular weight of 34,000 dalton. It is formed rapidly and in large amount as both intrinsic and extrinsic mechanisms stimulate its formation.

Functions of Thrombin in Blood Coagulation

1. It converts fibrinogen to fibrin monomers by removing fibrinopeptides A and B from fibrinogen. Fibrin monomers then form fibrin polymers (clot).
2. It activates formation of prothrombin activator by stimulating the activation of VIII, V, and XIII. Thus, it provides positive feedback to the coagulation process.
3. It is a potent activator of platelets.
4. It activates procarboxypeptidase B that inhibits plasmin-mediated fibrinolysis.
5. It has also an anticlotting activity. It binds to cofactor thrombomodulin on endothelial cells that allows thrombin to activate protein C to be activated. Thus, thrombin balances the coagulation and anticoagulation processes in the body.
6. It helps in repair of vessel wall. It has growth factor and cytokine-like activities that play role in inflammation, wound healing and atherosclerosis.

Inhibitors of thrombin: The primary inhibitor of thrombin in plasma is antithrombin III. Heparin cofactor II also inhibits thrombin.

Formation of Fibrin from Fibrinogen

This is the final stage of blood coagulation in which thrombin acts as an enzyme to convert fibrinogen to fibrin. In this process, first, the fibrin monomers are formed and afterward, they are polymerized to fibrin thread (blood clot). This occurs in three steps:
1. Proteolysis of soluble fibrinogen
2. Polymerization of fibrin monomers
3. Stabilization of fibrin polymer

Proteolysis of Soluble Fibrinogen

Fibrinogen has three domains: two peripheral (D) domains and one central (E) domain.
1. Thrombin binds with central domain and proteolytically releases two fibrinopeptides A and B from aminoterminals of Aα and Bβ chains of each fibrinogen molecules.
2. Release of fibrinopeptides leads to the formation of fibrin monomer (Flowchart 21.1).
Polymerization of Fibrin Monomers

Fibrin monomers join to form **protofibrils**.
1. About 15 to 20 protofibrils aggregate to form **thick fibers of fibrin**.
2. Protofibrils also branch out to form a meshwork of interconnected thick fibrin fibers. This is called **polymerization of fibrin monomers**.
3. Thrombin initiates the process of polymerization and simultaneously activates XIII.
4. XIIIa completes the process of polymerization.

Stabilization of Fibrin Polymer

Fibrin stabilizing factor (XIIIa) stabilizes the fibrin polymers by cross-linking them.
1. XIII is converted to XIIIa by thrombin.
2. **Calcium acts as a cofactor** for this conversion.
3. **Covalent cross-linking** of fibrin polymers provides adequate strength to the fibrin thread and to the fibrin meshwork.
4. The stabilized fibrin meshwork is the blood clot.
5. Red cells and platelets are trapped inside the fibrin meshwork to give the volume to the clot.

Clot Retraction

The clotted blood consists of fibrin meshwork containing red cells and platelets trapped within the clot. **Fibrin threads spread in all directions** and adhere to the endothelial wall. When blood is allowed to clot in a test tube, the **fibrin mesh spreads all around** trapping all the serum within it. However, within minutes to hours, clot shrinks expressing serum out of it. This phenomenon is called **clot retraction**.
1. The process of clot retraction is believed to occur in vivo that causes **consolidation of thrombus** (intravascular clot).
2. Clot retraction is the **function of platelets**.
3. For effective clot retraction to occur, normally functioning **platelets must be present in adequate number**.
4. Retracted clot decreases the efficiency of thrombolysis (fibrinolysis). Therefore, a **thrombus rich in platelets is resistant to fibrinolytic agents**.

**Mechanism of Clot Retraction**

The platelets form spicules (filopodia) that extend along the fibrin threads.
1. Fibrin strands tug with the filopodia. Also, protofibrils of thick fibrin strand get embedded within the filopodia by the action of membrane cytoskeleton.
2. Later, platelets shrink with contraction of their filopodia. This causes **internalization of fibrin within the contracted platelets**. Thus, retraction of clot occurs.
3. **Thrombin and calcium** accelerate clot retraction.
4. **Glycoprotein IIb/IIIa** receptors on platelets facilitate clot retraction.

**Functions of Clot Retraction**

A retracted clot is a **consolidated and stable thrombus**, which not only firmly seals the opening in the injured vessel, but also has other functions. The functions of retracted clot are as follows:
1. Retracted clot (thrombus) strongly seals injured vessel.
2. It facilitates wound healing.
3. It prevents thrombolysis.

**Prolongation of Clot Retraction Time**

Normally, clot retraction begins within thirty seconds after clot formation. However, the process of retraction is very slow. About 50% retraction occurs at the end of one hour and completes in 18 to 24 hours.
1. Clot retraction time is said to be prolonged when retraction is less than 50% at the end of one hour.
2. In **Glanzmann thrombasthenia**, deficiency of IIb/IIIa receptors results in inhibition of clot retraction that causes prolongation of clot retraction time.
3. **Platelet deficiency** also prolongs the clot retraction time.

**ANTICLOTTING MECHANISM (Fibrinolysis)**

Tendency of blood to clot in vivo is prevented by naturally occurring anticlotting mechanisms. Thus, there is a balance between clotting and anticlotting mechanisms.
1. In our body, normally, there is a low level of activation of coagulation factors. This results in a **basal coagulation** of blood. The basal coagulation may be due to minor injuries to blood vessels that occur during normal daily activities (**normal vascular stress**). However, coagulation process proceeds only when enough thrombin is generated in response to a significant vascular injury.
2. Moreover, the basal coagulation is balanced by the activity of basal anticoagulation, which is evidenced by the presence of low levels of protein C and tissue plasminogen activator activity in normal individuals. Anticlotting mechanisms include three naturally occurring systems:

1. Presence of naturally occurring anticoagulants in the blood
2. Interaction between thromboxane $A_2$ and prostacyclin
3. An important role played by vascular endothelium.

**Mechanism of Fibrinolysis**

The process of blood coagulation automatically initiates the anticlotting mechanisms so that intravascular clot does not spread beyond the site of injury. Fibrinolysis occurs in three steps:

1. Activation of protein C
2. Activation of plasmin
3. Fibrinolysis

**Activation of Protein C**

Thrombin which is produced by clotting mechanism acts as an enzyme to activate protein C to its active form. The anticlotting mechanism activated by thrombin can also be initiated by thrombomodulin, a hormone secreted from endothelial cells of blood vessel. Thrombomodulin activates protein C (Fig. 21.2).

**Activation of Plasmin**

Activated protein C inactivates the inhibitors of plasmin activator. This, in turn, activates plasminogen activator, which promotes formation of plasmin from plasminogen. Activated protein C along with its cofactor protein S also inactivates Va and Villa into their respective inactive forms. This aids in prevention of coagulation.

**Fibrinolysis**

Plasmin acts as an enzyme to cause fibrinolysis (lysis of clot).

1. This process is facilitated by cofactors thrombin, tissue-type plasminogen activator and urokinase-type plasminogen activator.
2. Fibrin is degraded by plasmin to fibrin degradation products (FDP) (Clinical Box 21.1). The details of fibrinolysis by plasmin are given below.

**Clinical Box 21.1**

FDP level indicates the rate of fibrinolysis: Activation of clotting process as occurs in DIC activates the anticlotting mechanism (fibrinolysis). Fibrinolysis causes accumulation of FDP in plasma, which is subsequently excreted in urine. Hence, measurement of FDP in urine is an index of rate of fibrinolysis as well as intravascular coagulation.

**Functions of Plasmin**

Functions of plasmin can be broadly divided into two categories: Fibrinolytic actions and nonfibrinolytic actions.

**Fibrinolytic Actions**

Plasmin cleaves both fibrinogen and fibrin.

1. Plasmin initially cleaves $\alpha$ and $\beta$ chains within the D domain of fibrinogen that releases $A\alpha$ and $B\beta$ fragments.
2. Subsequently, plasmin cleaves polypeptide chains connecting D and E domains that forms, D, E and Y fragments.
3. Degradation of fibrin by plasmin results in production of fibrin degradation products (FDP), such as D-dimers.

**Nonfibrinolytic Actions**

Plasmin has many functions other than fibrinolysis:
1. Plasmin is involved in tissue remodeling.
2. Plays a role in inflammation and tumor cell invasion.
3. Controls ovulation and embryogenesis.
4. Regulates development of neurons.
5. Plasmin plays a role in activation of growth factors.

**Plasminogen**

Plasminogen is a polypeptide consisting of 791 amino acids. Its molecular weight is 92,000 and plasma half-life is approximately two days. It has two chains: a heavy chain containing 560 amino acids and a light chain of 231 amino acids. Plasminogen is synthesized mainly in liver.
1. The gene for plasminogen formation is located on chromosome 6.
2. Activation of plasminogen occurs from cleavage by plasminogen activators of the bond between arginine and valine at 560 and 561 positions respectively.
3. Thus, plasminogen is converted into plasmin, an active protease.

**Plasminogen Activators**

There are two major endogenous plasminogen activators: the tissue plasminogen activator and urokinase.

**Tissue Plasminogen Activator (t-PA)**

t-PA is a polypeptide having 527 amino acids and molecular weight 72,000. The gene for t-PA is located on chromosome 8. It is synthesized primarily by endothelial cells. The half-life of t-PA is very short, about 5 minutes.
1. Thrombin, histamine, bradykinin, epinephrine, ADH, acetylcholine and gonadotropins control the secretion of t-PA.
2. Though, normally t-PA is a poor plasminogen activator by itself, in the presence of fibrin, its activity increases enormously.
3. Fibrin facilitates t-PA activity by increasing affinity of t-PA for plasminogen (Clinical Box 21.2).

**Urokinase and Streptokinase**

Urokinase plasminogen activator (u-PA) is a glycoprotein consisting of 411 amino acids. The gene for u-PA is located on chromosome 10. It is formed by endothelial cells, macrophages and renal epithelial cells.
1. It exists in **two forms**: high molecular weight u-PA (molecular weight of 54,000) and low molecular weight u-PA (molecular weight of 33,000).
2. Though both the forms have ability to activate plasminogen, only high molecular weight u-PA binds to u-PA receptor.
3. Physiologically, **u-PA is a more effective activator of plasminogen** than t-PA even in the presence of fibrin. u-PA has lower affinity for fibrin than t-PA.
4. **Streptokinase** is a variant of urokinase.

**Clinical Box 21.2**

| t-PA and urokinase are used in treatment of AMI: | t-PA and urokinase for their fibrinolytic activity are used for lysis of intracoronary clot in acute myocardial infarction (AMI). t-PA is very effective for this purpose as it causes lysis of clot at the site of thrombosis. |

**Inhibitors of Fibrinolysis**

Inhibitors of fibrinolysis can be divided into two categories: plasmin inhibitors and plasminogen-activator inhibitor.

**Plasmin Inhibitors**

Plasmin is inhibited by serpins, a family of serine protease inhibitors. They form an irreversible complex with the active site serine of the target protease.
1. α₂-antiplasmin is a serpin peptide containing 452 amino acids. Though it is synthesized by liver and kidney, it is a constituent of α₂-granules of platelet.
2. α₂-macroglobulin is a nonserpin plasmin inhibitor, formed by endothelial cells and macrophages.

**Plasminogen-Activator Inhibitors (PAI)**

There are two PAIs: PAI-1 and PAI-2.
1. **PAI-1** is single chain polypeptide containing 402 amino acids, secreted by liver, monocytes, endothelial cells and adipocytes. This is the most important and rapidly acting physiologic inhibitors of t-PA and u-PA.
2. **PAI-2** is secreted by placenta, monocytes and tumor cells. It is less effective than PAI-1 in inhibiting plasminogen activators.

**Plasmin Generation Defects**

**Fibrinolytic Deficiency**

Fibrinolytic deficiency is usually due to plasminogen deficiency. There are **two types** of congenital plasminogen deficiencies: **type 1** and **type 2**.

- **In type 1 plasminogen deficiency**, both concentration and function of plasminogen are reduced.
- **In type 2 plasminogen deficiency**, though the concentration of plasminogen is normal its function is reduced.

The patient with plasminogen deficiency exhibits repeated episodes of thrombophlebitis, intracranial and mesenteric venous thrombosis, and pulmonary embolism (Application Box 17.1). Mutation in plasminogen activators also results in decreased fibrinolysis.

**Enhanced Fibrinolysis**

This usually occurs due to congenital or acquired loss of fibrinolytic inhibitor activity.
1. **Deficiency of \( \alpha_2 \)-antiplasmin** is a common cause. The patient presents with bleeding diathesis. In promyelocytic leukemia, bleeding occurs due to high level of plasmin generation and deficiency of \( \alpha_2 \)-antiplasmin.

2. **Acquired \( \alpha_2 \)-antiplasmin deficiency** may be seen in liver disease, DIC, nephritic syndrome and thrombotic therapy.

### Application Box 17.1

**Pregnancy is a hypofibrinolytic state:** In pregnancy, overall fibrinolytic activity is reduced. This leads to increased fibrin deposition, as suggested by increased D-dimer levels. The PAI levels also increase in pregnancy. The hemostatic and fibrinolytic imbalance is increased in preeclampsia. This predisposes to intravascular thrombosis.

### Regulation of Blood Coagulation

Blood coagulation at the site of injury is a life saving process as it prevents loss of blood volume. However, once the clot (fibrin-platelet plug) is formed, the process of clotting must be terminated to avoid thrombotic occlusion in the adjacent normal areas of blood vessel. If clotting remains unchecked, coagulation of blood can spread to the entire vascular tree with modest procoagulant stimulus.

Coagulation in a normal blood vessel or circulation is highly dangerous. Fluidity of blood and absence of thrombosis (intravascular clot) are important physiological states that are essential for normal circulation and blood supply to tissues of the body.

The balance between coagulation and anticoagulation is due to play of various regulatory mechanisms, as listed below:

1. **Dynamism of blood flow:** Flow of blood is a dynamic process. When the rate of blood flow decreases, as occurs in vascular stasis, intravascular coagulation is facilitated. Thus, continuous and dynamic flow of blood should be maintained to prevent intravascular coagulation.

2. **Role of vascular endothelium:** Vascular endothelium plays an important role in restricting coagulation process to the site of injury.
   - Damage to vascular endothelium initiates the clotting mechanism by exposing its collagen and negatively charged particles.
   - Once adequate hemostasis is achieved, thrombomodulin, a hormone secreted by endothelial cells of blood vessel prevents further blood coagulation by activating protein-C-protein S complex.
   - Also, protease inhibitors AT-III and tissue factor pathway inhibitor are expressed on the surface of the endothelial cells.
   - Endothelial cells also inhibit platelet activation by releasing prostacyclin and EDRF that inhibit platelets (Refer to Fig. 20.11, Chapter 20).

3. **Heparin-antithrombin-III system:** Heparin is a naturally occurring anti-coagulant, secreted from mast cells and basophils. Heparin acts by activating the antithrombin III activity. Heparin-antithrombin III complex prevents activation of clotting factor IX, X, XI and XII.

4. **Negative feedback by thrombin:** Thrombin, which is a major mediator of blood coagulation, initiates the process of anticlotting mechanism (fibrinolysis). Thus, coagulation is an autoregulatory process.

5. **Role of liver:** Many coagulation factors are plasma proteins, formed mainly in the liver. Therefore, in liver diseases, clotting time is prolonged. Also, liver plays an important role in preventing intravascular coagulation by removing activated clotting factors from blood. This hepatic clearance of activated clotting factors is accelerated when clotting is spontaneously activated.

6. **Role of platelets:** In addition to its role in primary hemostasis, platelets contribute to coagulation in various ways.
   - Following platelet activation, platelet phospholipids (platelet factor 3 and 4) released to their surface act as cofactors to accelerate the formation of Va, VIIia and Xla. Cofactors Va and VIIia are rapidly localized to the membrane of activated platelet.
   - Also, factor IXa formed by VIIia-tissue factor complex binds to the platelet surface. This leads to the formation of IXa-VIIia complex on the platelet surface, following which factor X is recruited from the plasma to the platelets and is activated to Xa on platelet membrane. Thus, **platelet plays an important role in activation of factor X**, which is a crucial step in blood coagulation. Thus, major clotting reactions occur in close interaction with platelets (Refer to Fig. 20.8, Chapter 20).
   - As platelets adhesion and aggregation are localized at the injured vessel wall, platelets help in restricting clotting reactions to the site of injury.

### ANTICOAGULANTS

Anticoagulants prevent blood from clotting. They are mainly used:

1. For collection of blood sample for laboratory investigations
2. For preserving blood for transfusion
3. For anticoagulation therapy

#### Anticoagulants for Blood Collection

Anticoagulants are added to the blood sample especially during collection of blood by venipuncture, when whole anticoagulated blood is required for laboratory investigations. Though several anticoagulants are available for the purpose, commonly used are EDTA, trisodium citrate, double oxalate, sodium fluoride, and heparin.

1. While EDTA is used frequently for hematologic tests, citrated blood is used for coagulation studies and for preserving blood in the blood bank.
2. Use of heparin and fluoride (oxalated) is limited for the determination of blood gases and pH, and plasma glucose respectively.

**EDTA (Ethylene-diamine Tetra-acetic Acid)**
The sodium and potassium salts of EDTA are the commonly used and most powerful anticoagulants.
1. It acts by its **chelating effect on the blood calcium**. It inactivates calcium by forming insoluble complex with it. As calcium is an important cofactor for blood coagulation, chelation of calcium prevents blood to clot.
2. The chelating effect of EDTA is achieved at a concentration of 1.2 mg of the anhydrous salt per ml of blood.
3. Excess EDTA irrespective of its salts, affects both red cell and leucocyte morphology by causing shrinkage and degenerative changes. Therefore, EDTA in excess of 2 mg/ml of blood results in **decrease in PCV and increase in MCHC**. Platelets also swell and disintegrate causing an **artificially high platelet count**, as the platelet fragments are large enough to be counted as normal platelets.

**Sodium Citrate**
Trisodium citrate is the commonly used anticoagulant in coagulation studies. It is prepared as 0.106 M solution of trisodium citrate in distilled water and then sterilized.
1. It **prevents coagulation by inactivating calcium ions**.
2. For coagulation studies like determination of prothrombin time or partial thromboplastin time, 9 volumes of blood are added to 1 volume of sodium citrate solution (9 : 1).
3. It is also used in **collection of blood for estimation of ESR by Westergren method**, where 4 volumes of venous blood are added to 1 volume of the sodium citrate solution (4 : 1).

**Double Oxalate**
As this anticoagulant contains ammonium and potassium oxalates, it is called **double oxalate**. Potassium oxalate alone causes shrinkage of red cells whereas ammonium oxalate increases their volume. Hence, double oxalate is also called **balanced oxalate**.
1. It is prepared as the solution containing 1.2% ammonium oxalate and 0.8% potassium oxalate. Usually, 0.25 or 0.5 ml of the double oxalate solution is taken in a penicillin bottle and evaporated in an oven or in an incubator and then kept for collecting blood.
2. The oxalates form an **insoluble complex with the calcium** in the blood, and thereby prevent coagulation.

**Sodium Fluoride**
Sodium fluoride is used mainly for collecting blood specimen for **plasma glucose estimation**. Fluoride is an **inhibitor of glycolytic enzymes** and thus prevents loss of glucose. However, as fluoride is not a strong anticoagulant, it is mixed with the oxalate.

**Oxalates**
Oxalates of sodium, potassium, ammonium or lithium act as anticoagulant. They form **insoluble complexes with calcium**.

**Heparin**
Heparin is a natural constituent of blood. Sodium, lithium, potassium and ammonium salts of heparin are commercially available.
1. It prevents coagulation for approximately 24 hours by neutralizing thrombin. It **facilitates action of antithrombin III**. Thus, it **prevents formation of fibrin from fibrinogen**.
2. Usually, it is used at a concentration of 10–20 IU per ml of blood.
3. It is commonly used for osmotic fragility test, blood gas determination and pH assays.
4. It is also commonly used in anticoagulation therapy and in preventing blood coagulation during animal experiments.

**Anticoagulants for Treatment (Anticoagulation Therapy)**
Anticoagulants are used for **treatment or prevention of thrombosis** (intravascular clots). They are usually required for:
1. Management of thrombotic diseases like venous thromboembolism
2. Placement of mechanical heart valves as heart valve prosthesis is associated with risk of thromboembolism
3. Prevention of thromboembolism in chronic nonrheumatic atrial fibrillation
4. Prophylaxis after attacks of cerebral ischemia
5. Management of ischemic heart disease
6. Peripheral vascular diseases
7. Placement of central venous catheters.

**Oral Anticoagulants**
Routinely used oral anticoagulants are vitamin K antagonists, glycosaminoglycans, inhibitors of factor Xa and inhibitors of thrombin.

**Vitamin K Antagonists**
The commonly used vitamin K antagonist is warfarin. This is a coumarin derivative.
1. Warfarin is an acronym for WARF, i.e. Wisconsin Alumni Research Foundation that first synthesized it in 1942 (Coumarin of WARF, named as warfarin).
2. The four vitamin K-dependent coagulation factors are II, VII, IX and X. They undergo post-translational \( \gamma \)-carboxylation of approximately 10 glutamic acid residues in the N-terminal Gla-domain (the domain where \( \gamma \)-carboxylation of clotting proteins takes place is called the Gla-domain).

3. The \( \gamma \)-carboxylation of these cofactors is necessary to enable them to bind calcium and to localize enzymatic processes to a phospholipid surface like membrane of activated platelet.

4. When \( \gamma \)-carboxylation is reduced by 1 to 6 glutamic acid residues, coagulation activity of factors II, VII, IX and X is impaired significantly.

**Mechanism of action of warfarin**: Warfarin inhibits \( \gamma \)-carboxylation of about 3 to 10 glutamic acid residues, especially of factor II (prothrombin). Warfarin achieves this by inhibiting the reductase enzymes that cause formation of vitamin KH\(_2\) (Fig. 21.3).

- Vitamin KH\(_2\) is required for \( \gamma \)-carboxylation of vitamin K-dependent coagulation factors.
- During the process of \( \gamma \)-carboxylation, vitamin KH\(_2\) is converted to vitamin K-epoxide by vitamin K epoxide reductase, vitamin K-epoxide is converted back to vitamin KH\(_2\) by vitamin K reductase.
- Both these enzymes are inhibited by coumarin derivatives such as warfarin.

**Protein C and protein S** (the inhibitors of blood coagulation) also undergo \( \gamma \)-carboxylation and vitamin K antagonists prevent their activity by inhibiting the process.

*Dicoumarol* is another commonly used vitamin K antagonist.

**Glycosaminoglycans**

Oral heparin sulfate and iduronyl-glycosaminoglycan are used as anticoagulants.

**Inhibitors of Factor Xa**

Formation of Xa is the key step in blood coagulation. Therefore, selective inhibitor of Xa is a potent antithrombotic agent without affecting bleeding time as demonstrated in animal models. However, its use in human is under trial.

**Inhibitors of Thrombin**

Many low-molecular weight selective inhibitors of thrombin have been recently identified and are under clinical trials.

**Intravenous or Subcutaneous Anticoagulants**

Most commonly used intravenous anticoagulants are heparin and hirudin.

**Heparin**

Heparin is a glycosaminoglycan consisting of chains of alternating residues of D-glucosamine and iduronic acid. Due to its variation in chain lengths, heparin is available as LMW-heparin and HMW-heparin, molecular weight ranging between 5,000 to 30,000. Its anticoagulant activity is due to its facilitation of the effects of antithrombin III (AT-III).

1. The pentasaccharide component of heparin has high affinity binding to AT-III.
2. AT-III inactivates thrombin, Xa and IXa. However, heparin inhibition of thrombin is different from inhibition of Xa and IXa.

**HMW heparin**: HMW heparin molecules inhibit thrombin by forming a ternary complex in which it binds with both thrombin and AT-III, and facilitates the thrombin inhibition by AT-III. But for inhibition of Xa, AT-III/heparin complex does not require heparin to bind directly to factor Xa or IXa in a ternary complex.

**LMW heparin**: LMW heparin molecules are unable to bind thrombin and AT-III simultaneously. Therefore, they can not augment the inhibition of thrombin by AT-III. However, they retain the ability to inhibit factor Xa and IXa. LMW heparin is as effective as unfractionated heparin for the treatment of venous thromboembolism or acute coronary syndrome. It is given subcutaneously and is cost-effective in comparison to IV heparin.

**Hirudin**

Hirudin is a polypeptide containing 65 amino acids. It is produced by the salivary glands of *Hirudo medicinalis*, a medicinal leech.

1. It is a naturally occurring most specific inhibitor of thrombin.
2. It is also produced by recombinant DNA technology. It directly inactivates thrombin by binding to the active site and main fibrinopeptide binding region of thrombin.
3. It has been tried in the treatment of acute coronary syndrome, patients undergoing coronary angioplasty and deep vein thrombosis.
4. It is mainly used as anticoagulant in patients who develop heparin-induced thrombocytopenia.
Laboratory investigations of bleeding disorders are carried out for patients who have a history of spontaneous bleeding or excessive bleeding after injury or surgery. Bleeding disorders are primarily due to the defects in formation of either in temporary hemostatic plug or in definitive hemostatic plug. Therefore, initial investigations aim at differentiating these two primary defects. If it is a coagulation disorder, tests are performed to detect the deficiency of clotting factor that has caused the disease and also to assess whether the defect is in intrinsic or extrinsic system.

Assessment of Defects in Temporary Hemostatic Plug

1. Bleeding time
2. Capillary fragility test
3. Platelet aggregation test
4. Platelet adhesiveness test

Bleeding Time (BT)
The normal BT by Duke method is 1 to 5 minutes and by Ivy method is 5 to 11 minutes. BT assesses platelet number and functions.

Capillary Fragility Test
This test measures the ability of the capillaries to withstand increased stress. Petechiae appear in the fore arm of the subject when the blood pressure cuff in the arm is inflated to a maximum pressure of 100 mm Hg for about 5 minutes.
1. Normally, zero to 10 petechiae appears.
2. More than 10 petechiae indicate capillary weakness, thrombocytopenia or both.

Platelet Aggregation Test
An aggregating agent is added to a suspension of platelets in plasma and the response is measured turbidometrically as a change in the transmission of light by the instruments called aggregometers. Measurement of platelet aggregation is an essential part of the investigation of any patient with suspected platelet dysfunction in a modern laboratory.

Platelet Adhesiveness Test
This test measures the ability of platelets to adhere to glass surface. When anticoagulated blood is passed through a plastic tube containing glass beads at a constant rate, some platelets will adhere to the glass beads.
1. The percentage difference of the platelet count done prior to and after passage through the glass bead column is calculated.
2. The normal range is 75 % to 95 % of platelet retention.
3. The platelet adhesiveness test is nonspecific. It is abnormal in several platelet functional disorders.

Assessment of Defects in Definitive Hemostatic Plug

1. Clotting time
2. Prothrombin time
3. Prothrombin consumption test
4. Partial thromboplastin time
5. Activated partial thromboplastin time
6. Thrombin time
7. Plasma recalcification time
8. Clot retraction time

Clotting Time (CT)
Determination of CT is routinely performed before any surgical procedure. It is usually performed by two methods: capillary tube method, and Lee-White (venipuncture) method.
1. The capillary method is used routinely in clinical laboratories. The normal range of CT by capillary glass tube method ranges from 2 to 8 minutes. CT is prolonged in diseases in which there is deficiency of clotting factors.
2. If the CT is prolonged more than 10 minutes, the patient should be subjected to more detailed investigations for the identification of the missing coagulation factors.
3. The normal range of CT by Lee-White method ranges from 5 to 12 minutes.

Prothrombin Consumption Test
This test is performed to determine the quantity of prothrombin remaining in the serum after clot is formed. Normally, prothrombin is used if it is converted to thrombin. Increased serum prothrombin results from a quantitative or qualitative platelet deficiency.

Prothrombin Time (PT)
PT detects the integrity of stage 2 clotting process. In this, preparation of rabbit brain emulsion (which contains tissue thromboplastin) is added to plasma in the presence of calcium. This, in the presence of factor VII, triggers stage 2 of the coagulation mechanism, and the clotting time is recorded after the addition of calcified thromboplastin to the plasma.
1. Normal PT is 12 to 16 seconds. Prolonged PT suggests the possibility of deficiency of factor II, V, VII, and X.
2. In stage 2, prothrombin is converted to thrombin which triggers the transformation of fibrinogen to fibrin. Thus, abnormal prothrombin time suggests defect in stage 2.
Chapter 21: Blood Coagulation

Partial Thromboplastin Time (PTT)
PTT detects the integrity of stage 1 clotting process. The platelet substitute in the form of partial thromboplastin is prepared from rabbit brain as chloroform extract. The extract is mixed with test plasma containing excess of calcium, which leads to clot formation.
1. Normal PTT is 60 to 80 seconds. PTT is prolonged when there is a deficiency of one or more clotting factors XII, XI, IX, VIII, X, V, II, and I.
2. Abnormal PTT indicates stage 1 defect and missing of one or more of these intrinsic factors.

Activated Partial Thromboplastin Time (APTT)
APTT is a more reliable test than PTT in evaluating the coagulation disorders. Its use in conjunction with PT provides a simple method for differentiating between stage 1 intrinsic defects and deficiency of other factors. The platelet substitute, in the form of partial thromboplastin, is prepared from rabbit brain. This is incubated with a contacting agent (kaolin) to provide optimal activation of the intrinsic coagulation factors. The clotting time is determined after the addition of an excess of calcium.
1. Normal APTT is 35 to 40 seconds.
2. APTT is prolonged in deficiencies of factor XII, XI, X, IX, and VIII.
3. APTT is mainly estimated in hemophilias that involve deficiencies of factor VIII, IX or XI.

Thrombin Time (TT)
TT assesses the integrity of stage 3 of blood coagulation. Thrombin (commercially available) is added to the plasma along with calcium and clotting time is determined.
1. Normal value of TT is 15 to 20 seconds.
2. Thrombin time detects the effectiveness of the final stage of coagulation in which fibrinogen is converted to fibrin.
3. A prolonged TT is considered to be due to either a decrease in fibrinogen concentration or the presence of dysfunctional fibrinogen.

Plasma Recalcification Time (PRT)
PRT assesses efficiency of intrinsic system of coagulation. When excess of calcium is added to the citrated plasma, clotting occurs. As platelet factor 3 acts as a cofactor for coagulation, clotting occurs in less time in platelet rich plasma than in platelet poor plasma.
1. Normal value of PRT of platelet rich plasma is 100 to 150 seconds and of platelet poor plasma is 135 to 240 seconds.
2. PRT is a screening test to detect the deficiencies of the factors of the intrinsic pathway, especially XII, XI, IX, VIII, X, V, and II (all coagulation factors except VII and XIII).

Clot Retraction Time
It assesses the clot stability and platelet functions (for details of clot retraction time, refer to previous chapter).

ABNORMALITIES OF COAGULATION

Hemorrhagic disorders are broadly classified into inherited and acquired defects.
1. Acquired defects are more common than inherited defects and platelet defects are more common than the coagulation defects.
2. Deficiencies of factor VIII (hemophilia) and factor IX (Christmas disease) are more common inherited coagulation defects.
3. The common acquired defects are thrombocytopenia, vitamin K deficiency, disseminated intravascular coagulation and liver failure resulting in clotting defects.

Hemophilia A

Etiology
Hemophilia A, also known as classic hemophilia, is a bleeding disorder that occurs due to deficiency of factor VIII. It is an X-linked recessive hereditary disease. Though it is less common than von Willebrand disease, it is more common than other inherited defects of coagulation. Women are carriers and generally do not suffer from the disease as they are protected by the second X-chromosome which is usually normal.

Clinical Features
The disease manifests with the bleeding tendency which appears in infancy, but in mild cases, may appear in adult life.
1. Soft tissue hematomas and hemarthroses (bleeding into joints) leading to severe crippling hemarthropathy are highly characteristic of the disease.
2. In severe cases, spontaneous hemarthropathy from infancy is the common feature.
3. In mild to moderate cases, continuation of hemorrhage secondary to trauma or surgery is the feature.
4. Bleeding usually persists from days to weeks inspite of formation of clots.
5. Bleeding may also occur spontaneously into tissues, and cavities of the body.

Diagnosis
Patients have prolonged activated partial thromboplastin time (APTT). Prothrombin time and bleeding time are normal. Assay of factor VIII in plasma is diagnostic. Functional factor VIII coagulant activity can also be measured.

Treatment
The treatment consists of transfusion of fresh blood (as on storage factor VIII is rapidly lost), or transfusion of factor
VIII-concentrate. Many plasma products are available for raising factor VIII to hemostatic level. Fresh-frozen plasma and cryoprecipitate both contain factor VIII. Attempt should be made to avoid aspirin, nonsteroidal anti-inflammatory drugs and other drugs that interfere with platelet aggregation.

Christmas Disease (Hemophilia B)

Etiology
Christmas disease or hemophilia-B occurs due to deficiency of factor-IX (antihemophilic factor-B or Christmas factor). This is a sex-linked recessive hemorrhagic disease.

Features
The disease is clinically indistinguishable from hemophilia A. Bleeding episodes are clinically identical to those in hemophilia A. Therefore, this is also called hemophilia-B. Hematoma, hemarthroses and crippling hemarthropathy occur.

Diagnosis
In most cases, PT is normal and partial thromboplastin time (PTT) is prolonged. Specific assay of factor IX coagulant activity confirms diagnosis.

Treatment
The specific treatment of hemophilia B is the replacement of factor IX.

Scientist contributed
In 1947, Dr Alfredo Pavlovsky, a doctor in Buenos Aires, Argentina, distinguished two types of hemophilia in his lab—A and B. He reported that the blood from some hemophilic patients corrected the abnormal clotting time in others. In 1952 this was called Christmas disease, after the family in which it was discovered.

von Willebrand Disease

Etiology
von Willebrand disease (vWD) is the most common inherited bleeding disorder in humans that occurs due to deficiency of von Willebrand factor (vWF). In 1926, Eric von Willebrand described this bleeding disorder in both genders of 24 persons of a 66 members of family from Åland Island.
1. vWF plays a central role in hemostasis as it serves as a carrier for factor VIII and is essential for adhesion of platelets to the injured vessel wall.
2. Therefore, deficiency of vWF leads to defects in the formation of both temporary and definitive hemostatic plugs.

Variants
There are different variants of vWD: Type 1, type 2A, type 2B, type 2M, type 2N and type 3.
1. Type 1 is the most common variant, which occurs due to decrease in 20–50% in quantity of vWF.
2. Type 2 variants are mainly qualitative abnormalities of vWF.
3. Type 3 is the most severe form in which vWF is grossly decreased.
   Factor VIII activity is decreased in type 1, decreased or normal in type 2, and markedly decreased in type 3.

Clinical Features
Mucocutaneous bleeding is the most commonest presentation in type 1. Epistaxis, easy bruising, hematoma, menorrhagia and GI bleeding are common. In type 3, patients suffer from severe bleeding and present with hemarthroses and muscle hematomas like hemophilia A. Type 2 presents with moderate symptoms.

Diagnosis
As vWF is primarily responsible for platelet adhesion, prolongation of bleeding time is a standard screening test for vWD. However, clotting time is prolonged or normal depending on the degree of deficiency of factor VIII. Quantitative and functional assays of plasma vWF are diagnostic.

Treatment
Desmopressin (DDAVP), an analogue of ADH increases factor VIII activity, vWF-Ag concentration and ristocetin cofactor activity. Therefore, DDAVP is very useful in type 1 and 2 diseases. However, vWF replacement therapy is required in type 3 disease.

Disseminated Intravascular Coagulation (DIC)

Definition and Etiology
DIC is a clinicopathological syndrome in which there is widespread intravascular coagulation that occurs due to procoagulants that are introduced into or produced by blood circulation.
1. The procoagulant activity overcomes the natural anticoagulant mechanisms. This is also called consumption coagulopathy or defibrination syndrome.
2. This is a hemorrhagic disorder in which diffused intravascular coagulation results in defects of hemostasis.
3. In this disease, coagulation factors and platelets are overutilized. This results in bleeding.
4. The most common procoagulant stimulus is the tissue factor (tissue thromboplastin) exposure to the blood, that activates extrinsic pathway of coagulation (Fig. 21.4).
5. Activation of plasmin causes excess fibrinolysis, resulting in increased levels of fibrin degradation product (FDP)

Common causes of DIC are:
1. Septic abortions
2. Amniotic fluid embolism
3. Gram-negative septicemia
4. Fungemia
5. Severe trauma
6. Severe eclampsia
7. Burns (burn sepsis)
8. Snake bite (Russell viper)
9. Sometimes in hemolytic transfusion reactions.

Manifestations
The clinical manifestations of DIC include two important features:
1. Multiorgan dysfunctions caused by widespread microembolism
2. Bleeding caused by consumption of platelets, fibrinogen, factor V and factor VIII.

Therefore, this is also called consumption coagulopathy. There is also activation of secondary fibrinolysis (hence, called defibrination syndrome).

Diagnosis
Laboratory features include thrombocytopenia, hypofibrinogenemia, increased d-dimer and fibrin degradation product (FDP) and prolonged PT, PT and thrombin time (TT). Diagnosis is usually done by demonstrating FDP in urine and decreased concentration of coagulation factors and fibrin monomers in blood.

Treatment
Treatment is based on early diagnosis, elimination of the precipitating factors, and replacing coagulation factors and platelets. Blood component therapy is needed for those who bleed excessively.

Thrombosis
Thrombus is an intravascular clot. Normally, a balance is maintained between the processes of coagulation and anticoagulation and therefore thrombus is not formed. However, in pathological situations, intravascular clotting occurs. Three factors (Virchow’s triad) predispose to the formation of thrombosis. These are:
1. Endothelial injury: Injury to vascular endothelium occurs in chronic and sustained hypertension, ulcerated atherosclerosis, arterial diseases etc. Injured site becomes the site for platelet adhesion and aggregation and intravascular clot formation.
2. Sluggishness of blood flow: Stasis of blood promotes thrombosis (as described above).
3. Hypercoagulability of blood: Increased activity of procoagulants such as fibrinogen, prothrombin and other coagulants leads to thrombosis.

Platelet aggregation at the site of injury initiates the process of thrombosis. Venous thrombosis is more common than arterial thrombosis.
1. One common example is thrombosis of lower limb veins in varicosities.
2. Deep vein thrombosis is not uncommon.
3. Thrombosis also occurs in cardiac chambers and valve leaflets.

   The major complication of thrombosis is thromboembolism. Emboli are dislodged from thrombus and circulate to be lodged in microcirculation in visceral organs, such as brain (cerebral embolism), lungs (pulmonary embolism), heart (coronary embolism) and intestine (intestinal embolism). Coronary and cerebral thrombosis leads to ischemic tissue death (infarction), which causes heart attack and stroke respectively. Prophylactic anticoagulation and antiplatelet therapy is the mainstay of prevention of complications of thrombosis.

---

### CHAPTER SUMMARY

### Key Concepts

1. Blood coagulation is initiated when tissue factor (tissue thromboplastin) is released into blood following tissue injury that activates VII, which is called extrinsic pathway of clotting mechanism, or, exposed collagen activates Factor XII through the intrinsic system. Finally, factor X is converted to Xa. This is the first stage in clotting.
2. In the second stage, prothrombin is converted to thrombin, and thrombin converts fibrinogen to fibrin in the third stage.
3. Clot retraction, which is the function of platelets, makes the clot stable.
4. Fibrinolysis is initiated by plasmin that checks the spread of clot beyond the site of injury.
5. Increased FDP level in blood and urine, the marker of excess fibrinolysis, is diagnostic of DIC. DIC is a state of consumptive coagulopathy.
6. In pregnancy, fibrinolytic activity is less.

### Important to Know (Must Read)

1. In examinations, ‘Mechanism of blood coagulation’ usually comes as a Long Question.
3. In Viva, examiners may ask… name the clotting factors, stages of blood clotting, steps of intrinsic and extrinsic pathways of clotting, clot retraction and its importance, mechanism of fibrinolysis, mechanism of action of Vitamin K antagonist, anticoagulants and their mechanisms, tests to detect defects in extrinsic and intrinsic mechanisms of clotting, and causes, features and treatment of common coagulation disorders.
4. Anticoagulants are frequently asked for as they are commonly used in clinical as well as laboratory practices.

“The great are strongest when they stand alone.  
A God-given might of being in their force,  
A ray from self’s solitude of light the guide;  
The soul that can live alone with itself meets God.”

Sri Aurobindo (in ‘SAVITRI’)
A neuron is the structural and functional unit of the nervous system. Its primary function is to receive the various stimuli and transmit the signals to other neurons and tissues. The neuron is an excitable cell where message transmission occurs in the form of action potentials. There are about $10^{11}$ neurons present in the human central nervous system (CNS). There are also supporting cells called glial cells, which are 10 to 30 times more in number than the neural cells.

**Structure of a Neuron**

A neuron has three parts: a cell body, dendrites, and an axon that ends at axon terminal (Fig. 22.1).
Cell Body

Cell body, also known as soma or perikaryon, is the center of the neuron. It contains the nucleus and cytoplasm containing cell organelles. The plasma membrane of the soma is a bilayered lipid protein membrane, called plasmalemma.

Cell Organelles

Cell organelles are mainly numerous Nissl granules, many mitochondria, Golgi apparatus and lysosomes. Cytoplasm also contains cytoskeletal proteins like neurofilaments, microtubules and actin microfilaments (Fig. 22.2).

1. **Nissl granules**: Also called Nissl bodies, are stacks of rough endoplasmic reticulum with their membranes studded with ribosomes and polysomes. Nissl granules extend into the dendrites, but not into the axon.

2. **Neurofilaments** (Neurofibrils): Another distinctive feature of neurons is the presence of networks of fibrils permeating the cytoplasm. These neurofibrils consist of microfilaments and microtubules. In Alzheimer’s disease, the neurofilaments form a characteristic neurofibrillary tangle.

Nucleus

The nucleus usually contains one nucleolus; sometimes there may be two nucleoli, but centrioles are absent.

Functions of Soma

1. Soma contains the genetic information and is capable of protein synthesis. Though neuron is an active cell, it has lost the capacity to regenerate as indicated by the absence of centriole.

2. The soma at one end gives rise to small branching processes called dendrites and at the other end a long process called axon.

</tr>
</tbody>
</table>

Dendrites

The numerous short extensions from the cell body are called dendrites.

1. They increase the cell surface area many folds. Dendrites have dendritic spines, that help in increasing the surface area for receiving information.

2. In neurons of cerebral and cerebellar cortex, small knobby projections called dendritic spines further increase the surface area.

3. Dendrites receive the incoming signals from other cells and transmit it to the cell body.

4. At some areas of the brain, they can cause protein synthesis, also generate and conduct the action potentials.

5. On an average, there are about 10,000 dendrites per neuron present in the CNS.

Axon

Axon or the axis cylinder of the neuron forms the nerve fiber. It is a long tubular process that extends away from the cell body to transmit output signals to target organs. Dendrites transmit impulses toward cell body, whereas axons carry impulses away from cell body (Table 22.1).

1. The cytoplasm is known as axoplasm that contains mitochondria, Golgi apparatus, and cytoskeletal proteins.

2. The axon arises from a thickened, tapered area of the cell body called the axon hillock.

3. The initial portion of the axon is known as the initial segment.

4. The axon hillock continues as initial segment and this part is known as axon hillock—initial segment portion of the neuron.

5. The action potential is generated at the initial segment in motor neurons and at the first node of Ranvier in sensory neurons.

**Axon terminal**: The terminal part of axon loses myelin and divides into several branches, called telodendria. The endings of telodendria form bulb like enlargements.
called terminal buttons or synaptic knobs. The buttons contain neurotransmitter vesicles.

Types of Axon
Axons are of two types: myelinated and unmyelinated.

Myelinated Axons
In the peripheral nervous system (PNS), myelinated axons have a sheath around, called myelin sheath (Figs. 22.3A and B).
1. Myelin sheath in PNS formed by the Schwann cells. The large diameter somatic nerve fibers as well as the preganglionic fibers of the autonomic nervous system are myelinated.
2. In the CNS of mammals, myelination is carried out by oligodendrocytes. Each oligodendrocyte projects several processes that wrap around many axons.

Role of Schwann Cell in Myelination
The double layers of the membrane of a single Schwann cell wrap several times (about 100 times) over 1 mm length of the axon forming a covering of 8–10 µm thickness (Figs. 22.3A and B).
1. The adjacent layers stick to each other tightly with the help of a protein called protein zero ($P_0$) present in the Schwann cell membrane.
2. The extracellular portion of $P_0$ in one layer locks to the extracellular portion of $P_0$ in the apposing layer resulting in compaction of myelin.
3. Mutation of $P_0$ cause defective myelination and decreased conduction as occurs in various peripheral neuropathies.
4. The nucleus of the Schwann cell lies beneath the plasma membrane in the outermost layer (Fig. 22.3A). Thus, the myelin sheath extending along the length of an axon is formed by many Schwann cells, which are present at regular intervals along the course of the axon.
5. The gaps between the Schwann cells are called the nodes of Ranvier (Fig. 22.3B), where the plasma membrane is exposed to the ECF. Each node is 0.5–1.0 µm in length and the internodal distance is 1–2 mm.
6. In multiple sclerosis, an autoimmune disease, patchy destruction of myelin occurs causing decreased conduction velocity in both motor and sensory neurons.

Myelinogenesis
Myelin sheath when present is seen outside the axolemma. The cells providing this sheath for axons in the peripheral nervous system are called Schwann cells and in CNS are oligodendrocytes. The nature of this sheath is best understood by considering the mode of its formation.
1. An axon lying near a Schwann cell invaginates into the cytoplasm of Schwann cell. In this process the axon comes to be suspended by a fold of the cell membrane of the Schwann cell. This fold is called mesaxon (Fig. 22.4).
2. In some situations the mesaxon becomes greatly elongated and comes to be spirally wound around the axon, which is thus surrounded by several layers of cell membrane. Lipids are deposited between adjacent layers of the membrane. These layers of the mesaxon, along with the lipids, form the myelin sheath.
3. Outside the myelin sheath a thin layer of Schwann cell cytoplasm persists to form an additional sheath that is called neurilemma (also called the neurilemma sheath or Schwann cell sheath).
4. An axon is related to a large number of Schwann cells over its length. Each Schwann cell provides the myelin sheath for a short segment of the axon. At the junction of any two such segments there is a short gap in the myelin sheath. These gaps are called the nodes of Ranvier (Fig. 22.5).
5. The nodes of Ranvier have great physiological importance. When an impulse travels down a nerve fiber it does not proceed uniformly along the length of the axis cylinder, but jumps from one node to the next. This is called saltatory conduction (in unmyelinated neurons the impulse travels along the axolemma). Such conduction is much slower than saltatory conduction and consumes more energy.
6. The segment of myelin sheath between two nodes of Ranvier is called internode.
Composition of Myelin Sheath

Myelin contains protein, lipids, and water. The main lipids present include cholesterol, phospholipid, and glycosphingolipids. Other lipids are present in smaller amount.

Important Note

Myelin sheath defects: Myelin sheath can be seriously impaired and there can be abnormal collections of lipids, in disorder of lipid metabolism. Various proteins have been identified in myelin sheath and abnormality in them can be the basis of some neuropathy.

Objectives of Myelination

Myelination serves following four purposes.
1. It increases the speed of conduction.
2. It reduces energy expenditure by the cell.
3. It provides a protective covering to the axon.
4. It is responsible for the color of the white matter of the brain and spinal cord.

Timing of Myelination during Development

Myelination of different types of nerve fibers takes place at different times.

1. The sensory fibers of the dorsal column system first get myelinated, which occurs at 4th–5th month of intrauterine life.
2. The corticospinal tract fibers start myelinating at two months of age and the process gets completed at about 2nd year of life, when the child has learned to walk (Application Box 22.1).

Application Box 22.1

Axonal Growth: During development of a neuron, axonal growth depends on the interaction between the growing axon and the surrounding tissue environment. At the growing end is present a growth cone, which is motile and contains actin. The direction of axonal growth is determined by cell adhesion molecules, influenced by trophic factors secreted from target cells and guided by glial cells.

Unmyelinated Axons

Unmyelinated axons do not have myelin sheath.
1. The Schwann cells are present near these axons, but their mesaxons do not completely spiral around them (Fig. 22.6).
2. Another difference is that several such axons may invaginate into the cytoplasm of a single Schwann cell.
3. Somatic nerve fibers of very small diameter, postganglionic sympathetic neurons of the autonomic nervous system, dorsal root fibers and most of the fibers in invertebrates are unmyelinated.
4. The speed of conduction of impulse is slower in unmyelinated nerve fibers (Table 22.2).

Scientist contributed

Theodor Schwann advanced the concept of cellular organization of living beings, described the structure of neurilemma (covering of the nerve) and showed the necessity of air for embryonal growth. His intense study on digestion was important, in which he discovered pepsin and its action, and highlighted the importance of bile in digestion. His discovery of yeast and its role in purification and fermentation was an important revelation. He is popularly remembered for his discovery of myelin sheath and myelogenesis (Schwann cells that form the covering of myelinated neurons) of axons; hence these cells are known as Schwann cells.

Axoplasmic Transport

Transfer of substances between cell body and axon terminal is called axoplasmic transport.

1. Various proteins, organelles and other cellular substances required for the development, growth, and maintenance of the neuron are transported mainly along the length of the axon.

2. Axoplasmic transport can be abolished by application of colchicine, dinitrophenol, azide, cyanide, and prolonged anoxia.

3. Colchicine disrupts the movement of microtubules; others block the process of oxidative phosphorylation.

Types of Axoplasmic Transport

In the axoplasm, transport process can occur in both directions by different transport mechanisms. Accordingly, they are called anterograde, retrograde, and transneuronal transports.

Anterograde Transport

The transport of materials from the cell body toward the axon terminals is known as anterograde transport. For example, various neurotransmitters synthesized in the cell body are packaged in vesicles and get secreted at the nerve endings through axoplasmic microtubules. Anterograde transport process is mapped by $[^{3}H]$-leucin. The rate of transport process may be fast or slow.

Fast axoplasmic transport: Fast axoplasmic transport occurs at the speed of about 400 mm/day, which is accomplished by kinesin, a microtubule associated protein that transports many organelles, vesicles and membrane glycoproteins.

Slow axoplasmic transport: Slow axoplasmic transport occurs at the rate of about 0.5–2 mm/day. Various structural proteins like actin, neurofilaments and microtubules get transported by slow transport. It has an important role in supplying the required materials for the regeneration of axons following nerve injury.

Retrograde Transport

Transport of substances from the axon terminals to the cell body is known as retrograde transport. It occurs at a speed of about 200 mm/day, brought about by dynein, another microtubule associated protein. This mechanism keeps the soma informed about the synaptic environment. Retrograde transport is mapped by horse-radish peroxidase.

The examples of retrograde transport are:

1. Transport of viruses: The chickenpox virus, known as varicella zoster that causes herpes simplex reaches cell body from nerve terminals in the skin by retrograde transport. The virus may remain in a dormant state in nerve root for many years before causing herpes zoster afterwards.

2. Transport of toxins: Tetanus toxin at motor neuron ending is transported to the cell body by this retrograde process.

3. Transfer of nerve growth factor: Nerve growth factor is taken up by presynaptic terminal and transferred to soma by retrograde transport.

4. Reuptake of synaptic transmitters: Neurotransmitters like norepinephrine (NE) released at the nerve terminals are rapidly removed from the synaptic cleft by reuptake.
into the presynaptic neuron. In the presynaptic terminal, NE is repackaged into vesicles or deaminated by mitochondrial monoamine oxidase. This reuptake is an active retrograde transport process. Some of the vesicles may be transported back to the cell body and this may provide a feedback signal to the cell body for further synthesis of transmitters. Choline is also taken up by the axon terminal and reused for new Ach synthesis.

**Transneuronal Transport**

Trophic substances like nerve growth factors are transported across the synapse to the presynaptic membrane of another neuron. This is called transneuronal transport. This helps in maintenance of the synaptic contacts.

**FUNCTIONS OF NEURONS**

The cell body and dendrites serve as the receptor zone to receive the information, axon hillock and initial segment for generation of action potential, axon for transmission of nerve impulse, axon terminal for discharge of neurotransmitters (Fig. 22.7).

**Cell body:** It maintains the functional and anatomical integrity of the axon. The proteins associated with synaptic transmitters are synthesized in Nissl granules of the cell body and are transported to axon terminal by axoplasmic flow.

**Dendrites:** They form the receptor zone of the neuron, i.e. they receive impulses and transmit the impulses toward the cell body. In this region, non-conducted local potential changes generated by synaptic connections are integrated.

**Axon:** The initial segment is the site where propagated action potentials are generated. The axonal process transmits propagated impulses from the cell body to the axon terminal.

**Synaptic knobs:** This is the nerve ending where arrival of action potentials results in the release of synaptic transmitter.

**Important Note**

**Concentration of voltage gated Na**⁺ **channels:** Na⁺ channels are highly concentrated in the nodes of Ranvier and the initial segment in myelinated nerve fibers.

**METABOLISM AND GROWTH OF NEURONS**

**Metabolism**

Neurons are metabolically active cells as mitochondria are present in adequate numbers. Neurons are always active as the membrane potentials and neuronal cytosolic activities are continuous phenomena. About 70% of total energy required is used to maintain polarization of the membrane by the action of Na⁺-K⁺ pump. During the peak activity, the metabolic rate of nerve doubles compared to skeletal muscle cell metabolism.

**Special features of neuronal metabolism are:**
1. The excitability, conductivity and recovery process from the activities can happen in a nerve for a considerable period in the absence of oxygen.
2. Chemical changes in the nerve are similar to that in muscles, i.e. pyruvic acid is formed and if O2 supply is insufficient, lactic acid accumulates.
3. Energy requirement of the resting nerve to maintain polarization of the membrane is supplied primarily by combustion of sugar and phospholipids.
4. During activity, hydrolysis of ATP and creatine phosphate supply energy for the propagation of the nerve impulse.
5. The nerve cells are rich in K⁺ and vitamin B₁ that further assist in metabolism. Vitamin B₁ is essential for oxidation of pyruvic and lactic acids in the neurons.

**Growth of Neurons**

Various factors affecting neuronal development, growth and survival have been isolated and studied. These can be broadly arranged into two groups:

1. **Neurotrophins**
2. **Other growth factors:** Other factors affecting neural development such as ciliary neurotrophic factor (CNTF), glial cell line-derived neurotrophic factor (GDNF), leukemia inhibitory factor (LIF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), transforming growth factor (TGF), insulin like growth factor (IGF-I), etc.

**Neurotrophins**

Neurotrophins are trophic proteins to the neurons, as they promote nerve growth and survival. They are produced by the nerves, muscles, glands, and astrocytes.
Chapter 22: Structure and Functions of Neurons

Known neurotrophins are:
1. Nerve growth factor (NGF),
2. Brain-derived neurotrophic factor (BDNF),
3. Neurotrophin-3 (NT-3), and
4. Neurotrophin-4/5

**Nerve Growth Factors**
Nerve growth factor (NGF) is the first neurotrophin to be identified. It promotes the growth of sympathetic nerves and some sensory nerves. NGF is made up of 2α, 2β, and 2γ subunits.
1. The α subunits have trypsin-like activity.
2. The β subunits are similar to insulin and have nerve growth-promoting activity.
3. The γ subunits are serine proteases.
NGF decreases apoptosis of neurons by acting through tyrosine kinase A receptor.

**Brain-derived Neurotrophic Factor (BDNF)**
BDNF promotes growth of peripheral sensory nerves. It acts through tyrosine kinase A.

**Neurotrophin 3**
The neurotrophin-3 (NT-3) promotes growth of cutaneous mechanoreceptors. It acts through tyrosine kinase A, B, and C.

**Neurotrophins 4 and 5**
They act through tyrosine kinase B. Exact function is not known.

**TYPES OF NEURONS**

Neurons are classified according to the number of processes, length of axon, functions of neurons, and patterns of dendrites.

**According to the Arrangement of Axon**
According to the arrangement and number of processes, the neurons are classified into unipolar, pseudounipolar, bipolar, and multipolar neurons (Figs. 22.8A to D).

**Unipolar Neurons**
They have a single process (Fig. 22.8A). They are usually found in invertebrates. In vertebrates, they are found in ANS.

**Pseudounipolar Neurons**
In pseudounipolar neurons, axon after originating from soma splits into central and peripheral processes (Fig. 22.8B). The example is dorsal root ganglion cell (primary sensory neurons with cell bodies in dorsal root ganglion).

**Bipolar Neurons**
In these neurons, two processes arise from the cell body (Fig. 22.8C). The example is the bipolar cell of retina.

**Multipolar Neurons**
In multipolar neurons, many processes arise from the soma (Fig. 22.8D). The example is a spinal motor neuron.

**According to the Length of Axon**
According to the length of the axon, neurons are classified into two categories: Golgi type 1 and type 2.

**Golgi Type 1**
These are the neurons with short axons. Dendrites of these neurons terminate near the soma. The example is cortical inhibitory neurons.
Golgi Type 2
Axons of Golgi type 2 neurons are long. Cortical motor neurons (neurons that give rise to corticospinal tract) are the examples.

According to Function
According to functions, neurons can be divided into sensory and motor neurons.

Sensory Neurons
These are the neurons that carry impulses from the receptors to the central nervous systems. These are called afferent neurons (afferent fibers).

Motor Neurons
These are the neurons that carry impulses from the central nervous system to the target organs. These are called efferent neurons (efferent fibers).

According to Dendritic Pattern
According to dendritic pattern, two types of neurons are present: pyramidal cells and stellate cells.

Pyramidal Cells
Dendrites of these cells spread like pyramids. The example is hippocampal pyramidal neurons.

Stellate Cells
Radial shaped spread of dendrites occurs in these cells. The examples are cortical stellate cells.

ARRANGEMENT OF NEURONS AND NEUROGLIA

Arrangement of Neurons in Nerve Fibers
The neuronal structures are present in endoneurium, perineurium, and epineurium (Figs. 22.9A and B).

Endoneurium
In the peripheral nerves each nerve fiber with its Schwann cell and basal lamina is surrounded by a layer of connective tissue called endoneurium.
1. The endoneurium contains collagen, fibroblast, Schwann cells, endothelial cells and macrophages.
2. Many nerve fibers together form bundles or fasciculi.
3. Endoneurium holds adjoining nerve fibers together and facilitates their aggregation to form fasciculi.

Perineurium
Each fasciculus is surrounded by thicker layer of connective tissue called perineurium.
1. The perineurium is made up of layers of flattened cells separated by layers of collagen fibers.
2. The perineurium probably controls diffusion of substances in and out of axons.
3. A very thin nerve may consist of single fasciculus, but usually a nerve is made of several fasciculi.

Epineurium
The fasciuli are held together by a fairly dense layer of connective tissue that surrounds the entire nerve and is called the epineurium.
Flowchart 22.1: Types of neuroglia in the nervous system (PNS and CNS).

(PNS: Peripheral neurons system; CNS: Central neurons system).

Important Note

Clinical Correlation of Neuronal Structures:

- The epineurium contains nerve fibers. Loss of this fat in bedridden patients can lead to pressure on nerve fibers and paralysis.
- Blood vessels to a nerve travel through the connective tissue that surrounds it. Severe reduction in blood supply can lead to ischemic neuritis and pain.

Neuroglia

In addition to neurons, the nervous system contains several types of supporting cells called neuroglia (Flowchart 22.1). As neuroglia are present mostly in CNS, their structure and functions are discussed in first chapter of Neurophysiology, in Section XI.

CHAPTER SUMMARY

Key Concepts

1. Neuron is the structural and functional unit of the nervous system.
2. Neurons are divided into myelinated and unmyelinated, based on the presence or absence of myelin sheath. Myelination improves the speed of conduction.
3. Myelination of axon in PNS occurs by Schwann cells and in CNS by oligodendroglia.
4. The cell body and dendrites serve as the receptor zone to receive the information from other neurons. Axon hillock and initial segment are the sites of generation of action potential. Axon is meant for transmission of nerve impulse. Axon terminal is for discharge of neurotransmitters into the synapse.
5. Neurotrophins are the main nerve growth factors.

Important to Know (Must Read)

1. In examinations, usually Long Questions are not asked from this chapter.
2. Structure of neuron, Mechanism of myelination, Axoplasmic transport, Types of neurons, and Neurotrophins are usually Short Questions in exams.
3. In Viva, examiners may ask…… different parts of neurons and their functions, how the myelination occurs and what are the functions of myelination, functions of Schwann cells, types of axoplasmic transport, types of neurons, special features of metabolism of neurons, axoplasmic transport, types of neurons with examples for each, and different neurotrophins.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Appreciate the distribution and working of ion channels on the neuronal membrane.
2. Understand the importance of electrotonic potentials.
3. Define rheobase, chronaxie and utilization time and draw the strength-duration curve.
4. Draw a labeled schematic diagram of nerve action potential (AP) and describe the ionic basis of each phase of AP.
5. Define refractory periods (ARP and RRP) of nerve AP and explain their importance.
6. Explain the mechanism of propagation of action potential along the axon and understand the importance of saltatory conduction.
7. List the differences between graded potential and action potential.

The student MAY also be able to:
1. Describe the mechanism and genesis of electrotonic potentials.
2. Describe the mechanism of strength-duration curve.
3. Explain the application of nerve potential in various aspect of neuromuscular physiology.

Electrophysiological Aspects

For nerve impulses to be transmitted from neuron to neuron, the action potential must be generated and propagated along the nerve cell membrane. All these events depend on the activities of ion channels present on the membrane of the neurons.

Neuronal Ion Channels

Like any other cell membrane, neuronal membrane possesses numerous ion channels like Na⁺, K⁺, Ca²⁺, Cl⁻, etc. They are broadly categorized into three types:

i. Nongated or leaky channels

ii. Gated (voltage-gated, ligand-gated and mechanical-gated) channels.

iii. ATP-driven pumps:

1. The nongated or leaky channels of Na⁺, K⁺, Cl⁻ are present throughout the neuronal membrane.
2. The voltage-gated Na⁺ channels are concentrated at the nodes of Ranvier.
3. The voltage-gated Ca²⁺ channels are mainly present at the axon terminals, where they play important role in the secretion of neurotransmitters.

4. The mechanical-gated Na⁺ channels are involved in the genesis of receptor potential in the somatic sensory nerve endings.

5. Ligand-gated ion channels are present predominantly on dendritic spines, dendrites and cell body of the neuron. They are important for receiving information from other neurons at synaptic sites, in the form of released neurotransmitters.

Distribution of Na⁺ Channels

In myelinated neurons, the number of Na⁺ channels per square micrometer of membrane in different segments of the neuron is as follows:

1. At cell body: 50–75
2. At initial segment: 350–500
3. On the surface of the myelin: 25
4. At the nodes of Ranvier: 2000–12,000
5. At the axon terminals: 20–75

Thus, the channels are concentrated in areas where the action potential is first initiated (initial segment) and in regions where it is regenerated (nodes of Ranvier) during its propagation.
In unmyelinated neurons, about 110 Na⁺ channels are present per square micrometre of the axonal membrane. Abnormalities of channels are called channelopathies (Clinical Box 23.1).

**Clinical Box 23.1**

Channelopathies: The diseases caused due to the structural or functional changes in the ion channels are known as channelopathies. Those affecting neurons include episodic and spinocerebellar ataxias, some forms of epilepsy and familial hemiplegic migraine.

**Recording of Nerve Responses**

To study the various activities and properties of a nerve, intracellular and extracellular recording methods are adopted. For both recordings, electrical stimulus is usually used as it is convenient to apply the stimulus and accurately measure the strength of the stimulus.

**Intracellular Recording**

Usually, an isolated single giant axon taken from invertebrates such as cuttlefish (sepia) or squid (Loligo) is used for experimental set-up. As their fiber diameter is large (about 500 µm) it allows vertical penetration of microelectrode (diameter of 100 µm). The tip of the recording electrode is placed inside the axon, and the reference electrode is kept on the surface of the axon. A steady negative potential of −70 mV is recorded by the cathode ray oscilloscope (CRO) in the resting set-up. Then on application of a stimulus, the monophasic response obtained, is observed.

**Extracellular Recording**

In this type of recording, both the recording and reference electrodes are placed on the external surface of the isolated nerve fiber or on the skin surface of the intact animals or human beings. When the set-up is arranged, at rest, no potential is recorded by the CRO. Since both the electrodes are placed in same environment, both pick up the same voltage and there is no potential difference. On stimulation, a biphasic response is observed.

**Terms Used for Membrane Potentials**

Certain terms are used to explain the change in membrane potential relative to the resting membrane potential (RMP):

1. When there is a voltage difference between the inside and outside of the membrane, the membrane is said to be polarized.
2. When a stimulus allows influx of positive charges or efflux of negative charges, it decreases the membrane potential (i.e. the membrane potential approaches towards zero) and the stimulus is called a depolarizing stimulus. Thus, the membrane is said to be depolarized when the membrane potential becomes positive or less negative in relation to RMP.
3. After the depolarization phase, return of the potential towards the resting value is known as repolarization.
4. Similarly, as the interior of the cell becomes more negative in relation to RMP, due to influx of negative charges or removal of positive charges, the membrane is said to be hyperpolarized. In this state, the membrane potential is more negative in relation to RMP.

**GENESIS OF NERVE POTENTIALS**

The ability of the cells to generate action potential in their membrane is known as excitability. Nerve is a highly excitable tissue, which can be stimulated by electrical, chemical and mechanical forms of energy. When a stimulus is applied, it induces ions to flow across the membrane and alters the ionic balance on both sides of the membrane, producing a voltage change. With application of a stronger stimulus, much larger disturbance in ionic balance occurs. However, the ionic balance is promptly restored by 2 factors (repolarizing forces):

1. Diffusion of ions across the cell membrane
2. Increased activity of Na⁺-K⁺ ATPase.

The voltage changes across the membrane generate electrical signals, which on recording show a wave like pattern. The transient and small voltage changes spread along the length of the nerve fiber and die out after some time. When the stimulus is strong enough, the response does not die out fast, rather, it travels along the whole length of the axon, being regenerated at regular intervals. This phenomenon is possible because the neuronal membrane is a biological membrane studded with different ion channels, whose activation time is modifiable with change in external environment.
The message transmission occurs by means of generation and propagation of the electrical signals in the axon from one end to the other. These generated signals can be of two types:
1. Electrotonic or graded potentials
2. Action potentials.

Graded potentials spread the signal over short distances, whereas action potentials transmit the message throughout the length of the plasma membrane. Another type of response is seen in neuronal membrane that is called local response.

Electrotonic or Graded Potentials

Definition
Electrotonic potentials are local, nonpropagated potentials of small magnitude, in response to a depolarizing or hyperpolarizing stimulus of lesser strength.

Types
Electrotonic potentials are two types: catelectrotonic and anelectrotonic.

Catelectrotonic potential: When a membrane is electrically stimulated, the cathodal end of the stimulator evokes a depolarizing response called catelectrotonic potential.

Anelectrotonic potential: The hyperpolarizing potential produced due to stimulation at the anodal end is known as anelectrotonic potential (Fig. 23.1).

Concept
In the resting state, negatively charged ions are lined along the interior of the membrane and positively charged ions are lined along the exterior of the membrane:

1. With the application of a cathodal stimulus of smaller strength to a small area of the membrane, few Na+ ions enter through the leaky sodium channels into the cell.
2. At that instant, at the site of stimulus, the inside of the membrane becomes positive compared to the previous resting state.
3. With application of greater strength of stimulus, more positive charges enter into the cell and the voltage change is larger.
4. The repolarizing forces try to neutralize the disturbance in RMP, created by the Na+ entry. K+ tends to come out of the cell and Cl- enters through the leaky channels to maintain the electrical neutrality. Also, Na+ moves away by diffusion from the site of stimulus. Moreover, activity of the Na⁺-K⁺ ATPase is increased pumping 3 Na⁺ out and 2 K⁺ in. All these lead to the gradual return of the membrane potential towards the resting value.

In the neuron, graded potentials are recorded from the membranes of dendrites and cell body.

Properties of Graded Potential

1. Graded in nature: The term graded potential comes from the fact that the potential change increases in a stepwise manner with application of increasing strength of stimulus, i.e. the magnitude of potential change is proportionate to the stimulus strength.
2. Decremental conduction: Graded potentials decay progressively with time and distance, which is known as decremental conduction:
   i. When recorded near the site of stimulus, the amplitude of the potential is larger and recorded at a farther place, it is smaller. The potentials die out within a distance of 3 mm from the site of stimulus.
   ii. If recorded immediately after the application of the stimulus, the amplitude is larger and with delay in recording, the amplitude is smaller.
3. Depolarizing or hyperpolarizing nature: If the change in potential is plotted in the y-axis and time in the x-axis, the graph will be like a wave (Fig. 23.1), which primarily depends on the type and strength of the stimuli:
   i. With application of increasing strength of cathodal stimulus, more positive charges enter the cell and the graph displays gradually rising upward waveforms.
   ii. Similarly, when the membrane is stimulated with anodal end, due to entry of negative charges or removal of positive charges, the membrane potential becomes more negative; the graph displays a downward waveform.

Therefore, according to the type of stimulus, graded potentials can occur in either a depolarizing or a hyperpolarizing direction.

Fig. 23.1: Electrotonic potential and local response. (RMP: Resting membrane potential).
4. **Summation**: if a second stimulus is applied before the potential produced by the first stimulus has disappeared, both the potential changes are added together producing a larger and/or prolonged wave in the recording. This happens due to the arrival of more Na\(^+\) ions at the site of stimulus before neutralization of all Na\(^+\) influx caused by the first stimulus. Similarly the anelectrotonic potentials exhibit the property of summation.

**Forms of Graded Potentials**

Wherever a cell responds to a stimulus, graded potentials are produced along its membrane:
1. According to the type and location of the membrane from where they are recorded, they are described as **end-plate potential**, recorded from skeletal muscle membrane at neuromuscular junctions.
2. **Receptor potential**, recorded from sensory nerve endings.
3. **Synaptic potential**, recorded from membrane of postsynaptic neurons at neuro-neuronal junctions.
4. **Pacemaker potential**, recorded from pacemaker cells in the heart, intestine, etc. and so on.

**Local Response**

As the axon is stimulated with slowly increasing strength of stimuli, the amplitude of the electrotonic potential gradually rises. When the membrane potential is decreased by 7 mV, the pattern of graded potential is altered. The response becomes greater than what is expected for that strength of stimulus. This enhanced response is known as **local response**:
1. Similar to the graded potential, the local response gradually dies out with increasing distance.
2. Local response is seen only with a depolarizing stimulus of lower strength, and not with a hyperpolarizing one.

**Ionic Basis of Local Response**

As the applied cathodal stimulus is progressively raised from zero the **influx of Na\(^+\) ions through the leaky sodium channels** increases proportionately. Consequently, the membrane potential gradually **decreases from –70 to –63 mV**. At –63 mV, the few voltage-gated sodium channels start **opening**, which allows entry of some more Na\(^+\) ions. The **extra Na\(^+\) ions** entering into the cytoplasm are added to the existing Na\(^+\) influx, resulting in a heightened response called local response. This is observed within a potential change from –63 to –55 mV.

**Types of Stimuli**

**Threshold, Subthreshold and Suprathreshold Stimuli**

At membrane potential of –55 mV, the neuron starts generating action potentials:
1. This is termed as **firing or discharge** of the neuron and the membrane potential at –55 mV is known as the **firing level** or **threshold**.
2. The stimulus that brings the membrane potential to –55 mV is known as threshold stimulus. **Threshold stimulus** is defined as the lowest strength of stimulus that elicits an action potential.
3. The stimuli less in strength than the threshold are known as **subthreshold stimuli** and the stimuli higher in strength than the threshold are known as **suprathreshold stimuli**.

**Strength-Duration Relationship**

Strength and duration are two important aspects of a stimulus. Both of them have a complimentary role in determining the excitability of a tissue. These two parameters are inversely related to each other. The relationship between the strength and duration of stimuli depicted in graph form is known as **strength-duration curve** (Fig. 23.2):
1. To excite a tissue, the lowest amplitude of current required is termed as **rheobase**.
2. The minimum time for which the rheobase must be applied to elicit an action potential is known as **utilization time**. A stimulus weaker than rheobase does not excite the tissue and a stimulus stronger than rheobase requires less time (less than utilization time) to elicit a response.
3. **Chronaxie** is the time required for a stimulus of double the rheobase strength to produce an action potential.
4. Usually chronaxie gives us a better idea about the excitability of a tissue. The lesser the chronaxie, the greater is the excitability.
5. Nerves have a shorter chronaxie compared to muscles.

**Fig. 23.2**: Strength-duration curve.
Accommodation

If the intensity of a stimulus is slowly raised to the threshold value, the tissue fails to produce an action potential because it adapts to the stimulus. This phenomenon is known as accommodation:
1. During the slow depolarization, some of the voltage-gated Na⁺ channels start opening at a membrane potential of −63 mV. But, they soon get inactivated before another set of channel opens; because, the membrane takes longer time to arrive at the next level of potential.
2. Thus, the sufficient number of activated sodium channels required to fire an action potential is never accomplished. Like this, the membrane may attain the normal threshold level or even surpass that level, but action potential is not produced.
3. Besides, the potassium channels that open in response to the depolarization drain off the positive charges.

Action Potential

Definition

Action potential is defined as a transient change in membrane potential of about 100 mV, which is conducted along the axon in an all-or-none fashion.

It has following features:
1. It is characterized by a gradual depolarization to threshold, and a rapid ascent in the membrane potential followed by a phase of repolarization.
2. It travels along the axon with the same shape and amplitude being regenerated at regular intervals.
3. It is also known as an impulse or spike potential.

Duration and Amplitude

The duration of a single nerve action potential is about 1 msec, during which the membrane potential sharply rises from −70 to +35 mV, and then returns to its resting value.

Latent Period

Action potential is always preceded by a latent period, which is the interval between the application of a stimulus and the onset of action potential:
1. Duration of latent period depends on the distance between stimulating and recording electrodes and the type and diameter of nerve fiber.
   The action potentials never summate and a definite interval (refractory period) exists before the second action potential is fired.

Phases of an Action Potential

It has two phases, a phase of depolarization and a phase of repolarization:

i. The phase of depolarization is recorded as a sharp upward wave during which the membrane potential approaches zero and then attains a positive value. It consists of slow depolarization to threshold, rapid rising phase, overshoot and peak. During overshoot, the membrane potential crosses the zero or isopotential level and then at peak, it reaches a maximum potential of +35 mV.

ii. The phase of repolarization is recorded as down-stroke during which the membrane potential returns to the resting level. It includes a rapid falling phase and slower terminal part called after-depolarization.
   The phase of repolarization is followed by an after-hyperpolarization phase during which the membrane potential undershoots (becomes more negative) and then returns back to the resting level (Fig. 23.3).

Ionic Bases of Action Potential

The depolarization and repolarization phase of the action potential are due to sequential changes in membrane permeability to sodium and potassium leading to large fluxes of these ions across the membrane, along their gradients.

Depolarization is due to influx of sodium and repolarization is due to efflux of potassium. The voltage-gated Na⁺ and K⁺ channels contribute to the different phases of the action potential.

Depolarization

Depolarization is due to opening of voltage-gated Na⁺ channels, causing massive influx of sodium ions:
1. When a threshold or suprathreshold stimulus is applied, the influx of Na⁺ through leaky channels and later through opening of few voltage-gated Na⁺ channels decreases the membrane potential from −70 mV to −55 mV (threshold level).
2. At this threshold potential, there occurs simultaneous opening of a large number of the voltage-gated Na⁺ channels, increasing the membrane permeability to sodium ions several hundredfold. This leads to massive influx of sodium ions producing a swift, large and steep depolarization, changing the membrane potential to +35 mV (a change in membrane potential by 105 mV starting from the resting value of –70 mV to +35 mV).

The initial change in membrane potential by +15 mV (–70 mV to –55 mV) is essential for instantaneous activation of a large number of voltage-gated Na⁺ channels. At threshold level, the number of Na⁺ channels that have already opened, cause concomitant opening of almost all the Na⁺ channels in the stimulated part of the membrane (positive feedback control) (Application Box 23.1). The activation gate of Na⁺ channels opens that brings them to the activated state (for details, see below). Therefore, this process of simultaneous activation of huge number of Na⁺ channels is called auto-activation, which occurs very rapidly.

**Application Box 23.1**

**Hodgkin’s cycle:** The opening of few Na⁺ channels leading to further opening of other Na⁺ channels is called Hodgkin’s cycle. This is an example of positive feedback control in which a stimulus triggering an event further facilitates the process (Refer to Fig. 3.3, Chapter 3).

The concentration gradient as well as electrical gradient favors the entry of sodium ions across the membrane. In fact, there occurs reversal of membrane potential with the inside becoming positive than outside as the membrane potential crosses the isopotential value of 0 mV and finally attains a peak potential of +35 mV.

**Membrane Potential Remains Below Na⁺ Equilibrium Potential**

During depolarization, the membrane potential approaches but does not reach the equilibrium potential for sodium, which is +60 mV as derived from Nernst equation, because of the following three factors.

At the peak of the action potential:
1. Sodium influx abruptly ceases due to the closure of the inactivation gates of the Na⁺ channels. The Na⁺ channels open very fast, remain open for a very brief period, and they close very fast. The process of speedy closure is called rapid autodeactivation.
2. The voltage-gated potassium channels being fully open, allow the exit of positively charged K⁺ ions.
3. The electrical gradient for Na⁺ is reversed subsequent to the overshoot, i.e. after crossing RMP of 0 mV, inside of the cell membrane becomes positive and it hinders the positively charged Na⁺ to enter the positive interior, slowing down further sodium entry.

During an action potential, approximately 20,000 Na⁺ ions enter into the cell. The repolarizing forces try to restore the resting membrane potential, but the depolarization is large enough to overcome the opposing forces and produce an action potential.

**Repolarization**

Repolarization is due to opening of voltage-gated K⁺ channels, causing efflux of K⁺. Actually, these K⁺ channels are sensitive to the same depolarization that opens the voltage-gated Na⁺ channels but they open more slowly:

1. At the peak of the action potential, the voltage-gated Na⁺ channels enter a closed state whereas the voltage-gated K⁺ channels are fully open.
2. The membrane permeability to potassium ions increases several times causing increased potassium efflux. The K⁺ concentration is much higher inside the cell and at the peak of the action potential, outside of the membrane is negative in comparison to inside, which is positive (+35 mV).
3. These two factors favor the electrochemical gradient for potassium efflux.
4. Thus, the rapid falling phase of repolarization is brought about by decline in sodium influx together with increase in potassium efflux.
5. The termination of action potential due to activation of voltage-gated potassium channels is a negative feedback process.

Following the phase of rapid fall, once the membrane potential drops close to the isopotential level and moves towards RMP, the inside of the membrane becomes negative that limits the efflux of potassium. Thus, after-depolarization phase is due to the slower exit of potassium ions that considerably decreases the rate of repolarization and makes the repolarization curve oblique (less steep).

**Voltage-gated Na⁺ and K⁺ Channels**

The Na⁺ channel has two gates, an activation gate and an inactivation gate:

1. When the membrane is at rest, the inactivation gate is open and the activation gate is closed. This is the resting state of the channel in which Na⁺ influx cannot occur. The K⁺ channel has only one gate that remains closed during the resting state (Fig. 23.4A).
2. As the membrane is depolarized to the firing level, the activation gate of Na⁺ channel opens. This is the activated state of the Na⁺ channels in which, both the gates are open permitting massive influx of Na⁺ that brings the membrane potential to +35 mV (Fig. 23.4B).
3. The gate of the K⁺ channel start opening at the same time as the activation gate of Na⁺ channel, but K⁺ gates open slowly.
4. At the peak of the action potential, the inactivation gate of Na⁺ channel closes. This is the inactivated state of the Na⁺ channels, in which Na⁺ influx stops. Also, the activation gate of Na⁺ channel is about to close (Fig. 23.4C).
5. At this time, the gates of K⁺ channel are fully open allowing K⁺ efflux and causing rapid repolarization (Fig. 23.4D).
6. In the later part of repolarization, the activation gate of Na⁺ channel is closed and the inactivation gate starts opening slowly. This is the closed state of the Na⁺ channels (Fig. 23.4E).
7. By now, the K⁺ channel gates have started to close but they take a longer time to shut down completely (Fig. 23.4F).
8. Then the channels proceed to the resting state, where, the inactivation gate of Na⁺ channel is fully open; the activation gates of Na⁺ channels and the K⁺ channel gates are fully closed causing no ion movement across the channels.

**After-Hyperpolarization**

1. Following after-depolarization, the membrane reaches the resting potential (RMP). At this level, though most

of the voltage-gated K⁺ channels are closed, some of them still remain open allowing continued efflux of K⁺.
2. As a result, the membrane potential becomes more negative than the RMP, giving rise to the prolonged and slow undershoot, which is called as phase of after-hyperpolarization.
3. Finally, the K⁺ channels completely close, restoring the membrane potential back to the resting level.

** Ionic Conductance during Action Potential **

Conductance of an ion means the ease with which the ion passes through the plasma membrane. It indicates the permeability of the membrane to the ion. Conductance is reciprocal of resistance, offered by the membrane as well as the potential gradient across the membrane hindering the passage of the ion through the membrane:

1. The Na⁺ conductance rises gradually from the RMP to the firing level, and then it fast increases reaching a peak. At the peak of the action potential, it declines rapidly and comes to the base line.
2. The K⁺ conductance rises after the rise in Na⁺ conductance. Initially, the conductance increases at a much slower rate during the phase of depolarization. Just after the peak of the action potential, the conductance increases to its maximum during the rapid falling phase of repolarization. After that, the K⁺ conductance decreases but takes a long time to reach the base line (Fig. 23.5).

**Ionic Activity after Action Potential**

At the end of an action potential, the ionic composition on both sides of the membrane is altered. This leaves more sodium and less potassium inside the cell:
Chapter 23: Nerve Potentials

1. The ionic composition is restored by **increased activity of the Na⁺-K⁺ ATPase**.
2. The number of ions that take part in generation of a single action potential is very little compared to the total number of ions in the cell (1 of every one million Na⁺ go into the cell and about the same number of K⁺ come out of the cell during an action potential). This produces a negligible change in the intracellular ionic concentration.
3. However, if this imbalance was not taken care of, in the long run, following repeated generation of action potentials, it would be difficult to generate action potentials further, because slowly the concentration gradients of sodium and potassium across the membrane will cease to exist.

**Effects of Extracellular Ionic Changes**

1. When the **extracellular Na⁺ concentration is decreased**, the amplitude of the action potentials becomes smaller than usual because the concentration gradient for Na⁺ that drives sodium into the cell is reduced.
2. When the **extracellular Na⁺ concentration is increased**, the amplitude of the action potentials may increase.
3. When the **extracellular K⁺ concentration is decreased**, the membrane potential becomes more negative as the resting K⁺ efflux is increased favoured by the increased concentration gradient across the membrane.
4. When the **extracellular K⁺ concentration is increased**, the membrane potential come closer to the firing level and the membrane becomes more excitable.
5. When the **extracellular Ca²⁺ concentration is decreased**, the electrical potential difference across the membrane is decreased, as the inside becomes less negative compared to outside. The RMP come closer to the firing level, so that, the magnitude of depolarization needed to reach the firing level is less. Hence, decrease in extracellular Ca²⁺ concentration increases the excitability of the tissue, as observed in hypocalcemic tetany, occurring in hypoparathyroidism.
6. If the **extracellular Ca²⁺ concentration is increased**, the RMP goes away from the firing level due to increased potential difference across the membrane. Consequently, the magnitude of depolarization needed to reach the firing level is more, decreasing the tissue excitability.

**Ion Channel Blockers**

**Na⁺ Channel Blockers**

The drugs like lidocaine, procaine ‘etc., and neurotoxins like tetrodotoxin, saxitoxin’ etc., block the voltage-gated Na⁺ channels and hinder the generation of action potentials.

**Local Anesthetics**

Lidocaine and procaine are used clinically as local anesthetics during various surgical procedures. When injected into the affected tissue or sprayed over an area, the ionizable hydrophobic drug molecules diffuse readily through the plasma membrane and block the Na⁺ channels and decrease the transmission of pain and other sensations. Axons with a smaller diameter are more sensitive to the local anesthetics than the large diameter fibers.

**Membrane Toxins**

The neurotoxins like tetrodotoxin (TTX) is found in ovaries of puffer fish and in tissues of salamanders, and saxitoxin (STX) is accumulated in the tissues of shellfish. Both are lethal paralytic toxins and eating a small quantity of tissue containing the toxins can lead to death. These animals have survived by developing resistance against the toxins’ i.e. they have TTX-resistant or STX-resistant sodium channels.

**K⁺ Channel Blockers**

The voltage-gated K⁺ channel blockers are tetraethylammonium (TEA) and 4-aminopyridine (4-AP). These chemicals along with TTX are used extensively by scientists in electrophysiological research, like study of voltage-clamp techniques.

**Na⁺–K⁺ ATPase Blocker**

Drugs like digitalis and dinitrophenol block the Na⁺–K⁺ ATPase pump.

**All-or-None Law**

**Definition**

All or none states that the action potential occurs with a constant amplitude and shape irrespective of magnitude of the stimulus. A **subthreshold stimulus** fails to excite the tissue. Only a stimulus of **threshold magnitude** elicits an action potential. If **suprathreshold stimuli** are applied, the action potentials resulting from them have the same amplitude, duration and form as those produced by threshold stimuli, provided the experimental conditions like electrical potentials on both sides of the membrane, concentration of ions in ICF and ECF, ‘temperature’ etc. remain same (Fig. 23.6).

**Mechanism**

The activation gates of voltage-gated Na⁺ channels open as soon as 15 mV of depolarization is achieved. Following that, any extra degree of depolarization is of no further use, as the membrane automatically achieves another +90 mV of depolarization (−55 to +35 mV):

1. Thus, **after the threshold level is achieved**, the amount of sodium influx becomes independent of the stimulus factor.
2. The number of voltage-gated Na⁺ channels over the axonal membrane of unmyelinated axons as well as at the nodes of Ranvier in myelinated axons remain fairly constant.
3. Once the action potential is formed, it appears with its maximum size and shape, otherwise it does not form at all.
4. Therefore, the action potential follows the all-or-none law; i.e. the action potential occurs with a constant amplitude and shape whether the stimulus is of threshold or suprathreshold magnitude.

**Refractory Periods**

During the action potential, the stimulated area of the membrane happens to be unresponsive to a second stimulus in most part, and later it requires a stronger stimulus to get excited again. The length of time during which the membrane is unresponsive to a second stimulus no matter how strong is the stimulus, is known as refractory period. The periods of total and relative refractoriness are known as absolute and relative refractory periods respectively.

**Absolute Refractory Period**

**Definition and Duration**

Absolute refractory period (ARP) is defined as the period in the action potential during which, application of a second stimulus of any strength and duration does not produce another action potential. The ARP corresponds to the period from the time the firing level is reached until repolarization is about one-third complete (Fig. 23.7).

**Mechanism**

At the peak of the action potential, the inactivation gates of the voltage-gated sodium channels close and they remain in that inactivated state for some time before returning to the resting state. These sodium channels can reopen in response to a second stimulus, only after attaining the resting state. Hence, even if a stronger stimulus is applied during this interval, it will not produce a second action potential, and the membrane is said to be in its absolute refractory period.

**Relative Refractory Period**

**Definition and Duration**

Relative refractory period (RRP) is defined as the period following ARP during which, application of a suprathreshold stimulus can elicit a second action potential. The RRP starts from the end of ARP to the start of after-depolarization.

**Mechanism**

The following factors contribute to RRP:
1. All the sodium channels present at the site of stimulus do not achieve the open state or inactivated state or resting state, exactly at the same time. Few of them open when the membrane potential is ~63 mV, causing local response. By the time of relative refractory period, some of the channels have returned to their initial resting state. These channels in resting state can open their activation gate and allow the influx of Na⁺.
2. A suprathreshold stimulus can spread to larger area over the membrane and open extra voltage-gated sodium channel.

**Physiological Importance**

The absolute refractory period limits the number of action potentials that the nerve can fire in a given period of time. ARP serves two important functions:
1. ARP determines the rate of discharge of nerve fiber. In our body, nerves fire at a rate of 10 to 1000 impulses per second. Generally, large diameter nerve fibers have an ARP of about 0.4 msec, with a firing rate of 2500 impulses per second, whereas small diameter fibers have an ARP of about 4 msec, with a firing rate of 250 impulses per second.
2. The ARP is also responsible for the one-way conduction of action potentials (this will be discussed under the propagation of action potential).
Thus, only a suprathreshold stimulus and not any threshold stimulus can open up sufficient number of sodium channels to elicit an action potential during the RRP.

The excitability of the membrane keeps on changing in different phases of the action potential. Usually, the time the membrane potential is closer to the firing level, the membrane is more excitable; and the excitability of the membrane decreases, when its potential is away from the firing level. During the ARP, it is least excitable.

**Initiation and Propagation of Action Potential**

**Initiation of Action Potential**

The production of action potentials requires the presence of large number of voltage-gated ion channels that are present mostly on the axons. Therefore, it is the axon, not the cell body or the dendrites that generate and conduct the action potentials:

1. The action potential is first initiated in the specialized areas in the axon called the first node of Ranvier in sensory neurons and initial segment-axon hillock in motor neurons.
2. These areas are known as trigger zones that have a very high concentration of voltage-gated sodium and potassium channels.
3. The synaptic potential generated at the dendrites and, or the cell body is integrated by the cell body and transmitted to the axon hillock.
4. If this potential is sufficient to depolarize the membrane of the axon hillock to firing level, the membrane easily fires an action potential.

**Propagation of Action Potential**

Once formed, the action potential is regenerated at regular intervals to be transmitted from the initial segment of the axon to the axon terminal. This is known as the propagation of action potential. In myelinated axon, the speed and mode of propagation of action potential is different from that in unmyelinated axon.

The speed of conduction of the impulse depends on two factors:

1. **Myelination**: Conduction velocity is more in myelinated axon and is proportionate to the degree of myelination.
2. **Diameter of the axon**: Conduction velocity is proportionate to the diameter of the fiber. Fibers with larger diameter have faster rate of conduction. The large diameter fibers have less cytoplasmic resistance. So, the flow of ions across the membrane is easier.

**In Unmyelinated Axon**

At the site of genesis of an action potential, large influx of positive charges into the membrane occurs, which is known as current sink. The positive charges diffuse away from the site of accumulation. The adjacent membrane, which is in its resting state, has a potential of –70 mV:

1. This potential difference allows the positive charges to flow toward the adjacent negative area. Consequently, the potential of the adjacent membrane decreases and reaches the threshold value, as the fraction of Na⁺ ions that move to the nearby negative area are sufficient enough to bring the adjacent membrane to the firing level. This results in opening of the voltage gated Na⁺ channels present in that area, firing an action potential.
2. Similarly, from the site of second action potential, positive charges flow to the adjacent resting membrane and decrease its potential to the threshold level. This activates the voltage gated Na⁺ channels present in that part of the membrane resulting in another action potential.
3. In this manner, each point of the membrane gets depolarized to the firing level and produces an action potential.
4. As the depolarization and repolarization phases of the ensuing action potentials go on, there is a sequential opening and closing of sodium and potassium channels along the axonal membrane (Fig. 23.8).
5. The action potential does not move by itself but helps to generate a new action potential in the membrane ahead of it. As the number of voltage gated Na⁺ and K⁺ channels are distributed uniformly along the axon, the action potential arriving at the end of the axon is almost identical in appearance to the initial one. Thus, due to the local current flow produced following an action potential, there occurs serial depolarization of the adjacent membrane to the firing level and action potential travels, being successively regenerated along the membrane in an all-or-none manner.
6. At the same time, the exterior of the membrane which becomes negative due to current sink attracts flow of positive charges from the adjacent regions toward the site of application of stimulus. Thus, on both sides of the site of action potential, a circular pattern of current flow occurs across the membrane; i.e., inside the membrane, positive charges flow away from the site of action potential, whereas outside the membrane, positive charges flow toward the site of action potential. This circular pattern of current flow tries to restore the resting potential of the membrane where the action potential was previously generated.
In Myelinated Axon (Saltatory Conduction)
There are few voltage gated Na⁺ channels on the surface of the myelin:

1. **Myelin acts as an insulator** and does not allow free flow of ions across the membrane. Therefore, as the positive charges flow from the site of action potential to the adjacent area, large Na⁺ influx (as occurs during an action potential) does not occur in the myelinated portion of the membrane, though it may attend the threshold potential of –55 mV. Also, in the myelin sheath, the concentration of positive charges does not decrease fast because of less ‘leakage’. This helps the charges to spread farther along the axon.

2. The local current (the positive charges) travels like a graded potential and dies away 37% of its maximal strength over a distance of about 3 mm.

3. As the internodal distance is 1–2 mm, the local current definitely arrives at the adjacent node of Ranvier and decreases its membrane potential. Most importantly, the **voltage gated Na⁺ channels are present in large numbers at the nodes of Ranvier**. Therefore, as soon as the nodal membrane gets depolarized to threshold level, an action potential is quickly fired.

4. Thus, in the myelinated axon, the action potential is **generated at each node of Ranvier** (Fig. 23.9).

5. Because the action potential rapidly proceeds from one node to the next and pause at each node to get regenerated, the mode of propagation of action potential in myelinated axon is known as **saltatory conduction** (Latin word ‘saltare’ means to jump).

**Advantages in Myelinated Axon**
In myelinated axon, the velocity of conduction is faster. Besides, myelination also helps to conserve energy. Since the ionic flux occurs only at the nodes of Ranvier, the total membrane area across which ionic balance has to be restored is much less compared to the unmyelinated axon. Therefore, in unmyelinated axons, voltage-gated channels open throughout the axonal length causing activation of a larger number of Na⁺-K⁺ ATPase and higher expenditure of energy.

**Direction of Propagation of Action Potential**
In the motor neuron, the action potential is conducted from axon hillock toward axon terminal. In the sensory neuron, it propagates from the first node of Ranvier toward CNS. This is called **anterograde conduction** of impulse:

1. The axon contains a large number of voltage gated Na⁺ channels that promotes in quick generation of an action potential in the axonal membrane next to the trigger zone.

2. The action potential **does not travel from the axon back toward the trigger zone**. This is because; following depolarization, the area on the membrane where action potential was produced becomes refractory.

3. Therefore, though local currents from the site of next action potential tend to bring the membrane toward threshold value, the membrane does not fire an action potential, as the sodium channels remain inactivated.

4. Hence, the action potential can be conducted only in the direction away from the site of previous action potential.

5. The action potential can spread from the point of stimulus in both directions along the axon, if it is initiated between trigger zone and axon terminal.

**Differences between Graded Potential and Action Potential**
From the above discussions, we note that many differences exist between graded potentials and action potentials. The major differences are listed in Table 23.1.

# CHAPTER SUMMARY

## Key Concepts

1. Electrotonic potentials are local, non-propagated potentials of small magnitude, in response to a depolarizing or hyperpolarizing stimulus of lesser strength.

2. **Threshold stimulus** is the lowest strength of stimulus that elicits an action potential. This brings the membrane potential to –55 mV. The stimuli less in strength than the threshold are known as **subthreshold stimuli** and the stimuli higher in strength than the threshold are known as **suprathreshold stimuli**.

3. **Chronaxie** is the time required for a stimulus of double the rheobase strength to produce an action potential. Chronaxie indicates excitability of a tissue. Lesser the chronaxie, greater is the excitability.

4. In an action potential, **depolarization is due to influx of sodium** and **repolarization is due to efflux of potassium**.

5. Absolute refractory period (ARP) is defined as the period in the action potential during which, application of a second stimulus of any strength and duration does not produce another action potential. ARP is the period from the firing level to the one-third of repolarization.

6. The speed of conduction of impulse in myelinated neuron is much faster due to presence of large number of Na$^+$ channels at nodes of Ranvier that makes the conduction saltatory in nature.

## Important to Know (Must Read)

1. In examinations, usually **Long Questions** are not asked from this chapter.

2. Electrotonic potentials, Local response, Strength-duration curve, Labeled diagram and ionic basis of action potential, All or none law, Refractory period, Propagation of action potential along the axon, and Saltatory conduction, are usual **Short Questions** in exams.

3. In **Viva**, examiners may ask........ definition and importance of electrotonic potentials, meaning and ionic basis of local response, definition and importance of rheobase, chronaxie and utilization time, different phases and ionic basis of action potential, latent period, definition of firing level, threshold, subthreshold and suprathreshold stimuli, All or none law, definition of absolute and relative refractory period, their mechanisms and importance, how is action potential propagated in unmyelinated and myelinated axons, saltatory conduction, and differences between graded potential and action potential.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. List the properties of nerve fibers.
2. Classify nerve fibers and mention their functions.
3. Describe the degenerative (Wallerian degeneration) and regenerative changes following nerve injury.

The student MAY also be able to:
1. Describe the properties of nerve fibers.
2. Classify nerve fibers and mention their functions.
3. Explain the changes in nerve fibers following injury.

Properties of Nerve Fibers

Important properties of the nerve fibers are as follows:
1. Excitability
2. Conductivity
3. Unfatigability
4. Refractory period
5. All-or-none law
6. Summation
7. Accommodation

Refractory period and ‘All-or-none law’ of nerve fibers have already been described in the previous chapter.

Factors Affecting Excitability

1. Strength and duration of the stimulus
2. Effect of extracellular Ca^{++}
   i. Decrease in ECF Ca^{++} increases excitability of neuron by decreasing the amount of depolarization necessary to initiate the changes in the Na^{+} and K^{+} permeability that produces the action potential.
   ii. Increase in ECF Ca^{++} stabilizes the membrane by decreasing excitability. Ca^{++} entry contributes to depolarization.

Conductivity

On stimulation, action potential is generated in the nerve fiber, which is propagated along its entire length to the axon terminal (described in detail in the previous chapter).

Orthodromic and Antidromic Conduction

An axon can conduct in either direction. If the stimulus is applied in the middle junction of axon, the action potential initiated in the middle of it can travel in both directions, due to set-up of electronic depolarization on either side of the initial current sink.

Excitability

Excitability is the property by virtue of which cells or tissues respond to changes in the external or internal environments. It is due to the disturbances in the ionic equilibrium across the receptive zone of cell membrane. The nerve fibers are highly excitable tissues. They respond to various forms of stimuli—mechanical, thermal, chemical or electrical. In experiment set-up, ‘electrical’ stimulus is usually employed, because its strength and frequency can be accurately controlled, nerves respond well to chemical and thermal stimuli. The production of a wave of depolarization, and (excitation or activation) impulse demonstrates that a nerve has been excited.
1. Impulses normally pass from synaptic junction to the axon terminal, which is called **orthodromic conduction**.

2. Conduction in the opposite direction is called **antidromic conduction**, seen in sensory nerve supplying the blood vessels. **Axon reflex** is an example of antidromic conduction.

**Summation**

Application of a subthreshold stimulus does not evoke an action potential. However, if subthreshold stimuli are applied in rapid succession, they are summated and they produce an action potential. This property is called **summation**.

**Accommodation**

Application of continuous stimuli may decrease the excitability of the nerve fiber, a phenomenon called **accommodation**. More than nerve fiber, it is nerve endings that adapts. This decreases the transmission of impulse across the neurons.

1. If a nerve is submitted to the passage of constant strength of current, the site of stimulation shows decrease in excitability. The accommodation consists of a rise in threshold of the membrane during stimulation

2. A similar feature observed at at nerve endings is called **adaptation**.

3. Thus, nerve fiber accommodates while the nerve endings adapt.

**Unfatigability**

Nerve fibers cannot be fatigued, even when they are stimulated continuously. This is because the nerve fibers primarily conduct impulses (propagation of action potential) that do not involve expenditure of energy (ATP).

**CLASSIFICATION OF NERVE FIBERS**

Based on function, nerves are classified as motor, sensory and secretomotor, and based on myelination, they are classified as myelinated and unmyelinated. Likewise, though there are many classifications of nerve fibers, the most appreciated and popular classification is of **Erlanger and Gasser**, which is based mainly on their diameter and conduction velocity.

**Scientists contributed**

Joseph Erlanger (1874–1965)  
Herbert S. Gasser (1888–1963)

The **Nobel Prize in Physiology or Medicine for the year 1944** was awarded jointly to two neurophysiologists from USA, Joseph Erlanger and Herbert Spencer Gasser, “for their discoveries relating to the highly differentiated functions of single nerve fibers”. They worked extensively on nerve fiber types and the classification of nerve fibers is named after them ‘Erlanger-Gasser classification’.

**Erlanger-Gasser Classification**

This is the most popular classification of nerve fibers, based on their diameter and conduction velocities. Broadly fibers are classified into three categories: A, B and C.

**Type A Nerve Fibers**

These are the fastest conducting fibers with conduction velocity ranging from 70 to 120 m/sec. The fiber diameter varies from 12 to 20 µm. Type A fibers are further subdivided into α, β, γ and δ fibers (Table 24.1).

1. **Aα fibers** supply extrafusal fibers in skeletal muscles and also carry proprioception.
2. **Aβ fibers** carry touch pressure sensation and act as motor fibers.
3. **Aγ fibers** supply intrafusal fibers in muscle spindles.
4. **Aδ fibers** are mainly fast conducting nociceptive fibers.

**Type B Nerve Fibers**

These are preganglionic autonomic afferent and efferent fibers. They have a diameter of less than 3 µm and conduction velocity ranging from 3 to 15 m/sec.

**Type C Nerve Fibers**

These are unmyelinated fibers. They are subdivided into two broad categories: **dorsal root fibers** that carry various...
sensations and have diameter of 0.4 to 1.2 µm and their conduction velocity varies from 0.5 to 2 m/sec, and post-ganglionic sympathetic fibers with diameter 0.3 to 1.3 µm and conduction velocity of 0.7 to 2.3 m/s (Table 24.1).

**Numerical Classification**

Sensory nerve fibers are typed into Ia, Ib, II, III and IV. A comparison of the numerical classification and the later classification is shown in Table 24.2.

**Classification by Susceptibility to Various Agents (Hypoxia, Pressure and Local Anesthetics)**

**Hypoxia:** Type B fibers are most susceptible to hypoxia. Type C is the least susceptible.

**Pressure:** Type A fibers are most susceptible to pressure and type C is the least. This is because of fiber diameters.

**Local anesthetics:** Type C fibers are most susceptible to local anesthetics and type A is least susceptible.

### APPLIED ASPECTS

#### Demyelinating Diseases

**Multiple Sclerosis**

In multiple sclerosis, patchy loss of axonal myelin occurs at several areas in the nervous system, resulting in decreased conduction velocity along the fiber.

1. The pathways commonly affected are pyramidal tracts, cerebellar tracts, medial longitudinal fasciculus, optic nerve and posterior columns.
2. The symptoms vary depending on the site of affection. The usual symptoms are sensory abnormalities (decreased or abnormal sensations or pain), muscle weakness, fatigue, spasticity, optic neuritis, diplopia and ataxia (poor coordination).

**Demyelinating Form of GBS**

In demyelinating form of Guillain-Barre syndrome, loss of myelin causes abnormal conduction.

### Nerve Injury

When a nerve is sectioned, the distal part of the nerve separated from the cell body degenerates. This is called **Wallerian degeneration**. The proximal portion of the axon still attached to the cell body and then develops a growth cone and grows distally toward the distal portion; the changes associated are known as **regenerative changes**. The soma gets informed about the injury by absence of substances transported retrogradely from the axon terminals.

#### Grading of Nerve Injury

Based on severity, nerve injury is typed into five degrees:

1. **First-degree injury** is transient loss of function that occurs due to a mild pressure on the nerve. The temporary loss of function is mainly caused by local ischemia following obstruction to the blood flow. Nerve fibers completely recover within few hours to few weeks.
2. **Second-degree injury** includes nerve damage with intact endoneural tube. This occurs due to prolonged pressure on the nerve. The regeneration is delayed but complete as endoneural tube is intact.
3. **Third-degree injury** is the severe damage to the nerve fiber that interrupts endoneural tube.
4. **Fourth-degree injury** refers to a severe damage to the nerve associated with disorganization of nerve fasciculi.
5. **Fifth-degree injury** is the complete transection of the nerve. The degenerative changes occur early.

#### Degenerative Changes (Wallerian Degeneration)

The degenerative changes occurring in the distal segment of the axon are called **Wallerian degeneration**, named after its discoverer August Waller. The changes are as follows (Figs. 24.1A to D):

1. **Transmission of Impulse:** Shortly after the injury, synaptic transmission occurring at the axon terminal stops within hours.
2. **Axonal changes:** The axon swells and the terminals retract from the postsynaptic target. Gradually, over a period of several weeks, the axon and all its terminals degenerate. If the axon is myelinated, round...
fatty enlargements form all over the myelin sheath that looks like a series of beads (Fig. 24.1B). The myelin sheath breaks down but the myelinating cells remain viable (Schwann cell in the PNS and oligodendrocyte in the CNS). The debris created by the disintegration of the axon and its myelin is devoured by macrophages and Schwann cells in the PNS and microglia in the CNS. The phagocytic process is rapid in the PNS than in the CNS.

3. **Effect of stimulation:** On stimulation, the distal axon can conduct an action potential up to 3 days; this ability is impaired from 3rd to 5th day, and action potential cannot be initiated after the 5th day.

4. **Changes in soma and the stump:** Following injury, degenerative changes are seen in the soma and, to some extent in the proximal stump. These changes are known as **retrograde degeneration.** The changes are:
   i. Cell body swells and becomes rounded.
   ii. The nucleus also swells and moves to an eccentric position (Fig. 24.1B).
   iii. Endoplasmic reticulum instead of being closer to the nucleus reassembles around the periphery of the cell body.
   iv. The ribosomes appear disorganized.
   v. The Nissl granules gradually disintegrate and are stained weakly with basic dyes; this is known as **chromatolysis** (Fig. 24.1C).

**Regenerative Changes**

The soma tries to repair the axon by synthesizing new structural proteins that fills up and distends the cisterns of the rough endoplasmic reticulum. This is known as **axonal reaction.** Chromatolysis is reversible, if the neuron survives and re-establishes its contact with the appropriate target.

**Axonal Changes**

The proximal end of the axon develops **many sprouts** (Fig. 24.1C).

1. The sprouts elongate by formation of a **growth cone** at their growing ends (Fig. 24.1D).
2. The Schwann cells that had survived the degeneration **multiply** and **form rows** along the pathway previously taken by the disintegrated distal axon.
3. Out of the many sprouting branches, one branch finds the way through the Schwann cells and finally **reinnervates the original target structure.**
4. The regeneration rate of the growing axon is about 1–4 mm/day.
5. The Schwann cells then lay down their bilayered membrane to form the myelin sheath around the newly formed axon.

**Somatic Changes**

The soma regains its size. The number of Nissl granules slowly reappears. Other organelles also reappear. The cell loses excess fluid and regains its normal size. The nucleus occupies the central position (Fig. 24.1E).

**Changes in Target Structure**

Following degeneration of the nerve, the neurotransmitter release at axonal terminal decreases.

1. Decreased neurochemical at the synaptic cleft leads to **upregulation of the receptors** in the target structure.
2. Therefore, when a neurotransmitter is released following regeneration, the response of the target tissue to the neurotransmitter is increased. This is called denervation hypersensitivity (for details, refer to next chapter).

Factors Influencing Regeneration
Successful axonal and somatic regeneration depends mainly on four factors: severity of the injury, degree of damage to the cell body, site of injury and secretion of neurotrophins.

Severity of Injury
If the gap between the proximal and distal parts is more than 3 mm, the multiple outgrowths intermesh and form a tumor-like swelling called neuroma.

1. If neuroma is formed, successful regeneration can never occur.
2. If the neuroma involves sensory fibers, pain is felt at the site when touched.

Condition of Soma
If the axonal damage is close to the cell body, a larger part of the neuronal membrane and cytoplasm is lost. In such situations, the neuron often dies instead of regenerating.

Location of Injury
In the CNS, a single oligodendroglia sends out many processes to myelinate several (around 15) axons. Therefore, even though the axonal sprouting occurs, the oligodendroglia cannot form a path along which the sprouts can grow. Besides, glial scars formed by astrocytes pose obstruction in the pathway of the growth cone. Hence, axons in the CNS regenerate less successfully than axons in the PNS.

Neurotrophins
When specific neurotrophins are administered to the site of injury, the growth of the regenerating sprout is enhanced and enmeshing of the branches does not occur.

CHAPTER SUMMARY

Key Concepts
1. Nerve fibers are highly excitable tissues, strictly follow all-or-none law, and they do not exhibit fatigability.
2. Nerve fibers are classified based on their fiber diameter and conduction velocity. A fiber has maximum diameter (12–20 µm) and maximum conduction velocity (70–120 m/s). Type C fibers are most susceptible to local anesthetics.
3. The degenerative changes in the distal segment following nerve injury are called Wallerian degeneration.
4. The target organ (muscle) responds more to stimuli due to upregulation of receptors. This phenomenon is called denervation hypersensitivity.
5. Neurotrophins facilitate regeneration.

Important to Know (Must Read)
1. In the examinations, ‘degenerative and regenerative changes following nerve injury’ may sometimes come as a Long Question.
2. ‘Properties of nerve fibers, Erlanger-Gasser classification of nerve fibers, Wallerian degeneration, Regenerative changes following nerve injury’ are usual Short Questions in exams.
3. In Viva, examiners may ask about the properties of nerve fibers, definition of refractory period, All-or-none law, types of classification of nerve fibers, Erlanger-Gasser classification of nerve fibers, types of nerve fibers, features of Wallerian degeneration, regenerative changes following nerve injury.
Neuromuscular Transmission

Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Draw the schematic diagram of neuromuscular junction (NMJ).
2. Describe the events of neuromuscular transmission at presynaptic, synaptic and postsynaptic parts of NMJ.
3. Classify neuromuscular blockers and give their mechanism of action.
4. Name the common disorders of NMJ and give their physiological basis.
5. Understand the mechanism of denervation hypersensitivity.

The student **MAY** also be able to:
1. Explain the physiological basis of etiology, features and treatment of myasthenia gravis and Lambert-Eaton syndrome.

The junction between a motor neuron and a muscle fiber is known as the neuromuscular junction (NMJ). This is also called **myoneural junction** or **motor end plate**, through which action potential from the neuron is transmitted to the muscle fiber. At this junction, the neuronal membrane and the sarcolemma remain apposed to each other, but do not touch.

1. The nerve endings release vesicles containing **acetylcholine** (ACh) that diffuse across the gap and initiates action potential in the muscle fiber.
2. The NMJ is the most extensively studied and best understood synaptic connection in the nervous system where **chemical synaptic transmission** was first studied.
3. It is readily visible under the light microscope, has a relatively simple mechanism and easily accessible to experimentation. Therefore, it is an ideal site for **studying the basic features of chemical transmission**.

**Presynaptic Portion (Axon Terminal)**

The neurons innervating skeletal muscle fibers are known as **motor neurons** that have their cell bodies in anterior horn of the spinal cord or in the brainstem. Their axons are myelinated and are the **largest-diameter axons in the body**.

The **features of presynaptic portion** of NMJ are:
1. As the axon of motor neuron approaches the muscle fiber, it **loses its myelin sheath** and divides extensively into **several fine branches** of about 2 µm in diameter, called **axon terminals**.
2. The terminals are covered by Schwann cells, known as **teloglia** (glial cells at terminals).
3. Each terminal forms a junction with a single skeletal muscle fiber, midway along its length. Thus, each muscle fiber is supplied by one motor neuron terminal. The motor neuron, including its axon and axon terminals and the muscle fibers supplied by it are called a **motor unit**.
4. Each terminal is expanded at its end to form a knobby structure, called **synaptic knob (terminal button)**, which contains plenty of mitochondria and neurotransmitter vesicles (Fig. 25.1). The terminal button lies in the groove (**synaptic trough**) in the surface of the muscle fiber, but outside the muscle cell membrane. Presence of large number of mitochondria indicates higher metabolic activity at terminal region.

**STRUCTURE OF NEUROMUSCULAR JUNCTION**

The anatomy of neuromuscular junction may be broadly divided into three parts: Presynaptic, synaptic and postsynaptic portions.
Section 3: Nerve and Muscle

5. The vesicles are clustered around specific points called **active zones**. The membrane at the active zones is modified to form **dense bar** that contains numerous **voltage-gated Ca\(^{++}\) channels**. These channels mediate ACh release.

### Synaptic Cleft

This is the gap between the terminal button and the muscle fiber, which is about 40–100 nm wide.

1. The muscle fiber is covered by a layer of amorphous connective tissue called the **basement membrane** or **basal lamina**, consisting of collagen, glycoproteins and other extracellular matrix proteins.
2. The basement membrane in the cleft contains the enzyme **acetylcholine-esterase** (AChE), which is anchored to the collagen fibrils and is secreted into the basement membrane by the presynaptic terminal and the muscle fiber.
3. AChE rapidly hydrolyzes ACh into acetate and choline. The basal lamina helps organize the presynaptic buttons with the postsynaptic junctional folds.

### Postsynaptic Portion (End Plate Membrane)

The postsynaptic portion of the neuromuscular junction is known as the end-plate membrane (**motor end plate**). This is the part of the sarcolemma that lies directly under the terminal button (Fig. 25.1).

1. The area of the end plate membrane increases many times as it is thrown into several folds called **junctional folds**.
2. The endplate membrane contains numerous **ACh receptors** (AchR), which are concentrated at the crests of the junctional folds. It also contains voltage-gated Na\(^{+}\) channels.

### ACh Receptors at NMJ

ACh receptors (AChR) at NMJ are **nicotinic type**. An average end plate contains about 15–40 million AChR, which accounts for about **10,000 AchR per square micrometer** of end-plate membrane.

1. The AChR protein is a **chemically gated ion channel** that undergoes a configurational change and opens when two molecules of ACh bind to it.
2. The channel is **blocked by α-bungarotoxin**.
3. Because of its larger pore diameter (0.8 nm), AChR is permeable to both Na\(^{+}\) and K\(^{+}\). But, as the electrochemical gradient is favorable for Na\(^{+}\) entry, more sodium moves in than potassium coming out resulting in **net Na\(^{+}\) influx**.
4. AChR allows the **passage of only cations** because the anions are repelled by the fixed negative charges present in it.

### MECHANISMS OF NEUROMUSCULAR TRANSMISSION

Neuromuscular transmission (NMT) is the transmission of impulse from the motor neuron to the skeletal muscle fibers supplied by the neuron. Mechanisms involved in NMT are broadly divided into **three parts**: presynaptic events, synaptic-cleft events and postsynaptic events.

### Presynaptic Events

The purpose of presynaptic mechanism is to release acetylcholine into the synaptic cleft. This occurs in following steps:

1. Arrival of an action potential at the axon terminal **depolarizes the membrane** of the terminal buttons.
2. This causes activation and **opening of the voltage-gated calcium channels**, which leads to **calcium influx**.
3. Increased cytoplasmic calcium concentration increases movement of microtubules and microfilaments that leads to **migration of neurotransmitter vesicles** to the inner surface of the presynaptic membrane.
4. The vesicles **fuse with the membrane** and discharge their contents into the synaptic cleft by **exocytosis**. Various membrane proteins present in the vesicular membrane as well as in the neuronal membrane are involved in the fusion process. Effective interaction between **synaptobrevin**, a vesicular membrane protein with **syntaxin**, a neuronal membrane protein occurs in the presence of SNAP-25, α/γ SNAP, NSF and many other associated proteins.

**Quantal Release**

Depolarization of the terminal button causes synchronous releases of about 60–200 vesicles from different parts of the presynaptic membrane. All the vesicles are roughly of the same size. Each vesicle contains around 4000–10,000 AcCh molecules.

1. The vesicle or the multimolecular **packet of ACh** is known as **quantas**, and, the process of release is known as **quantal release** of neurotransmitter.

2. With each action potential, the presynaptic terminal discharges about the same amount of neurotransmitter, collectively known as a “quantum of neurotransmitter” or “**quantal content**”, which is synonymous with “number of vesicles released”.

**Scientists contributed**

Ulf von Euler (1905–1983)

Julius Axelrod (1912–2004)

The Nobel Prize in Physiology or Medicine 1970 was awarded jointly to Sir Bernard Katz, Ulf von Euler and Julius Axelrod “for their discoveries concerning the humoral transmitters in the nerve terminals and the mechanism for their storage, release and inactivation”. They contributed to the understanding of synaptic transmission, especially they explained the mechanism of presynaptic events.

**Events at the Synaptic Cleft**

The released ACh molecules diffuse across the synaptic cleft and **bind to the receptors present at the post-synaptic membrane**.

1. On their way to the end plate membrane, some ACh molecules are **hydrolyzed by AChE**, and some **diffuse out of the synaptic cleft**.

2. However, the amounts that arrive at the end plate region and get bound to AChR, is **sufficient enough** to produce an action potential in the muscle fiber.

**Events at the End Plate**

The major purpose of postsynaptic mechanism is to **generate action potential in sarcolemma** adjacent to end plate. This occurs in following steps (Flowchart 25.1):

1. The binding of ACh to AChR in the end-plate membrane allows Na⁺ influx, producing a rapid local depolarization of the motor end plate known as **end plate potential (EPP)**.

2. EPP decreases the membrane potential to the firing level and opens the voltage-gated Na⁺ channels resulting in an **action potential** at the membrane adjacent to the end plate region. The voltage-gated Na⁺ channels are present all over the sarcolemma.

3. The action potential propagates along the sarcolemma and T-tubule network, activating the contractile machinery. As the motor end-plate is present at the middle of a muscle fiber, action potential **propagates in both directions**.

4. The binding of ACh to AChR is **loose and reversible**. Soon ACh diffuses away and gets **rapidly hydrolyzed by AChE to acetate and choline**.

5. The action of ACh is terminated leading to closure of ion channels, cessation of end plate potential and consequently action potential. The membrane potential of the end plate **returns to the resting state**.

6. The acetate diffuses away into the extracellular fluid and choline is taken up by the presynaptic terminal to be reused for the synthesis of new ACh.

All these events at the neuromuscular junction occur in a **few milliseconds** and can be repeated several times per second without fatigue.
End Plate Potential (EPP)

The EPP is like a graded potential, the amplitude of which is proportionate to the amount of neurotransmitters released.
1. EPP decays slowly with time and distance from the end plate region, which is known as decremental conduction. As AChE rapidly hydrolyzes ACh, the amplitude of EPP decreases with time.
2. Because the ACh-gated ion channels (AChR) are localized to the end plate membrane, EPP is generated at and confined to the end plate region only and therefore, the amplitude of EPP declines progressively with increasing distance from the end plate region.

EPP vs EPSP

In the CNS, most presynaptic neurons generate excitatory postsynaptic potential (EPSP) less than 1 mV, so that several EPSPs are required to attain the threshold and generate an action potential in the postsynaptic neuron. Whereas, in NMJ, the amplitude of an EPP is much larger compared to an EPSP in CNS.
1. Stimulation of a single motor neuron produces an EPP of about 70 mV.
2. EPP of this magnitude is much bigger than that required (15 mV) to bring the membrane potential to firing level.
3. Therefore, stimulation of a motor nerve always produces action potential in each muscle fiber supplied by it; i.e. all the muscle fibers in a motor unit contract in response to discharge of its motor neuron. In skeletal muscle, the EPP is always a depolarizing potential.
4. The EPP rises quickly resulting in an action potential as soon as the end plate membrane attains threshold level. During intracellular voltage recording, the magnitude of EPP gets flanked by the rising phase of action potential (Application Box 25.1).
The EPP was first recorded in 1950 by Paul Fatt and Bernard Katz by application of curare to the end plate membrane that blocked the Ach receptors, thereby decreased the amplitude of EPP below threshold level.

Application Box 25.1

Safety factor of EPP: A stimulated motor neuron produces an EPP of about 70 mV. Under normal circumstances, the amount of neurotransmitters released is enough to activate about 10 times the number of receptors required to produce an EPP that can bring the membrane potential to firing level. Due to this 10-fold safety factor, stimulation of a motor neuron never fails to excite an action potential in the muscle fibers of its motor unit. This reserve helps to elicit muscle contraction even in different pathological situations like (i) decrease in number or function of ACh receptors, (ii) decline in the quantity of ACh released, and (iii) abnormal voltage-gated Na+ channels in the end plate region.

Miniature End Plate Potential

When the motor nerve is at rest, spontaneously occurring potentials of minute amplitude (0.1 to 4 mV) are recorded from the postsynaptic membrane. These potentials are known as miniature end plate potential (MEPP).
1. They occur several times a second and have all the properties of an EPP.
2. MEPP occurs due to release of the contents of a single Ach vesicle by exocytosis (a quantal event) that opens around 2000 Ach channels in a very small area of the end plate membrane.

BLOCKADE OF NEUROMUSCULAR TRANSMISSION

The neuromuscular transmission is disrupted at different steps by drugs, chemicals, toxins and trauma. Failure to generate required EPP leads to paralysis of the skeletal muscles. The paralysis of the respiratory muscles endangers the life of the patient and has to be taken care of immediately. The drugs causing muscle relaxation are used during surgery and in some hyperactive states. The blockade can occur at presynaptic or postsynaptic level.

Presynaptic Blockade

Interruption of events taking place at the presynaptic axon terminal leads to impaired calcium influx causing decreased vesicle release.

Botulinum Toxins

The bacterium Clostridium botulinum releases a toxin that causes a paralytic disease called botulism.
1. The botulinum toxin is one of the most potent natural toxins, a minute amount of which causes serious illness.
2. The lethal dose for an adult human is around 2 to 3 µg.
3. Botulinum toxin B, D, F and G inactivate synaptobrevin, a vesicle membrane protein that is required for the binding and fusion of ACh vesicles with the plasma membrane of the axon terminal.
5. Thus, the botulinum toxin inhibits the release of acetylcholine from the axon terminals resulting in cessation of muscle contraction (flaccid paralysis) (Clinical Box 25.1).

Clinical Box 25.1

Clinical Uses of Botulinum Toxin: The paralytic effect of botulinum toxin is utilized for therapeutic and cosmetic purposes. Local injections of highly diluted toxin (botox treatment) produce muscle relaxation at the desired site. It is injected into the lower esophageal sphincter to treat achalasia cardia; into extraocular muscles to decrease their overactivity, which is used in the management of strabismus and blepharospasm; into facial muscles to reduce aging-related skin wrinkle and is used in cases of cervical dystonia. However, it can also be a lethal bioterrorism agent by dispersing it as an aerosol or by contaminating the food supply.
Hemicholinium
The drug inhibits choline uptake by the presynaptic terminal resulting in depletion of ACh. Consequently, the EPP decreases and action potential cannot be formed.

Postsynaptic Blockade
A variety of agents can act on the postsynaptic membrane interfering with generation of EPP by different mechanisms. They may be classified into competitive blockers and depolarizing blockers.

Competitive Blockers
Competitive blockers are blockers that block the receptors on postsynaptic membrane. Curare and gallamine are examples of competitive blockers of AChR. These substances diffuse to the end plate membrane and compete with ACh for AChR. Their attachment with AChR does not lead to opening of ion channels, as they do not have the biological activity of ACh. Moreover, they do not get hydrolyzed by AChE. So, the ACh binding sites in the receptors remain occupied permanently. In these conditions, motor nerve releases ACh, but ACh fails to bind to its receptor resulting in absence of EPP and lack of muscle contraction.

Curare
Curare is a plant product used as a South American arrowhead poison for hunting. The animal hit by such arrow suffers from paralysis in all skeletal muscles including the respiratory muscles. Consequently, the animal dies of asphyxiation.

Gallamine
Gallamine is given before surgery to relax the skeletal muscles.
1. It reduces the required dose of general anesthetic as well as bleeding and other complications.
2. As the respiratory muscles are also relaxed, patients are supported with artificial ventilation.

Depolarizing Blockers
Drugs like succinylcholine and carbamylcholine have the biological activity of ACh, but they are not hydrolyzed by AChE. Therefore, their action is long lasting. When they bind to AChR, the ion channels remain open in the end plate. The maintained depolarization keeps the voltage-gated Na⁺ channels in an inactivated state and blocks subsequent action potentials. There are other drugs that produce the blockade by inactivating AChE reversibly or irreversibly.

Reversible AChE Inhibitors
These agents compete with ACh to bind to AChE, thereby, prevent the hydrolysis of ACh by AChE. The accumulated ACh at the synaptic cleft binds to AchR, leading to a depolarizing block.
1. This is of use in diseases like myasthenia gravis, where excess ACh is a requirement in the face of decreased AChR.
2. Neostigmine and physostigmine (eserine) are examples of reversible AChE inhibitors. Their attachment with AChE decreases, when the concentration of the drug falls and so the block is removed after some time.
3. This block can be overcome by application of curare that attaches to AChR and reduces the effect of excess ACh on the end plate membrane.

Irreversible AChE Inhibitors
The organophosphorous compounds (pesticides like parathion, malathion and baygon) and nerve gases used in chemical warfare like disopropylfluoro-phosphate (DFP) and sarin, bind to AChE very tightly. This binding is irreversible.
1. Lack of hydrolysis of ACh produces sustained depolarization of the end plate resulting in no further contractions in response to subsequent nerve stimulation.
2. Poisoning with these agents lead to skeletal muscle paralysis and death from asphyxiation.
3. Nerve gases also cause accumulation of ACh at the cardiac pacemaker cells. Therefore, in cases of nerve gas exposure, atropine (a muscarinic receptor antagonist) is given as antidote.

NEUROMUSCULAR DYSFUNCTIONS

Myasthenia Gravis
It is a neuromuscular disorder of autoimmune nature, characterized by weakness and fatigability of skeletal muscles that gradually worsens as the muscles are used.

Etiology
Myasthenia gravis results from a decrease in the number of AChR present on the motor end plate due to production of circulating autoantibodies against these receptors (Figs. 25.2A and B). Moreover, the postsynaptic folds are flattened, or simplified. Due to these changes, though ACh is released normally, the magnitude of the end plate potential falls below the threshold for initiating a muscle action potential.

The anti-AChR antibodies have following three major functions:
1. They compete with ACh to bind to AChR, producing receptor blockade.
2. They induce endocytosis of AChR.
3. They damage the postsynaptic membrane.
Section 3: Nerve and Muscle

Features

1. **Fatigue**: Normally, on repeated stimulation of the motor nerve, the amount of ACh released per action potential gradually decreases (presynaptic rundown). But the amount is enough to generate an EPP well above the threshold level. In myasthenic patients, due to the postsynaptic changes along with the presynaptic rundown, after a few motor nerve impulses, the successive contractile responses become feeble, causing fatigue. So there is decremental response to repetitive nerve stimulation on EMG recording from the affected muscle.

2. **Women are affected more** than men in a ratio of 3:2.

3. The muscle weakness increases during prolonged use of the muscle and improves after rest or sleep. Thus, the patient feels better in the morning, but symptoms aggravate toward evening or after exertion.

4. **The extraocular muscles and eyelids are often involved** early in the course of the diseases. Therefore, diplopia and ptosis (drooping of eyelids) are early symptoms (Fig. 25.3).

5. **Physiological Basis of Treatment**

   Current modalities of treatment are as follows.

   1. **Administration of AChE inhibitors**: Examples of these drugs are pyridostigmine and neostigmine. They increase the concentration of ACh at the neuromuscular junction.

   2. **Thymectomy**: Recently it has been observed that immune responses mediated by T cells are part of the pathophysiological mechanisms. Thymectomy is therefore helpful. It blunts down the immune response and improves the condition.

   3. **Immunosuppression**: Immunosuppressive drugs glucocorticoids and azathioprine are useful. They inhibit the immunological mechanisms.

   4. **Plasmapheresis**: Plasmapheresis removes AChR antibodies from plasma.

Lambert-Eaton Myasthenic Syndrome

It is a presynaptic disorder of the neuromuscular junction due to production of autoantibodies against voltage-gated Ca\(^{++}\) channels. The decreased Ca\(^{++}\) influx in the presynaptic axon terminals results in impaired ACh release from the nerve endings. The muscular weakness is primarily seen in the limb muscles. Patients show incremental response to repetitive nerve stimulation as Ca\(^{++}\) level raises with each action potential. Thus, with prolonged contractions, muscle strength increases.
NERVE ENDINGS IN SMOOTH AND CARDIAC MUSCLES

The smooth and cardiac muscle cells are innervated by autonomic nervous system. There are no well-defined end plate regions or precise synaptic terminals.

1. Especially in smooth muscles, the neurotransmitter vesicles are present in dilated areas of the axon all along its length. These dilated portions (swellings) are known as varicosities (Fig. 25.4).

2. On stimulation of the neuron, the neurotransmitters are released and then diffused to the adjacent muscle fibers, initiating action potentials in many fibers simultaneously.

3. In a noradrenergic nerve, there can be as many as 20,000 varicosities per neuron. This type of synaptic arrangement is called synapse en passant.

4. The depolarizing potentials produced in the smooth muscle cells are known as excitatory junction potentials (EJPs).

5. EJPs are like graded potentials and can be summated. The hyperpolarizing potentials produced in the smooth muscle cells are known as inhibitory junction potentials (IJPs).

DENERVATION HYPERSENSITIVITY

When a neuron is cut and the distal axon degenerates, the target tissue innervated by its synaptic terminals becomes more reactive to the neurotransmitter secreted at the nerve endings. This phenomenon of increased responsiveness is known as denervation hypersensitivity. This is seen in both skeletal and smooth muscles. Due to degeneration of the nerve endings, the chemical is no more released from the terminals. The tissue reacts to the neurotransmitter present in the circulation, where concentration of the chemical is lower than at the synaptic endings.

The hypersensitivity occurs due to three reasons:

1. Increased number of receptors at the postsynaptic membrane (up-regulation). Both number and distribution of receptors increase. For example, after degeneration of the motor nerve, the AChR appears all over the sarcolemma (Fig. 25.5B), whereas normally it is confined to the end plate region only (Fig. 25.5A).

2. Increased responsiveness (sensitivity) of receptors to the chemical.

3. In case of noradrenergic neurons, the reuptake of neurotransmitter molecules by the presynaptic terminals is decreased resulting in higher plasma noradrenaline concentration.
### Key Concepts

1. Arrival of an action potential at the axon terminal causes opening of the voltage-gated calcium channels, and causes calcium influx. Calcium mediated exocytosis of neurotransmitter vesicles is facilitated by membrane proteins synaptobrevin and syntaxin.
2. Binding of Ach to AChR causes Na\(^+\) influx that leads to genesis of end plate potential (EPP).
3. EPP at threshold causes activation of voltage-gated Na\(^+\) channels causing influx that causes genesis of muscle fiber action potential.
4. Botulinum toxin causes presynaptic blockade and curare causes postsynaptic blockade (competitive blockade of AChR) of neuromuscular transmission.
5. Myasthenia gravis results from a decrease in the number of AChR present on the motor end plate due to production of circulating autoantibodies against these receptors.
6. When the distal axon degenerates, the target tissue innervated by its synaptic terminals becomes more reactive to the neurotransmitter secreted at the nerve endings, which is known as denervation hypersensitivity. This is due to increased number of receptors as well as sensitivity of receptors to chemicals.

### Important to Know (Must Read)

1. In examinations, ‘Structure of NMJ and Neuromuscular transmission’ usually come as a **Long Question**.
2. Mechanism of neuromuscular transmission, end-plate potential, Neuromuscular blockers, Denervation hypersensitivity, are usual **Short Questions** in exams.
3. In **Viva**, examiners may ask…… Structure of NMJ, Steps of neuromuscular transmission, Meaning and importance of Quantal release, role of syntaxin and synaptobrevin, Features of end-plate potential, and how it differs from action potential, Name and mechanism of presynaptic blocker, Name and mechanism of post-synaptic blocker, Neuromuscular blockers, Cause, features and treatment of myasthenia gravis, Special feature of autonomic innervation in smooth muscle, and Definition and mechanism of denervation hypersensitivity.
Structure of Skeletal Muscle: Physiological Aspects

**CHAPTER 26**

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:
1. Understand the organization of muscle fibers and fibrils in skeletal muscle.
2. Name the contractile proteins in the skeletal muscle and give their functions.
3. Draw the labeled diagram of sarcomere.
4. Draw the picture of sarcotubular system (STS) and give function of each component of STS.

The student **MAY** also be able to:
1. Describe the details muscle proteins.
2. Describe the role of STS in muscle contraction and relaxation.

For muscle contraction, muscles use chemical energy to generate force. All muscles transduce a chemical or electrical command into a mechanical response. The trigger for muscle contraction is the rise in free cytosolic Ca\(^{2+}\) concentration. However, on the basis of structure, metabolism, control mechanisms and contractile properties like rate and duration of contraction, fatigability and the ability to regulate contractile strength, muscles can be classified into three types:
1. Skeletal muscle
2. Smooth muscle
3. Cardiac muscle.

Skeletal muscle, as the name implies, is attached to the skeleton (bones). Its contraction supports and moves the skeleton (through joint movements). The contraction in skeletal muscle is mostly under voluntary control and is initiated by discharge of the motor neuron supplying it. Skeletal muscle is capable of rapid force development and shortening. It can maintain contractile force for relatively longer periods.

**Structure of Skeletal Muscle**

A typical skeletal muscle contains many muscle bundles or fascicles. Each fascicle consists of large number of muscle fibers arranged parallel to each other (Figs. 26.1A and B). Connective tissue layers in the muscle bundles are epimysium, perimysium and endomysium (Fig. 26.2).

![Figs. 26.1A and B: Structure of skeletal muscles. (A): Muscle bundle; (B) Muscle fiber.](image)

1. The connective tissue layer around the muscle is called **epimysium**.
2. The layer covering each fascicle is known as **perimysium**.
3. The layer surrounding each muscle fiber is termed as **endomysium**.

The blood vessels and nerves supplying the muscle fibers are present within the perimysium. All the three layers are made up of collagen and elastin that helps to transmit the force from the muscles to the bones. Muscles are usually attached to bones by collagen fibers known as tendons.
Myocyte

The structural unit of muscle is muscle fiber that is a single skeletal muscle cell (myocyte). The cell membrane of myocyte is known as sarcolemma and the cytoplasm as sarcoplasm (Fig. 26.1B).

1. The muscle fibers are long, cylindrical, multinucleated cells, extending the entire length of the muscle, and attach to tendons at both ends.
2. They are 10–100 µm in diameter and may extend up to 20 cm in length.
3. In embryonic fibers, the nuclei are centrally placed; but following differentiation after birth, they lie beneath the sarcolemma, hence peripherally placed (Fig. 26.3A).

The important functions of sarcolemma are:
1. It transmits the wave of depolarization originating at the motor end plate over the entire cell surface to initiate contraction.
2. Besides shielding the muscle fiber, the sarcolemma contributes to the parallel elastic resistance, i.e. the resistance to stretch offered by all the connective tissue layers.
3. It has no gap junctions or tight junctions, thereby promotes electrical separation between fibers.

Myofibrils and Organelles

Characteristically, the sarcoplasm is filled with myofibrils that extend along the axis of the cell and are connected to the tendons at both ends of the muscle fiber.

1. Each myofibril is 1 µm in diameter and consists of cylindrical bundles of two types of myofilaments that are referred to as thick and thin filaments.
2. The sarcoplasm contains the usual cytoplasmic organelles including mitochondria (sarcosomes), sarcoplasmic reticulum, and Golgi apparatus.

Development of Myocytes

The muscle fibers are formed during fetal development by the fusion of a number of undifferentiated, mono-nucleated cells, known as myoblasts.

1. At the time of birth, the differentiation of skeletal muscle fibers is complete. These differentiated fibers continue to increase in size during growth from infancy to adulthood, but no new fibers are formed from myoblasts.
2. After birth, following destruction of skeletal muscle due to any cause, the existing muscle fibers do not divide to replace the damaged fibers. Instead, new fibers are formed by differentiation of satellite cells that are located in the adjoining myocytes.

Fig. 26.2: Connective tissue layers in the muscle bundles (epimysium, perimysium, and endomysium).

Figs. 26.3A and B: Longitudinal section through skeletal muscle showing multinucleate myocytes (A) and photomicrograph showing transverse striations (B). 1. Peripherally placed nuclei; 2. Transverse striations.
3. Though the satellite cells are capable of forming a large number of new muscle fibers, that may not be adequate enough to restore a severely damaged muscle to its full strength. In such situations, hypertrophy (increase in cell size) of the remaining muscle fibers usually compensates for the loss.

4. Recently, it has been demonstrated that a transcription factor called myogenin stimulates fibroblasts to become muscle cells.

**Striations:** The most striking feature of skeletal muscle is the presence of striations due to alternate light and dark bands throughout the length of the fiber as seen through a light microscope (Fig. 26.3B).

1. The dark band is also called **A band** because it is anisotropic to polarized light.
2. The light band is known as **I band** because it is isotropic to polarized light (refer to Fig. 26.1B).

Each myofibril is made up of units called **sarcomere** that contains different muscle proteins (see below).

**Muscle Proteins**

There are three types of proteins in skeletal muscle:
1. **Contractile proteins:** myosin and actin
2. **Regulatory proteins:** troponin and tropomyosin
3. **Attachment proteins:** titin, nebulin, alpha actinin, desmin, myomesin, and dystrophin

**Contractile Proteins**

There are two contractile proteins in skeletal muscle: myosin and actin.

**Myosin**

There are thick and thin filaments in muscle. The thick filaments are polymers of myosin II (MW 480,000). Myosin filament is a bundle of myosin molecules. The head of myosin molecules projects from the filaments that are arranged in a helical manner (Fig. 26.4). The filament is composed of following units:

1. Two intertwined heavy chains,
2. Two regulatory light chains, and
3. Two alkali (essential) light chains.

The myosin II has three regions: two globular heads, neck (hinge region) and a long tail (Fig. 26.5).

**Myosin Head**

Each head is made up of amino terminal portions of one heavy chain forming a complex with two light chains, one regulatory and one alkali.

1. The myosin head contains two binding sites, one for actin and one for ATP (Fig. 26.6).
2. The ATP binding site functions as an ATPase (hydrolyzes ATP).
3. The carboxy terminals of the heavy chains coil around each other in an alpha-helical configuration forming a long rod-like tail.
4. The alkali light chain stabilizes the myosin head and the regulatory light chain regulates its ATPase activity.

**Myosin Tail**

The tail of each myosin molecule lies along the axis of the thick filament, and the two globular heads extend out to the sides, forming the cross-bridges.

**Myosin Hinge**

In the hinge region, the tail joins the globular head.

**Arrangement of myosin molecules:** The myosin molecules aggregate with a definite directional arrangement, such that their tail-ends are directed toward the center of the thick filaments creating a bare region in the middle consisting of myosin tails only, while the globular heads point away from both sides of the tail.
Section 3: Nerve and Muscle

1. The site of the reversal of polarity of myosin molecules is the M line where slender cross connections preserve the organization and alignment of the thick filaments in the sarcomere (See below).
2. Besides titin, proteins like myomesin and C-protein contribute to the bipolar organization and packing of the thick filaments.

Actin

The thin filaments are made up of actins. The actin filament (F-actin) is made up of globular molecules of G-actin (Fig. 26.7).
1. G-actin is a globular protein with a diameter of 4–5 nm and MW 42,000.
2. G-actin molecules (monomers) are joined from front to back into long chains that wind about each other forming a double stranded alpha helical filament known as F-actin (or filamentous actin) that forms the backbone of the thin filament.
3. The cytoskeletal protein nebulin extends along the length of the F-actin and plays a role in the regulation of the length of the thin filament.
4. Each actin monomer contains binding sites for myosin, tropomyosin, troponin I, and other actin monomers.
5. As the F-actin undergoes a half-turn every seven G-actin monomers, a groove is formed down the length of the helix where lies the long, filamentous protein tropomyosin.

Regulatory Proteins

Regulatory proteins are tropomyosin and troponin.

Tropomyosin

Tropomyosin is a rod-shaped molecule (MW 70,000) composed of two strands of polypeptides intertwined in an alpha helical configuration with a length approximately equal to seven actin monomers. It is located in the groove between two chains of actin (Fig. 26.8).
1. The tropomyosin molecules are connected to one another serially that extends over the entire actin filament covering myosin-binding sites on the actin monomers.
2. The function of tropomyosin is to interfere with the binding of myosin head to actin.

Troponin

Troponin is a complex of three proteins: Troponin T, Troponin I, and Troponin C (Fig. 26.8)

Troponin T

Troponin T has molecular weight 30,000. It binds the troponin complex to tropomyosin.

Troponin I

Troponin I (MW 22,000) binds the troponin complex to actin. It is called I, because it inhibits the binding of actin to myosin by blocking the myosin binding site on actin.

Troponin C

Troponin C (MW 18,000) binds to calcium.

Note:

Interaction of troponin with tropomyosin: Each troponin complex interacts with one tropomyosin molecule, which in turn interacts with seven actin monomers. The troponin complex also interacts directly with the actin filaments. Troponin is known as the regulatory protein in the contraction of skeletal muscle.

Attachment Proteins

Titin

It is a large, elastic, filamentous, cytoskeletal protein, which extends from the Z line to the M line. It provides framework for the thick filaments by connecting the Z line to the M line. It prevents overextension of the thick filaments and maintains the central location of the A band.

Nebulin

This is a large, filamentous protein that extends along the length of the thin filaments. It is believed to play a role in stabilizing the length of the actin filaments during muscle development.

Alpha Actinin

Alpha actinin anchors the thin filaments to the Z line.
Desmin is present in the intermediate filament of cytoskeleton of myocyte. It connects the Z line to the sarcolemma. It also connects myofibrils to each other.

**Dystrophin**

It is a large rod like protein that anchors the thin filaments to the membrane spanning protein beta-dystroglycan, which in turn is connected to the extracellular matrix protein laminin through alpha-dystroglycan.
1. Dystrophin helps in transfer of force from the contractile system to extracellular regions through the transmembrane proteins.
2. These proteins are disrupted in the group of genetic diseases called muscular dystrophy.
3. Absence of these proteins or their mutations leads to muscle degeneration, weakness and even death.

**Myomesin**

It is present in the region of M disc. It binds the tail end of myosin filament to the disc.

**Sarcomere**

Sarcomere (in Greek; sarco means muscle, and mer means part) is the structural and functional unit of myofibril. A single myofibril may be composed of hundreds or thousands of sarcomeres that are joined end-to-end. In each myofibril, thick and thin filaments are arranged in a repeating pattern in the form of sarcomere (Fig. 26.9).
1. Sarcomere is defined as the portion of the muscle fibril between two successive Z lines.
2. The average length of a sarcomere is 2 µm.

**Structure**

Electron micrographic studies reveal the detailed structure of sarcomere (Fig. 26.10).

**Z Line**

The Z line or Z disc is a network of interconnecting proteins. It is oriented perpendicular to the axis of the muscle fiber. The thin filaments are anchored to the two sides of each Z line by alpha actinin.

**Thin Filament**

Each thin filament is 1 µm long and 7 nm in diameter.
1. It is composed of the contractile proteins actin, tropomyosin, and troponin in a ratio of 7:1:1.
2. From the Z line, the thin filaments project in parallel arrays toward the center of the sarcomere where they overlap a portion of the thick filaments.
3. Thus, each sarcomere contains two sets of thin filaments, one at each end. The Z disc not only binds the thin filaments of a single myofibril together, but connections between the Z discs also anchor each myofibril to its neighbors.

**Thick Filament and A Band**

The parallel array of thick filaments located in the middle of each sarcomere produces A band.
1. The thick filament is 1.6 µm long and 10 nm in diameter.
2. It consists of the protein myosin (see above).

**I Band**

I band lies between the ends of A bands of two adjacent sarcomeres and includes those portions of the thin filaments that do not overlap the thick filaments. The Z line bisects I band.
1. During muscle contraction, the length of the sarcomere (the distance between two Z lines) decreases. This results in shortening of I band but, length of A band remains unchanged (Fig. 26.11).
2. Thus, sarcomeric length is decided by the length of I band.

**H Band**

H band (H zone) is a narrow, light band in the center of A band. This is the portion of A band showing no overlap (represented by thick filaments only) as can be seen in a relaxed muscle.

**M Line**

A transverse M line runs through the middle of H band. The M line contains proteins that bind the parallel array of thick filaments.
1. Besides, the cytoskeletal protein, titin binds the thick filaments to the Z lines.
2. In fact, **titin filaments** extend from Z line to M line and thus, are linked to M-line proteins, thick filaments and Z line proteins.
3. Therefore, it plays a key role in organizing and maintaining the regular array of thick filaments in the middle of each sarcomere.

**Hexagonal and triangular arrangement:** A cross section through the overlap region of A band shows that each thick filament is surrounded by a hexagonal array of six thin filaments, and each thin filament is surrounded by a triangular arrangement of three thick filaments (Fig. 26.12).

**Cross-Bridges**

The globular heads of myosin II project from the surface of the thick filaments toward the thin filaments and bridge the gap between them.
1. These projections are known as **cross-bridges** (Fig. 26.13).
2. During muscle contraction, they attach to the thin filaments and pull them.

**Sarcotubular System**

Inside a muscle fiber, fibrils are surrounded by membranous structures known as sarcotubular system. The relationship of sarcotubular system with the I and A bands of sarcomere in a myofibrils is shown in Figure 26.14.

**Structure**

It consists of sarcoplasmic reticulum and T (transverse) tubules (Fig. 26.15).

**T-tubules**

The T-tubules, also called **sarcotubules** are tubular extensions of the sarcolemma, about 0.03 µm in diameter.
1. They penetrate to the center of the muscle fiber and surround the individual myofibrils at the junctions of A and I band.
2. The lumen of the T tubule contains extracellular fluid, which is a continuation of the ECF surrounding the muscle fibers.

3. Once initiated, an action potential is rapidly conducted along the sarcolemma over the surface of the muscle fiber as well as into the interior of the muscle cell by the way of the T-tubules so that deep lying myofibrils are fast activated.

**Sarcoplasmic Reticulum**

The sarcoplasmic reticulum (SR) in skeletal muscle corresponds to the endoplasmic reticulum found in other cells.

1. It forms an elaborate membranous network having extensive anastomosis around each myofibril and runs parallel to the myofilaments.

2. The slender tubules, about 0.04 µm in diameter, have an elongated portion in the middle and dilated region at both ends known as lateral sacs or terminal cisternae.

3. The cisternae lie in close contact with the T-tubules at the A-I junction.

4. The combination of the T-tubule membrane and its two neighboring cisternae is called a triad, which plays a vital role in linking membrane action potentials to muscle contraction (details see below). In cardiac muscle, it forms a diad due to the presence of one cistern.

**Receptors and Channel Proteins in STS**

The T-tubules are separated from the terminal cisternae by a narrow space of about 12–14 nm that contains areas of densities known as feet. The junctional feet involve two integral membrane proteins, one in the T-tubule membrane, and the other in the membrane of the terminal cistern.

1. The T-tubule protein is a modified voltage-sensitive calcium channel known as the dihydropyridine (DHP) receptor. It is so named because it is blocked by the drug dihydropyridine.

2. The DHP receptors are L-type calcium channels and they are clustered in groups of four called tetrads.

3. Primarily the receptor acts as a voltage sensor rather than a calcium channel.

4. The portion of the terminal cisternae membrane that faces the T-tubules contains proteins known as the ryanodine receptors. They are so called because they bind to the plant alkaloid ryanodine. They mainly act as calcium release channels.

5. There is also calcium ATPases present on the membrane of SR that pumps calcium back into the SR.

**Functions**

**Role of STS in Muscle Contraction and Relaxation**

Sarcotubular system (STS) plays a vital role in muscle contraction as it links T-tubular action potentials (excitation) with calcium release from the SR that activates the contractile machinery (contraction). When calcium is pumped back into the SR, decline in cytoplasmic calcium level leads to muscle relaxation. Thus, STS is crucial in both contraction and relaxation process by mediating calcium release and calcium uptake.
Mechanism of Calcium Release

Following depolarization at the motor end plate, action potentials propagate along the sarcolemma and down the T-tubule membrane.

1. Depolarization of the triad region of the T-tubules induces conformational changes in each of the four DHP receptor proteins, which leads to a conformational change in the ryanodine receptor resulting in opening of the ryanodine receptor channel.
2. Calcium is thus released from the terminal cisternae of the SR into the cytoplasm, activating cross-bridge cycling.
3. The entire process, starting from depolarization of the T-tubule membrane to the initiation of the cross-bridge cycling is termed excitation-contraction coupling.
4. Further, conformational change in DHP receptor allows calcium entry from the ECF into the cytoplasm through the DHP receptor channel and this increase in calcium level inside the cell can as well activate the ryanodine receptors resulting in calcium release. This mechanism is known as calcium-induced calcium release (CICR). However, this pathway has a much lesser role in contraction of skeletal muscle.
5. CICR plays an important role in cardiac muscle contraction.
6. Increase in Ca$^{2+}$ concentration near the sarcoplasmic reticulum is known as calcium spark.

Mechanism of Calcium Uptake

The membrane of the SR contains a protein called SERCA (Sarcoplasmic Endoplasmic Reticulum Calcium ATPase). This is so named as it is present in all cells in connection with the endoplasmic reticulum.

1. The protein is a Ca$^{2+}$ ATPase that pumps free calcium ions from the sarcoplasm to the SR, from where the calcium ions are moved to their storage sites in the terminal cisternae.
2. The pump relocates two molecules of Ca$^{2+}$ into the SR for each molecule of ATP hydrolyzed. It becomes active as soon as the Ca$^{2+}$ concentration in cytoplasm becomes high.
3. In the terminal cisternae, a Ca$^{2+}$ binding protein called calsequestrin, favors storage of calcium at high concentration.
4. With decrease in cytoplasmic calcium concentration, contractile activity ceases and relaxation process begins (Flowchart 26.1).

Functions of STS

1. It transfers action potential from the surface of the muscle fiber to the interior, closer to the myofibrils.
2. It raises cytoplasmic calcium concentration by calcium release from SR.
3. It ensures muscle relaxation by calcium reuptake by SR.
4. The cisternae of SR act as storage sites for calcium.
CHAPTER SUMMARY

Key Concepts
1. Sarcomere, the functional unit of muscle fibril, is the distance between two Z lines.
2. During muscle contraction, the length of the sarcomere decreases, due to shortening of I band, but the length of A band remains unchanged.
3. The globular heads of myosin project from the thick filaments toward the thin filaments and bridge the gap between them. Hence, this head region is called cross-bridges. During muscle contraction, cross bridge attach to the thin filaments and pull them.
4. T tubule of sarcotubular system that invaginates into the myofibril transmits action potential to the contractile machinery. Release of calcium from cistern causes muscle contraction and active pumping of calcium back into the cistern causes muscle relaxation.

Important to Know (Must Read)
1. In examinations, usually Long Questions are not asked from this chapter.
2. Muscle proteins, Sarcomere, Sarcotubular system, Role of sarcotubular system in muscle contraction, are usual Short Questions in exams.
3. In Viva, examiners usually ask… Type of muscle proteins, Structure and function of each muscle protein, what is cross bridge, What are the regulatory proteins and their functions, What are the attachment proteins and their functions, Definition and structure of sarcomere, What are the I and A bands and what are their significance, Components of sarcotubular system and function of each component, Name the receptors and channel proteins in sarcotubular system, and what are their functions, and, How sarcotubular system participates in muscle contraction and relaxation.
4. Types of muscle proteins, sarcomere and sarcotubular system are usually asked.
Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Describe the mechanism of excitation-contraction coupling in skeletal.
2. Understand the process of cross-bridge cycle.
3. Appreciate the relationship between the action potential and contractile response.
4. List the types of muscle contraction and the differences between them.

The student **MAY** also be able to:
1. Describe the detailed mechanism of cross-bridge cycle.

The action potential from sarclemma spreads to the interior of muscle fiber through T tubules and results in calcium release from cisternae. This increases sarcoplasmic calcium concentration. The muscle response to the action potential (through increased calcium) is the **excitation**, and the mechanical response is the **contraction** of the muscle. Calcium diffuses to troponin C and induces muscle contraction through a series of well controlled steps. Therefore, this phenomenon of pairing of electrical event with the mechanical event is called **excitation-contraction coupling**.

**Excitation-Contraction Coupling**

Increase in sarcoplasmic calcium concentration in response to arrival of action potential from sarcolemma leads to muscle contraction. The process is called excitation-contraction coupling.

1. The term contraction means attachment of myosin heads to actin and activation of the cross bridge cycles so that force is generated within to shorten the muscle fibers.

2. However, it may not always lead to shortening as occurs in isometric contraction. While lifting a heavy object, shortening occurs, but holding the object at a constant position, activates the cross bridge cycles without apparent shortening.

**Sliding-Filament Theory of Muscle Contraction:** In 1957, AF Huxley proposed the sliding filament theory of muscle contraction based on the changes observed in the lengths and widths of various bands and zones of the sarcomere. Shortening of a muscle fiber occurs due to **sliding of thin filaments over thick filaments** toward the center of the sarcomere (described below in “molecular mechanisms of muscle contraction”). It was observed that the length of A band does not change during contraction, but the H zone and I band decrease in width and the Z lines move closer together.

**Scientists contributed**

Sir Andrew Fielding Huxley was a Nobel Prize-winning English physiologist and biophysicist. He discovered the basis for propagation of nerve impulses (called an action potential) earned the **Nobel Prize in Physiology or Medicine in 1963**. He developed **interference microscopy** suitable for studying muscle fibers. In 1952, German physiologist Rolf Niedergerke joined him, and in 1954 together they discovered the mechanism of muscle contraction, popularly called the “sliding filament theory”, which established the foundation of understanding of muscle mechanics. He contributed enormously to the understanding of nerve impulses and muscle contraction. He was conferred a Knight Bachelor by Queen Elizabeth II in 1974, and was appointed to the Order of Merit in 1983. He was a fellow of Trinity College, Cambridge, until his death.
Molecular Mechanisms of Muscle Contraction

The molecular mechanism of muscle contraction is based on the principle that the sliding motion of the filaments occurs as a result of a cyclic interaction between the myosin cross bridges and the actin filaments, in the presence of calcium and ATP.

1. This is known as the cross bridge theory or the ratchet theory as the strokes are similar to the action of a ratchet.
2. The force generation and shortening are produced at the cross bridge sites where the chemical energy stored in the muscle is converted into mechanical energy.

Role of Troponin, Tropomyosin and Calcium

Calcium ions provide the most important chemical link in the regulation of muscle protein interactions during the course of excitation-contraction coupling.

1. In resting skeletal muscle, cytoplasmic calcium ion concentration is low, which is about $10^{-7}$ M in the region of the myofilaments. Troponin I is attached to myosin binding site on actin and partially covers the myosin binding site. Rest of myosin binding site is covered by tropomyosin filament.
2. Troponin I and tropomyosin inhibits myosin-actin interaction.
3. Troponin T is attached to tropomyosin.
4. Each tropomyosin molecule is held in this blocking position by troponin that is bound to both tropomyosin and actin.

5. Thus, the troponin-tropomyosin complex behaves as a relaxing protein that prevents undesirable contraction.

Troponin–Tropomyosin Interaction

Following propagation of action potential along the sarcolemma and down the T tubules, calcium is released from the SR and calcium concentration rises to $10^{-4}$ M in the sarcoplasm, which accounts for about 1,000-fold rise of the ion.

1. Calcium binds to troponin C and induces a conformational change in the troponin molecule.
2. This result in shifting of troponin I from the actin filament, allowing tropomyosin to move deeper into the actin groove, unmasking the myosin binding sites (Figs. 27.1A and B). Moreover, the conformational change alters the position of troponin T that drags tropomyosin away from the myosin-binding sites.
3. The exposure of the binding sites allows myosin heads to interact with actin and engage in cross-bridge cycling.
4. Thus, the troponin-tropomyosin complex regulates the contraction of skeletal muscle.
5. As the regulation of the contractile process by calcium is implemented through the actin filaments, it is also called actin-linked regulation.

Role of Calcium

An increase in cytoplasmic Ca$^{2+}$ concentration triggers the contractile process by removing the inhibition on cross bridge cycling. On the contrary, decrease in cytoplasmic Ca$^{2+}$ concentration leads to detachment of calcium from troponin that reverses the process and turns off contractile activity.

Figs. 27.1A and B: Role of troponin-tropomyosin interaction in muscle contraction. Binding of calcium with troponin C induces conformational change in the troponin molecule, which shifts troponin I from the actin filament, and simultaneously troponin T that drags tropomyosin away from the myosin-binding site on actin. Exposure of this binding site allows myosin heads to interact with actin and engage in cross-bridge cycling. Note, ATP is converted to ADP during this interaction.
1. In skeletal muscle, increase in cytosolic calcium in response to a single action potential is usually sufficient to saturate all troponin-binding sites on actin filaments.
   - At a calcium concentration of $10^{-4}$ M, there is full force development and the contractile system is fully saturated.
   - With further increase in concentration, there is only small increase in the force.
2. Whereas, in cardiac and smooth muscle, the amount of calcium regulates the degree of actin-myosin interaction as the contractile system is only partially saturated under normal conditions.

**Cross-Bridge Cycle**

The sequence of events that occur during the interaction between the myosin cross-bridges and the actin molecules is termed as a cross-bridge cycle.

1. During each cycle, cross bridge (myosin head) attaches to thin filament causing displacement of thick filament over thin filament followed by detachment of myosin head in a repetitive fashion.
2. ATP is required during the cycle; for the movement of the cross bridge as well as for its detachment.
3. However, all the cross-bridges do not go through the same phase at any instant during a cycle. This helps in a smooth and sustained contraction.

**Events in the Resting Muscle**

When the muscle is at rest, the cytoplasmic ATP gets attached to its specific binding site in the head of the myosin molecule and the globular head is not attached to actin.

1. The intrinsic ATPase activity of the myosin head breaks down ATP to ADP and Pi (Fig. 27.2A).
2. This results in rotation of the myosin head around the hinge in such a way that the globular head is positioned at 90° angle in relation to the thick filament, pointing toward, but not attached to the thin filament.
3. This rotation moves the myosin head about 10 nm along the thin filament, so that, the head is positioned against a new actin molecule. This resting conformation is known as the energized state or the 'cocked position' of the myosin head' in which, energy is stored in the form of Pi, similar to the potential energy stored in a coiled spring.
4. When most of the cross-bridges in a muscle are in this energized state, it keeps the muscle in a relaxed state. ATP hydrolysis in the resting muscle keeps the muscle prepared for future contraction.

**Events in the Stimulated Muscle**

When action potential arrives at the T-tubules, calcium is released from the SR and the myosin-binding sites on actin are exposed.

1. The myosin-ADP-Pi complex has higher affinity for actin, which is called as the charged or energized myosin head. The charged myosin head binds to actin forming the actomyosin complex, also called cross-bridge formation (Fig. 27.2B).
2. The binding of myosin head to actin has two effects:
   - First, Pi is released from myosin head producing the power stroke, i.e. a conformational change in which the myosin head bends on the hinge at an angle of about 45 degrees pulling the actin filament about 11 nm toward the center of the sarcomere (Fig. 27.2C).
   - Second, the binding causes the dissociation of ADP from the myosin head leaving the actomyosin complex in a rigid state. That means the myosin head stay attached to the actin molecule in the same position and at a 45° angle with respect to the thick and thin filaments.
3. For detachment to occur, a new molecule of ATP must bind to the myosin head and initiate next cycle. Usually, the sarcoplasmic ATP concentration in normal physiological conditions is always adequate to produce the necessary detachment of cross-bridges. So, the ADP-free actomyosin complex (attached state) quickly binds to ATP.
4. This decreases the affinity of myosin for actin resulting in detachment of cross-bridges from the thin filaments, called as detached state (Fig. 27.2D). Soon after, ATP hydrolysis occurs and the myosin head attains the energized state.

If the stimulus for contraction persists, i.e. the sarcoplasmic Ca$^{2+}$ remains elevated, then myosin-binding sites on actin get exposed and the next cross, bridge cycle ensues. The cycle can go on as long as the sarcoplasmic Ca$^{2+}$ remains high, ATP is available, and the physiological limit to shortening has not been reached.

**Effects of Cross-Bridge Formation**

During contraction, being attached to an actin molecule, each myosin cross-bridge pivots around its hinge. Each thick filament has 500–600 myosin heads, and each one can pivot about five times per second during a rapid contraction.

1. One stroke of a cross-bridge produces 11 nm displacement of the thin filament over the thick filament.
2. As long as the muscle is stimulated, these swiveling motions of many cross-bridges with each cross-bridge repeating its cycle many times, drag the thin filaments attached to successive Z lines toward the center of the sarcomere, producing large displacements of the thin filaments.
3. This leads to decrease in the sarcomeric length and ultimately muscle shortening.
4. When shortening does not occur as in isometric contraction, the repetitive binding and pull on the actin generate tension.
Figs. 27.2A to D: Cross-bridge cycle. (A) Resting state (cross-bridge is energized by braking down of ATP to ADP and Pi that provides energy; (B) Myosin head-ADP-Pi complex develops more affinity for actin and bind with actin to form actomyosin complex; (C) Myosin Head pulls actin filament that moves Z line toward center of sarcomere (power-stroke), and actomyosin complex is free of ADP and Pi; (D) ATP binds with myosin head and detaches it from actin filament (detached state).

Role of ATP in Cross-Bridge Formation
ATP is required for the detachment of myosin head from the thin filaments.
1. If most of the cross-bridges in a muscle remain in the detached state, it would produce relaxation in the muscle.
2. Not all the cross bridges remain in the detached state even in a completely relaxed muscle; some of them bind to actin and generate tension that contributes to the tone of the muscle.
3. If cellular ATP stores are depleted, as happens after death, the cross-bridges cannot detach and it is called a rigor cross bridge, the cycle stops there and the filaments remain in the attached state. This produces stiffening in the muscle, known as rigor mortis (Clinical Box 27.1).
Clinical Box 27.1
Rigor mortis: Stiffening of the muscle after death is called rigor mortis. Within 3 to 6 h of death, rigor mortis sets in as the ATP concentration decreases in cells, including muscle cells. The depletion of ATP fails to detach the cross-bridge. Therefore, muscle remains in a state of contraction or rigidity. The rigidity of rigor mortis completes in about 12 h and disappears about 40 to 60 h after death due to disintegration and putrefaction of muscle fibers. Due to rigor mortis, body remains in same position for a longer time. Thus, rigor mortis not only speaks about the time of death, but also the nature of death, which helps in medicolegal investigations in case of mysterious deaths.

The process of cross-bridge cycle can be summarized in four steps (Figs. 27.2A to D, as depicted above):
1. ATP hydrolysis in the myosin head leading to energized state of the myosin.
2. Cross-bridge formation in the presence of increased calcium.
3. Release of Pi and ADP from myosin head producing power stroke.
4. Binding of ATP to myosin head causing detachment of myosin from actin.

Note, during muscle contraction, Z lines move toward M line that decreases sarcomeric length (muscle shortening), and during muscle relaxation, Z lines remain wide apart (Figs. 27.3A and B). In this process of contraction and relaxation, A band remains constant and changes occur in I band and H zone. In extreme contracted state, I band and H zone almost obliterate.

Summary of Skeletal Muscle Contraction
Molecular basis of skeletal muscle contraction as discussed above is an elaborate process. For students to quickly revise, understand and memorize quickly, it is summarized in Flowchart 27.1.

Mechanism of Muscle Relaxation
Like muscle contraction, relaxation is also an active process.
1. The Ca$^{2+}$ ATPase present on the membrane of SR pumps Ca$^{2+}$ from the sarcoplasm into the SR (for details read the mechanism of calcium uptake by Sarco-Tubular System in previous chapter).
2. If no further action potential arrives at the myoneural junction, the activity of Ca$^{2+}$ ATPase decreases calcium concentration in the vicinity of the myofilaments to a very low level.
3. Consequently, very few calcium ions are available to bind with troponin.
4. This leads to **cessation of interaction** between actin and myosin.
5. The contractile activity stops and relaxation process begins (Flowchart 27.2).

Thus, contraction as well as relaxation in skeletal muscle requires energy in the form of ATP.

**Action Potential and Contractile Response**

**Action Potential**

The **resting membrane potential** of skeletal muscle is \(-90 \text{ mV}\). The action potential is generated at the end plate region and spreads at a speed of 5 m/sec along the sarcolemma and down the T tubules activating the myofilaments.

1. The **duration** of the action potential is 2–4 ms and **absolute refractory period** is 1–3 ms.
2. The **depolarization phase** of the action potential is due to **sodium influx** and **repolarization** is a manifestation of **potassium efflux**.
3. The action potential does not directly activate the contractile proteins but instead produces a state of increased cytosolic calcium concentration, which activates the contractile apparatus long after the electrical activity in the membrane has ceased (Fig. 27.4A).

**Contractile Response**

In response to the motor nerve discharge, the thick and thin filaments slide past each other producing shortening of the activated fibers. This contractile response (twitch contraction) can be recorded in a graphical form (Fig. 27.4B).

1. A **twitch** is defined as the mechanical response of single muscle fiber to an action potential consisting of a phase of contraction followed by a relaxation phase.
2. When the action potential and the twitch contraction are plotted on the same time scale, the contractile response begins about 2 ms after the onset of the action potential. This delay is known as the **latent period**, during which the excitation-contraction coupling takes place.

In nerve-muscle preparation, where a motor nerve is stimulated to obtain a contraction, the latent period occurs due to the time taken for:

1. Conduction of impulse along the axon from the point of stimulus.
2. Secretion of Ach, its diffusion through the synaptic cleft and generation of end plate potential.
3. Origin and spread of action potential along the sarcolemma and T tubules.
4. Activation of the contractile mechanism.
5. Overcoming the viscous resistance of the muscle.
6. Overcoming the inertia of the writing lever (if the twitch is being recorded).

Calcium released during a twitch can fully activate the contractile machinery, but the relaxation process starts soon after. So, the magnitude of peak tension developed is relatively low. The duration from the start of the contractile response to the attainment of peak tension is the **contraction time** and from the point of peak tension to
the end of contractile response is the relaxation time. The duration of the twitch is about 7.5 ms in the fast muscle fiber and may be up to 100 ms in slow muscle fiber. Normally, twitches occur occasionally in a healthy person. In the clinics, twitches are usually elicited while testing the tendon jerks (myotatic reflexes). In lower motor neuron diseases, presence of twitches that occur spontaneously helps to establish the diagnosis.

### Types of Contraction

**Tension** is the force of the contracting muscle acting on an object. **Load** is the force exerted on the muscle by an object, i.e. weight of the object against which muscle tension acts. Thus, muscle tension and load act against each other. When an object is to be lifted, muscle tension has to be more than the opposing load. Contractions are of two types:
1. **Isometric contraction**
2. **Isotonic contraction**

#### Isometric Contraction

When muscle contraction is associated with no apparent change in muscle length, the phenomenon is called isometric contraction. The muscle develops tension but does not shorten or lengthen; for example, when somebody is trying to lift a heavy object.

1. During this type of contraction, the cross bridges bind with the actin molecules and attempt to pull them but cannot drag the thin filaments because the load is greater than the tension exerted by the muscle fiber. This exerts a force on the thin filament, the isometric tension.
2. If isometric contraction is continued, cycling cross bridges again and again bind to the same actin molecule.
3. According to the law of physics, if displacement is zero (position of the object does not change), the work done (force × displacement) is also nil, though force is generated and energy is spent. Thus, in isometric contraction **no external work is done**.
4. Isometric tension can be recorded with the help of an isometric lever when the muscle is stimulated to contract with its two ends held at fixed points.

#### Isotonic Contraction

When muscle contraction is associated with no apparent change in muscle tone, the phenomenon is called isotonic contraction.

1. The shortening of the muscle fiber occurs due to sliding of thin over thick filaments. Examples of such muscle contractions are walking, running, lifting an object, etc.
2. Isotonic contraction is also known as **concentric contraction**.

| Table 27.1: Differences between isometric and isotonic contractions. |
|-----------------------------|-----------------------------|
|                            | Isometric | Isotonic |
| 1. Length of muscle         | Remains same | Shortening occurs |
| 2. Tension                  | Tension increases | No change |
| 3. External work            | No work done | Work is done |

The major difference from isometric contraction is that in isotonic contraction, the external work is done (Table 27.1).

### Positive and Negative Works

The muscle does **positive work** when an object is lifted from the ground. **Negative work** is done when a heavy object is lowered onto the ground.

1. In negative work, the muscle actively opposes the descent of the object by contracting, but, as the load exerted on the muscle is greater than the tension generated due to actomyosin interaction, the load pulls the muscle to a longer length. Such lengthening of the muscle is called **lengthening contraction** or **eccentric contraction**, for example, the extensors of the knee lengthen when somebody sits on the ground.
2. This is not an active process produced by cross bridge activation, rather a passive phenomenon, where external load stretches the muscle.

When stimulated, a muscle fiber always tends to shorten, unless an external lengthening force is present. While recording for isotonic contraction, one end of the muscle is fixed and the other kept free, so that on stimulation, the muscle shortens by contraction producing a constant force.

#### Processes in Isometric and Isotonic Contractions

When an object is to be lifted, initially tension increases in the muscle till it becomes equal to the downward pulling force (due to the weight of the object) without any change in muscle length, i.e. the fibers undergo isometric contraction.

1. Once the tension in the muscle is greater than the opposing load, shortening contraction of the muscle lifts the object and brings it to the new position; here the fibers undergo isotonic contraction.
2. Now, if the object is to be held in space in the new position, the fibers undergo isometric contraction, the tension generated being just equal and opposite to the load of the object.
3. Pushing against a wall is an example of isometric contraction if the elbow does not bend during the act, i.e. the distance between shoulder and hand remains unchanged.

CHAPTER SUMMARY

**KEY CONCEPTS**

1. Muscle contraction is an active process in which ATP is utilized, and muscle relaxation is also an active process.
2. Sliding filament theory of muscle contraction is based on cross-bridge formation, in which myosin head pulls the thin filament on thick filament.
3. During each cross bridge cycle, cross bridge (myosin head) attaches to thin filament causing displacement of thick filament over thin filament followed by detachment of myosin head in a repetitive fashion.
4. ATP is required during the cycle for the movement of the cross bridge as well as for its detachment.
5. In skeletal muscle, the contractile response (that lasts for about 15 ms) begins almost toward the end of electrical response (that lasts for about 4 ms). Therefore, skeletal muscle can be tetanized.

**Important to Know (Must Read)**

1. In examinations, “Describe the molecular basis of muscle contraction” is a very common Long Question. Cross bridge cycle may sometime come as long question.
2. Excitation-contraction coupling, Molecular basis of muscle contraction, Cross bridge cycle, Relationship between electrical and mechanical response in skeletal muscle, Types of muscle contraction, are usual Short Questions in exams.
3. In Viva, examiners usually ask… What is the meaning of Excitation-contraction coupling, Who described Sliding-Filament Theory, What is the meaning of Sliding-Filament Theory, Steps in molecular basis of muscle contraction, Mechanism of calcium release from cisterns, Mechanism of cross-bridge cycle, Role of troponins and tropomyosin, Steps of muscle relaxation, Relationship between electrical and mechanical response in skeletal muscle and its importance, and Types of muscle contraction.
4. Mechanism of skeletal muscle contraction is invariably asked in both theory and oral exams.
Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. List the properties of skeletal muscle.
2. Understand the link of muscle properties to function.
3. Name the energy sources in skeletal muscle.
4. Explain the mechanism of oxygen debt.
5. Define the motor unit and understand the concept of size principle.
6. Define different types of muscle heat and understand their importance.
7. Name the type of muscle fibers and basic differences between them.
8. Correlate the application of knowledge of function with dysfunctions.

The student **MAY** also be able to:
1. Describe each property of skeletal muscle.
2. Understand the mechanism of muscle fatigue and rigor mortis.

**Properties of Skeletal Muscle**

**Important Properties**

Important properties of skeletal muscles (in addition to the properties, like contractility, excitability, fatigability, etc.) are:
1. Summation of contraction
2. Staircase phenomenon
3. Tetanization
4. Post-tetanic potentiation
5. Length-tension relationship
6. Load-velocity relationship

**Summation of Contraction**

It states that isometric tension developed in a single fiber or a muscle depends on the frequency of the stimulus applied to it.

1. The action potential of the skeletal muscle is brief (1–4 ms) compared to its contraction time. The absolute refractory period (which includes the depolarization phase and part of the repolarization phase) of the action potential is over by the time contraction starts.
2. Thus, during the contraction period, if the motor neuron is stimulated repeatedly, it will generate several action potentials in the muscle fiber. The **contractile elements have no refractory period**; they do not follow-all-or none law and contraction can continue till Ca	extsuperscript{2+} and ATP are available.

If a second twitch is produced when the contraction phase of the first twitch is still continuing, the phase of contraction of the second twitch is added to the phase of contraction of the first twitch, resulting in a **summated contractile response** (Figs. 28.1A to C).

1. The Ca	extsuperscript{2+} released due to the second action potential is added to the Ca	extsuperscript{2+} released due to the first action potential, producing a higher sarcoplasmic Ca	extsuperscript{2+} concentration that results in a **bigger contractile response**. Therefore, the tension generated during summated response is greater than that of a single twitch. The tension increases further as the stimulus interval shortens (Fig. 28.1C).
2. Thus, repeated stimulation of the muscle before relaxation has occurred produces a phenomenon known as **summation of contractions**.

**Staircase Phenomenon**

If a skeletal muscle is stimulated rapidly (but below the tetanizing frequency) with a maximal stimulus, there is a progressive increase in the force of contraction for the
first few contractions, until a maximum uniform tension per contraction is reached. This is the staircase phenomenon or treppe (in German). Treppe is also seen in cardiac muscle. In 1871, Bowditch first described Treppe in the frog’s heart.

1. During repeated and rapid stimulation, if a second contraction occurs during the relaxation phase of the first one, the amplitude of the second twitch happens to be higher than the first one (Figs. 28.2A to D).

2. This is because when the muscle has not completely relaxed, the cytoplasmic calcium concentration remains elevated as all the calcium released due to the first stimulus has not been pumped back into the sarcoplasmic reticulum.

3. This leftover calcium is added to the calcium released during the second contraction and results in greater amplitude. Also, the heat produced during preceding contraction decreases sarcoplasmic viscosity and facilitates the enzymatic activity that increases the height of succeeding contractions.

4. In this manner, if subsequent contractions occur before the relaxation phase of the previous one is over, first few twitches gradually increase in amplitude.

5. This is known as staircase phenomenon as the graph is in an ascending order, like a staircase. The amplitude does not increase after a few contractions as the calcium level becomes saturated.

**Tetanization**

If the muscle is stimulated repeatedly at a very high frequency, continuous activation of the contractile mechanism occurs without any relaxation, resulting in a sustained contraction known as tetanus (tetanic contraction).

1. In complete/fused tetanus, there is no relaxation between the contraction phases.

2. In clonus or incomplete or unfused tetanus, there are periods of incomplete relaxation between the maintained contractions (Figs. 28.2C and D).

3. While the frequency of the action potentials progressively increases to tetanizing frequency, the tension generated in the muscle gradually rises and summed until a maximal tetanic tension is reached. Beyond this, tension does not increase further with increase in frequency of the action potentials.

The critical frequency (CF) at which summation of contractions occur differs from muscle to muscle since it depends on the twitch duration of a fiber.

\[
\text{CF} = \frac{1}{\text{Twitch duration (in sec)}}
\]

For example, a fiber has twitch duration of 10 ms or 0.01s. The CF for this fiber will be 1/0.01s = 100/s.

When a muscle is stimulated with a frequency more than CF, summation of contractions occurs. Stimulation of the muscle with less than CF produces distinct contractions with intermittent relaxations. A fast muscle needs a larger CF and a slow muscle needs a smaller CF to summate the contractions. The tension generated during a complete tetanus is usually about four times that of a single twitch.

1. Following a single action potential, enough Ca^{2+} is released to expose all the myosin-binding sites on actin molecules. But, the attachment of activated myosin heads to these sites takes time. Also, the Ca^{2+} concentration starts decreasing as the pumping back of Ca^{2+} into the sarcoplasmic reticulum commences immediately.
2. Therefore, all the cross-bridges are not engaged and the tension-generating mechanism is not saturated.
3. In a tetanic contraction, more and more Ca\(^{++}\) is released with each successive action potential, exhausting the pumping-back mechanism.
4. Thus, the cytosolic calcium remains at a constantly high level so that all the myosin-binding sites on the thin filaments are available.
5. Therefore, the tension generated during tetanic contraction is very high. Such contraction occurs in a disease called tetanus caused by the clostridium tetani.

**Post-Tetanic Potentiation**

When a single stimulus is applied to a muscle immediately after the tetanic contraction is over, the amplitude of contraction is higher than that of a single twitch. This phenomenon is known as post-tetanic potentiation.

1. Following tetanic contraction, the released Ca\(^{++}\) takes some time to be pumped back into the sarcoplasmic reticulum.
2. This left-over Ca\(^{++}\) is added to the Ca\(^{++}\) released by the next stimulus resulting in a higher cytosolic Ca\(^{++}\) level and, therefore, a bigger contraction.

**Length-Tension Relationship**

Isometric tension developed in a muscle depends on the initial length of the muscle. For the isometric tension to be recorded in an experimental set-up, the ends of the muscle are attached to two fixing points so that changing the distance between the fixing points can alter the length of the muscle.

1. When the muscle fiber is stretched, the tension registered by it is known as the passive tension, which is due to the elongation of the elastic titin filaments, not due to activation of the contractile elements.
2. If this stretched muscle is stimulated, the tension developed by it is known as the total tension.
3. At any length, the amount of tension actually generated by the cross-bridge movements is known as the active tension, which is the difference between the two values, that is the total tension minus passive tension.

The length-tension relationship graph (Fig. 28.3) shows that within physiological limit, the tension in the muscle increases, as the length is gradually increased.
1. The length of the muscle prior to contraction is called the **initial length**.

2. The length of the muscle at which it develops maximal isometric active tension is known as the **optimal length** or **resting length**, beyond which the tension generated on stimulation decreases until the muscle fibers are torn by the stretch.

3. It has been found that when the skeletal muscles in the body are relaxed, if the tendon is cut from its bony attachment, the muscle shortens about 20%. This indicates that the skeletal muscles are under a certain degree of stretch in the resting state.

4. Experiments have shown that this degree of stretch of resting muscles generates maximum tension on stimulation. Therefore, the term ‘resting’ length is used to describe the muscle length at which maximum response is produced when it is stimulated.

**Length-Tension Relationship in a Sarcomere:**

The length-tension relationship in skeletal muscle has been explained by the sliding filament mechanism of muscle contraction described earlier. According to this mechanism, during contraction, the amount of tension generated depends on the total number of cross-linkages formed due to interaction between actin and myosin molecules.

1. **At resting length**, there is utmost overlap between actin and myosin filaments that can lead to maximum tension development.

2. As the muscle is stretched beyond this length, overlap between thick and thin filaments decreases progressively and the active tension developed declines proportionately, such that, when there is no overlap, the tension generated becomes nil (Fig. 28.4).

3. On the contrary, when the length becomes less than the resting length, overlap decreases and the tension declines.

4. With extreme reduction in length, the thin filaments overlap each other in the center of the sarcomere so that the binding sites on actin are in the bare area of the thick filaments, producing minimal tension. The optimal sarcomeric length in frog muscle is 2.0–2.2 µm.

**Load-Velocity Relationship**

When a muscle contracts against a load (isotonic contraction), the velocity of fiber-shortening is inversely proportional to the degree of load. When there is no load, the muscle contracts with maximum velocity and the velocity decreases with increasing load on the muscle (Fig. 28.5).

1. When the load becomes equal to the maximal isometric tension the muscle can develop, the shortening velocity is zero. If the load increases further, the muscle lengthens (**lengthening contraction**).

2. This load-velocity relationship is a common experience in our day-to-day life. As we know, light objects can be lifted faster than heavy objects.

3. The rate of cross-bridge cycling in a muscle, which depends on its ATPase activity, determines the shortening velocity of that muscle. In general, a light load offers less resistance to the sliding of the filaments so that thin filaments move quickly over thick filaments allowing few cross-bridges to form at a time, producing less tension and faster contraction.

4. On the contrary, increasing the load on a cross-bridge slows its forward movement during a power stroke and reduces the ATP hydrolysis; the slower contraction allows more time for actomyosin interaction and greater tension development.

Now, if we correlate both the length-tension and load-velocity relationships in a skeletal muscle, we can derive that for any given load, the shortening velocity is maximal when the muscle is at its resting length. When a muscle is stretched by a load prior to start of contraction, the condition is known as free-loaded (pre-loaded); and when the load is applied to the muscle after it starts contracting, the condition is called after-loaded.
Energy Sources in Skeletal Muscle

Adenosine Tri-phosphate
Adenosine Tri-phosphate (ATP) is the immediate source of energy for contraction in skeletal muscles. During ATP hydrolysis, the terminal high-energy phosphate bond of ATP splits to form ADP and Pi, with release of 7.3 kcal for each mole of ATP hydrolyzed.

ATP + Pi + H2O → ADP + Pi + 7.3 kcal

The functions of ATP are as follows:
1. It supplies the energy required for cross-bridge movement during muscle contraction.
2. ATP binding to myosin breaks the actin-myosin interaction and allows the cross-bridge cycle to continue.
3. It provides energy to the Ca2+-Mg2+ ATPase pump that transports Ca2+ back into the SR and initiates relaxation.
4. The Na+/K+ pump in the sarcolemma utilizes the energy derived from ATP hydrolysis to maintain the membrane excitability (RMP).

In resting muscle, less ATP molecules are present in the sarcoplasm. Once contraction is initiated, ATP stores can sustain contraction for a fraction of a second. For contractions to continue, muscle requires an enormous supply of ATP, which has to be generated immediately. ATP is regenerated by the addition of one phosphate group to ADP by three pathways:
1. Phosphorylation of ADP by creatine phosphate
2. Oxidative phosphorylation of ADP in the mitochondria
3. Phosphorylation of ADP by the breakdown of glucose to CO2 and H2O.

Creatine Phosphate
Creatine phosphate (CP) is also called phosphorylcreatine. Phosphorylation of ADP by creatine phosphate is a very rapid, nonoxidative process, which provides ATP by transfer of a phosphate group from CP to ADP, catalyzed by the enzyme creatine kinase (CK).

CP + ADP ⇌ CK C + ATP

The concentration of CP is about five times that of ATP in the resting muscle. The above reaction is stimulated by a fall in ATP and a rise in ADP concentration. The amount of ATP that can be formed is limited by the initial concentration of CP in the sarcoplasm. The ATP supplied by this mechanism sustains contractions for a few seconds. During recovery period, the concentration of CP is restored back to the normal level by addition of ATP formed by glycolysis to creatine (C). Also some mitochondrial ATP transfers its phosphate group to creatine.

C + ATP ⇌ CK CP + ADP

As the levels of ATP and CP fall, other mechanisms are activated to provide ATP to the contracting muscle. At rest and during light exercise, muscle utilizes free fatty acids as its energy source. During moderate to heavy exercise, metabolism of glucose and glycogen has the primary role to generate ATP. In the presence of O2, aerobic glycolysis takes place, the end-products being CO2, H2O, and 38 molecules of ATP. If the O2 supply is inadequate, anaerobic glycolysis delivers lactic acid and 2 ATP per molecule of glucose.

Oxygen Debt
During rapid strenuous activity, even with the high respiratory rate and maximum possible dilation of the blood vessels, ATP generated by aerobic glycolysis is not rapid to meet with body’s energy need. In that case, anaerobic glycolysis occurs to fulfill the ATP demand. For example, when a person runs for an hour, around 95% of the energy spent comes from aerobic glycolysis and only 5% from anaerobic glycolysis whereas in a 100 meter dash completed in 10 seconds, 85% of the energy is derived from anaerobic glycolysis.

After the exercise is over, body has to accomplish the following functions:
1. Convert the surplus lactate into pyruvate
2. Replenish the ATP and CP stores in the muscle
3. To replaced the O2 that came from myoglobin.
4. For all the above functions, O2 is required. Therefore, even after the termination of the exercise, the respiratory rate remains high for some time according to the severity of the exercise. The amount of extra oxygen taken up by the body above the basal O2 consumption following exercise is known as oxygen debt (Application Box 28.1).

Application Box 28.1
Effects of training: Trained athletes can increase muscle oxygen consumption greatly than the nonathletes. They can also effectively utilize free fatty acids. Thus, they sustain exercise without loss of glycogen and accumulation of lactate. Hence, oxygen debt in them is much smaller even for severe exercise. They also practice more carbohydrate meal several days before the final competition to increase their muscle glycogen store.

Muscle Fatigue
When a skeletal muscle is repeatedly stimulated, the tension developed by the muscle gradually decreases, even though the stimulation continues. The decrease in muscle tension as a result of previous contractile activity is known as muscle fatigue. There is decline in the amplitude of contraction as well as the shortening velocity, and the relaxation period is prolonged. Fatigue can be of early or late onset and the rate of its progress can be fast or slow. In general, the factors affecting skeletal muscle fatigue are:
1. The type of fibers present in the muscle
2. The intensity and duration of the exercise
3. Availability of nutrients like oxygen and glucose
4. Accumulation of metabolites like lactic acid, H+, K+ and substance P
5. Previous regular training of the similar type of activity
6. CNS factor
Out of all these, the CNS factor plays an important role in delaying the muscle fatigue in human beings. As we know, motivation and encouragement significantly prolong the duration of exercise. They lead to secretion of certain neurotransmitters by an unknown mechanism that reduces the sensory inputs from the exercising muscle as well as the whole body, reaching the level of consciousness. One probable mechanism is that they activate the endorphin system. The degree and source of encouragement also affect fatigue significantly. A muscle that fatigues early also recovers early and the one that takes longer time also recovers late.

**Rigor Mortis**

During the cross-bridge cycle, binding of ATP to the myosin head breaks the actin-myosin interaction and brings in relaxation of the muscle. If cellular energy stores are depleted, as happens after death, cross-bridge detachment cannot occur due to lack of ATP. Therefore, the myosin heads remain in the attached state. Following death, the cytoplasmic calcium concentration remains elevated because of the following reasons:

1. Calcium is not pumped back into the sarcoplasmic reticulum in the absence of ATP.
2. Ca\(^{2+}\) diffuses from ECF into the cytoplasm. This is because after death, the muscle membrane becomes inactive, which cannot maintain the high gradient of Ca\(^{2+}\) between ECF and ICF, as occurs in life.
3. The inactive membrane of the SR cannot hold back Ca\(^{2+}\), which diffuses out of SR to the sarcoplasm.

The raised cytoplasmic calcium concentration initiates contraction by exposing the myosin heads on actin and permitting formation of cross-bridges that do not detach due to lack of ATP. This leads to stiffness in the muscle, which is known as rigor mortis. It starts about 3 to 4 h after death and gets completed in about 12 h after death. The stiffness disappears 48 to 60 h after death due to disintegration of muscle proteins.

**Heat Production in Muscles**

During muscle contraction, most of the energy is spent in the form of heat, part of the energy is used to do the work and a small portion is used to build up the ATP stores. The mechanical efficiency of a muscle is expressed as the percentage of total energy spent for the work done. In isometric contraction, work done is zero; so the mechanical efficiency is 0%, whereas in isotonic contraction, the efficiency lies between 20 and 25%, and can be as much as 50%. The amount of heat generated can be measured accurately with the help of sensitive thermocouples.

The heat generated is of the following types:

a. **Resting heat**: When the muscle is at rest, the heat generated due to basal metabolism is known as resting heat.

b. **Initial heat**: Initial heat is the heat liberated during muscle contraction in excess of resting heat. It can be further divided into two parts:

i. **Activation heat**, which is produced after the muscle is stimulated and before the contraction starts.

ii. **Shortening heat**, which is released during contraction leading to shortening and is proportionate to the degree of shortening.

iii. **Relaxation heat**: When a previously shortened muscle returns to its original length, the heat generated is known as relaxation heat.

iv. **Recovery heat**: This is the heat produced by the metabolic processes to restore the muscle to its resting state, in excess of resting heat. The recovery heat is liberated for a prolonged period and is equal in magnitude to the initial heat.

### Fiber Types in Skeletal Muscle

Based on the speed of contraction and the process of deriving energy from the body metabolism, skeletal muscle fibers can be classified into two categories: type I and type II (Table 28.1).

Type I Muscle Fibers
Muscles consisting mainly of type I fibers have many capillaries and high myoglobin content that imparts them the red color. This ensures an increased blood flow to supply more oxygen.

1. As there are plenty of mitochondria and the oxygen binding protein myoglobin, they synthesize ATP by oxidative phosphorylation and are named as oxidative fibers.
2. Due to their low myosin ATPase activity, they break down ATP slowly; thus, the rate of cross-bridge cycling is less causing a decreased contraction velocity and so they are known as the slow fibers.
3. They are more resistant to fatigue; that means they can remain contracted for longer time, thereby help maintain posture.
4. Therefore, type I fibers in back and proximal limb muscles are known as postural muscles.

Type II Muscle Fibers
Muscles containing mainly type II fibers have a greater contraction velocity and are mainly white muscles. They carry out fine, precise movements. The examples are intrinsic muscles of the hand and extraocular muscles of the eye.

Motor Units

Definition
A motor unit consists of a single motor neuron, its axonal branches and all the muscle fibers supplied by them (Fig. 28.6).

Size of a Motor Unit
The cell bodies of motor neurons are present in the anterior horn of the spinal cord. A single motor neuron branches out and innervates many muscle fibers. When a motor neuron discharges, contraction is produced in all the muscle fibers supplied by it.

1. The size of a motor unit can be large or small depending on the number of muscle fibers innervated by it.
2. In the intrinsic muscles of the hand, one motor neuron innervates less than ten muscle fibers so, stimulation of a motor unit produces a small rise in tension.
3. The back muscles have hundreds or even thousands of muscle fibers per motor unit, where activation of a single motor unit causes a large increase in tension.

Recruitment of Motor Units
At the resting state of the muscle, hardly any motor unit is activated. When a single motor neuron discharges, there is some rise in tension in the muscles of the concerned limb. If a greater total tension has to be attained, additional motor neurons fire and there is increase in the number of active motor units. The process of activating more number of motor units is called recruitment of motor units.

1. In hand muscles, gradual activation of motor units produces a stepwise increase in muscle tension because, with activation of each new unit, a small amount of tension is added. As the tension goes up in a graded manner, it can precisely be regulated. Therefore, the muscles carrying out skilled movements have smaller motor units, for which finer regulation of muscle tension is of primary importance.
2. In contrast, in back muscles, with recruitment of additional motor units, each time a huge amount of tension is added. Therefore, the back muscles are useful in maintenance of posture, as there is need to develop a greater tension to resist the downward pull of the gravity (Application Box 28.2).

Asynchronous discharge of motor units prevents fatigue: The motor units discharge asynchronously. When some of the motor units are active, other units are silent. Afterward, the active units go to rest and the silent units become active. At any instant of time, the inputs from different units are summed and this results in a smooth contraction of the muscle. This also helps the muscle to work for longer time without being fatigued.

Size Principle
All the muscle fibers in a motor unit are of the same type, i.e. the muscle fibers innervated by a spinal motor neuron are either oxidative or glycolytic in nature. Based on this,
the motor units can be designated as oxidative or slow and glycolytic or fast motor units. Usually the large diameter, fast-conducting motor neurons innervate the muscle fibers of the fast motor units and the small diameter, slow-conducting motor neurons innervate muscle fibers of the slow motor units. This is called the size principle. As the strength of contraction gradually increases, the small motor units are recruited initially, followed by the recruitment of large motor units. Thus, during the activity of mild to moderate intensity, the less fatigable, oxidative fibers mostly take part in the contractile activity, whereas the glycolytic fibers are recruited during more intense contraction. In general, a muscle has both types of motor units (Application Box 28.3).

**Whole-Muscle Contraction**

During any voluntary activity, muscles contract or relax around a joint to facilitate or inhibit movement in a particular direction. A whole muscle (for e.g. biceps or triceps) consists of many muscle fibers that are organized into several motor units. The central nervous system exerts a precise control over the voluntary movements by matching the force required by the act with the tension developed in the active muscles. Depending on the type and degree of activity, tension develops in the muscles in a smooth and graded fashion. The CNS achieves this by recruitment of more motor units and increasing the frequency of discharge of the motor units. The motor units discharge asynchronously and this results in a smooth and sustained contraction preventing early fatigue of the muscle.

The total tension developed in a muscle depends on the number of active fibers at any instant during contraction, which is decided by the following factors:

1. The total number of active motor units
2. The number of fibers present in each motor unit
3. The type of fibers present in each motor unit (based on the initial length of the fiber, its diameter and fatigability).

**Muscle Strength**

The strength of a muscle is measured by the maximum load it is capable of lifting. There are muscles of different lengths and shapes. Therefore, in order to compare the relative strengths of muscles, the maximum load it can lift in kilograms is divided by the cross-sectional area in square centimeters. The strength of human skeletal muscles is about 3–4 kg/cm², a value typical of all mammals. In the same age group, males have a higher value than females, the ratio being 1.0:0.65. The male hormone testosterone contributes to better development and growth of skeletal muscles. So, the differences are apparent in the postpubertal life. Genetic build plays a role. Also, regular and systematic training enhances muscle power.

**Applied Aspects**

**Muscular Dystrophy**

Muscular dystrophy (MD) includes a variety of degenerative muscle diseases that are due to mutations in the genes coding for the various components of the dystrophin-glycoprotein complex.

**Duchenne Muscular Dystrophy**

The commonest of muscular dystrophy is Duchenne muscular dystrophy (DMD), also called pseudohypertrophic MD, an X-linked recessive disease that affects mostly male children.

1. DMD is characterized by progressive muscular weakness that becomes apparent by age 4, and enlargement of affected muscles (muscle hypertrophy), especially of the calf muscles, and pelvifemoral muscles. Cardiomegaly is common.
2. Enlargement occurs due to gradual degeneration and necrosis of muscle fibers that are replaced by more fibrous and fatty tissue.
3. Typically, the child uses his hands to climb up, while getting up from the floor. By age 12, most sufferers are no longer ambulatory and death occurs by age 30.
4. The pathology is mainly due to absence of dystrophin in the muscles, caused by mutations of the dystrophin gene.
5. Dystrophin gene is a large gene, located in the p21 region of the X chromosome and has a high mutation rate.

**Baker’s Muscular Dystrophy**

Baker’s muscular dystrophy (BMD) is a less severe and rare form MD. It is similar in presentation to DMD, but patients often survive into adulthood.

1. In BMD patients, dystrophin is reduced in amount or present in an abnormal form. Research is underway to identify and stimulate the production of dystrophin-related proteins that may help to correct the symptoms of BMD.
2. A gene expressing a truncated form of dystrophin, called utrophin, has been inserted into mice using transgenic methods and has improved the myopathy.
3. In several forms of MD, laminin 2, a protein associated with the basal lamina of muscle cells and concerned
with mechanical connections between the exterior of muscle cells and the extracellular matrix, is absent along with dystrophin.

**Myopathies**
Mutations in the gene coding for the protein desmin cause skeletal and cardiac myopathies.

**Metabolic Myopathies**
Metabolic myopathies occur due to mutations in the genes coding for various enzymes involved in the metabolism of carbohydrates, proteins and fats. In these patients, muscle breakdown occurs due to accumulation of toxic metabolites.

**Inflammatory Myopathy**
Poliomyelitis is an inflammatory myopathy in which weakness of proximal limb muscles is an early feature. It is due to destruction of motor neurons present in the anterior horn of spinal cord by the poliovirus, resulting in paralysis of skeletal muscles. Death may occur due to respiratory failure.

**Myotonia**
These are conditions where muscle relaxation is prolonged after voluntary contraction. They are due to abnormal genes on chromosomes 7, 17 or 19 that lead to malfunction of Na⁺ or Cl⁻ channels.

**Focal Dystonias**
Dystonia means faulty contraction. Usually the abnormal contraction is limited to a small and specific region of muscles, so it is called focal dystonia.
1. These are neuromuscular disorders characterized by involuntary and repetitive or sustained skeletal muscle contractions that cause twisting, turning or squeezing movements in a body part.
2. They often result in abnormal postures, considerable pain and also physical impairment.
3. The common dystonias are spasmodic torticollis and cervical dystonia that usually affect neck and shoulder muscles, blepharospasm that affects eyelid muscles, strabismus and nystagmus that affect extraocular muscles, writer’s cramp that affect finger muscles, spasmodic dysphonia that affect muscles of speech apparatus including vocal cord and hemifacial spasm that affect facial muscles.
4. Injection of botulinum toxin into the affected muscles has shown promising results in the treatment of these disorders.

**Muscle Sprain**
Muscle sprain often occurs during sports activity or physical labor due to overstretching or forced extension of an active muscle.
1. Very often the myotendinous junction is injured or, at times, there is separation of the fibers.
2. Ultrastructural damage to the contractile elements especially at the Z lines may occur. Pain, soreness, weakness, and swelling are the usual symptoms.
3. Treatment includes ice packs, rest and immobility. Drugs to relieve pain may be prescribed and surgery is performed to correct the damage if needed.

**Muscle Cramp**
This is a painful condition due to involuntary tetanic contraction of skeletal muscle.
1. It is caused by generation of nerve action potentials at a very high rate.
2. This abnormal activity of nerve occurs in conditions like electrolyte imbalances in the extracellular fluid surrounding both the muscle and nerve fibers due to overexercise or persistent dehydration.

---

**CHAPTER SUMMARY**

**Key Concepts**
1. Skeletal muscle exhibits properties, such as summation of contraction, treppe, tetanization and typical length-tension and load-velocity relationship that are suited for its functions.
2. Major energy sources in skeletal muscles are ATP, and creatine phosphate.
3. After the termination of the exercise, the respiratory rate remains high for some time to meet the amount of extra oxygen taken up by the body above the basal O₂ consumption during exercise. It is known as oxygen debt. Oxygen debt is much less in athletes compared to nonathletes, even in severe exercise.
4. A motor unit consists of a single motor neuron, its axonal branches and all the muscle fibers supplied by them. At rest, hardly any motor unit is activated. For more muscle tension to be attained, additional motor neurons should fire and there should be increase in the number of active motor units. The process of activating more number of motor units is called recruitment of motor units.
### Important to Know (Must Read)

1. In examinations, ‘properties of skeletal muscle’ may be asked as a **Long Question**.
2. Treppe, Length-tension relationship, Load-velocity relationship, Oxygen debt, and Heat produced in muscle come as usual in **Short Questions** in exams.
3. In **Viva**, examiners usually ask: Name the properties of skeletal muscle, What is staircase phenomenon, Define treppe and speak about its mechanism and importance, What is the difference between tetanization and tetany, What are the critical frequency for tetanization, What is post-tetanic potentiation, Define initial length and resting length, What is passive tension, active tension and total tension, What is Length-tension relationship and Load-velocity relationship, Define oxygen debt, what is its mechanism and its importance, What are the types of heat produced in a muscle, How muscle fatigue can be delayed, What is rigor mortis and what is its mechanism, What are the types of muscle fibers and what are the differences between them, Define motor unit, What is motor unit recruitment, What is size principle, Name common muscle dystrophies and myopathies, What is the defect in Duchenne muscle dystrophy and what are the features in this problem.
4. Oxygen debt, length-tension relationship and motor units are invariably asked in both theory and oral exams.
On completion of study of this chapter, the student **MUST** be able to:

1. Classify smooth muscle, and mention the differences between them.
2. List the properties of smooth muscle.
3. Describe the mechanism of smooth muscle contraction.
4. List the special features of cardiac muscle.
5. List the differences between skeletal, smooth, and cardiac muscle.

The student **MAY** also be able to:

1. Describe the properties of smooth muscle and cardiac muscle.
2. Explain the differences between skeletal, cardiac, and smooth muscles.

**SMOOTH MUSCLES**

Smooth muscles are mainly present in the visceral organs and blood vessels. The distinctive features in smooth muscles and major differences from skeletal and cardiac muscles are:

1. They are characterized by absence of regular pattern of cross-striations as found in skeletal and cardiac muscles, hence the name *smooth muscles*.
2. The nerve supply to smooth muscles is through the branches of autonomic nervous system.
3. Another striking difference is that the length-tension relationship is not linear as in skeletal and cardiac muscle.
4. Smooth muscles can remain contracted for relatively longer periods without expenditure of much energy, a property that endows them with a better metabolic economy.

**Types of Smooth Muscles**

In some organs, groups of smooth muscle fibers behave as *syncytium*, like that of cardiac muscles and in few other organs they follow the functional properties of skeletal muscles. Based on this, they are classified into two types: single-unit smooth muscles, and multiunit smooth muscles.

**Single-unit Smooth Muscle**

The muscle fibers in single-unit smooth muscles are connected to each other by *gap junctions*.

1. The action potential generated at one place spreads rapidly to all the fibers of that unit. Therefore, contraction occurs simultaneously in all the fibers. Due to this *synchronous electrical and mechanical activity*, the fibers behave as a *syncytium* or a single unit.
2. Single-unit smooth muscles are far more abundant. They form the *walls of hollow viscera* such as the gastrointestinal tract, from the esophagus to the rectum, including the gallbladder and ducts of digestive glands; the ureters and urinary bladder; the uterus and small diameter blood vessels.
3. As they are present in many visceral organs, they are also called *visceral smooth muscles*.

**Multiunit Smooth Muscle**

Multiunit smooth muscles *do not have gap junctions*; therefore, they do not act as a syncytium.

1. They *resemble skeletal muscles functionally* as they are largely under neural control, though not under voluntary control.
2. They are abundantly innervated by the fibers of the autonomic nervous system.
3. The intrinsic muscles of the eye (ciliary body and iris), muscle in the large airways to the lungs, precapillary sphincters, and piloerector muscles are examples of multiunit smooth muscles.

**Functional Organization**

Though the structure of smooth muscles remains apparently same in various body parts, they accomplish different tasks at different body locations. For example, they regulate movement of fluids in the blood vessels, cause propulsive movements at different parts of GIT, expel the contents of the hollow organs like uterus, etc. To suit these varieties of functional needs, arrangements of smooth muscles differ in body parts.

Chiefly, arrangement of fibers is of three types:

1. **Circular**: Circular pattern of arrangement is seen in the blood vessels and in the airways of the lungs where contraction of the muscles narrows the diameter of the passage and reduces the flow. In sphincters, the contraction can totally block the passage and stop the flow.

2. **Circular and longitudinal**: Circular and longitudinal organization is found in GI tract, where an inner thick circular muscle layer and an outer thin longitudinal muscle layer regulate the many types of movements of intestine and promote the mixing and forward movement of the digested food.

3. **Circular, longitudinal and oblique**: Circular, longitudinal and oblique arrangement is typically found in the uterus and urinary bladder. When the increased contents of these viscera stretch these muscles, they contract and decrease the volume by expelling the contents.

**Structure**

Unlike skeletal muscle fibers that cannot multiply once differentiation is complete around birth, the smooth muscles are capable of dividing throughout the life of the individual. The special features of smooth muscles are as follows:

1. The cells are quite small in size compared to the whole tissue. The small size of cells is an advantage for smooth muscle for precisely controlling visceral functions.

2. Each smooth muscle fiber is a spindle-shaped cell, 100–300 µm long and 5–10 µm in diameter at the middle (Fig. 29.1).

3. Smooth muscle cells contain a single elongated nucleus at the center and few mitochondria. The cell derives energy mainly from glycolytic pathway.

4. The sarcoplasmic reticulum is well developed only in some types of smooth muscles; in others it is rudimentary.

5. Myofilaments are organized differently.

6. There are no sarcomeres and striations are not visible (Figs. 29.2A and B).

7. There is lack of an organized T tubular system.

8. The cell membrane shows invaginations called caveolae that increase the surface area.

**Myofilaments**

The cytoplasm contains three types of myofilaments: thick, thin, and intermediate. In addition to the filaments, the cytoplasm contains a calcium-binding protein called calmodulin, which is structurally related to troponin.

**Thick Filaments**

The thick filaments are about 2.2 µm long and composed of myosin molecules that are not arranged in a regular pattern around the axis of the filament as in the skeletal muscle. They are interspersed among the thin filaments (Fig. 29.3) and are much fewer than in skeletal or cardiac muscle.

**Intermediate Filaments and Dense Bodies**

The diameter of intermediate filaments is about 10 nm, which is present between the thick and thin filaments. Intermediate filaments provide cytoskeletal support and have negligible roles in contractile activity.
Section 3: Nerve and Muscle

1. Small, electron-dense, dark areas called dense bodies are present throughout the cytoplasm, as well as attached to the cell membrane.

2. Those associated with the cell membrane are often called membrane-associated dense bodies or patches, or focal adhesions. Dense bodies are functionally analogous to the Z lines in skeletal muscle fibers.

Thin Filaments
In smooth muscles, thin filaments are composed of actin and tropomyosin molecules but troponin protein complex is absent.

Organization of Filaments
The relationship between the thick and thin filaments is poor and they are less well organized.

1. In cross sections through the overlap region of the filaments, the geometric pattern as found in striated muscles are not seen.

2. Because of the absence of a highly organized arrangement of contractile apparatus, the length tension relationship in the smooth muscles is very much flexible.

3. The thick and thin filaments are obliquely oriented to the long axis of the cell. The actin filaments anchor to the dense bodies by means of the protein \( \alpha\)-actinin.

4. During the sliding-filament mechanism, the gap between the actin filaments reduces and the shortening force is transmitted through the dense bodies to the plasma membrane producing contraction of the muscle fiber.

Organization of Muscle Fibers
The smooth muscle fibers are organized in sheets and the cells are connected to adjacent cells by short strands of connective tissue. In addition, collagen and elastin fibers are embedded in a reticular connective tissue that traverses through the whole organ, connecting and holding the cells together.

1. Most importantly, the cells are linked to each other by gap junctions, by which many cells are activated at a time by single action potential.

2. With the help of the stroma and the gap junctions, the mechanical as well as electrical activities of the cells are coupled, so that contraction occurs in an integrated and coordinated fashion.

Innervations of Smooth Muscles
Smooth muscles exhibit a spontaneous, slow wave rhythm. Neural stimulation only modulates (increases or decreases) this basic pattern. Branches of the autonomic nervous system innervate the smooth muscles, most of which are supplied by sympathetic as well as parasympathetic fibers:

1. In response to a nerve action potential, neurotransmitters are secreted from the numerous varicosities present along the axon, and then diffuse to the adjacent tissues.

2. Since the release of neurotransmitters is not confined to the axon terminals, highly specialized neuromuscular junctions are absent in smooth muscles.

3. Unlike the skeletal muscle, the receptors for neurotransmitters are not gathered at the neuromuscular junctions, they are scattered along the postsynaptic membrane.

Electrical Properties
Unlike the skeletal muscle where the stimulus arrives in the form of an all-or-none action potential, in smooth muscles the contraction may or may not be preceded by an action potential. The smooth muscles react to a variety of stimuli, which may be neural (sympathetic or parasympathetic); hormonal (circulating catecholamines, serotonin, histamine, angiotensin, vasopressin, oxytocin, estrogen, and progesterone); chemical (hypoxia, hypercapnia, and \( \text{H}^+ \)); cold; and stretch. The transmission of nerve impulse in sympathetic and parasympathetic nerves supplying visceral muscles and properties of visceral muscle were studied in detail by Dale.

Scientists contributed

Sir Henry Hallett Dale (1875–1968) and Otto Loewi (1873–1961)

The Nobel Prize in Physiology or Medicine 1936 was awarded jointly to neurophysiologist from UK Sir Henry Hallett Dale and neurophysiologist from USA Prof. Otto Loewi “for their discoveries relating to transmission of chemical nerve impulses, especially in sympathetic and parasympathetic nerves”. Their pioneering works were in the field of transmission of nerve impulses, especially its chemical basis. Dale had also studied the details of smooth muscle functions.
**Characteristic Electrical Activities**

1. When the stimulus is excitatory, the membrane potential decreases and it increases in response to an inhibitory stimulus.
2. The membrane potential of visceral smooth muscles is variable (no fixed resting potential), ranging from −30 mV to −70 mV with an average of −50 mV.
3. The visceral smooth muscle shows spontaneous oscillations in a wave-like pattern. Some of the oscillations lead to action potentials that may occur in the rising or falling phase of the wave.
4. The multiunit smooth muscles do not discharge spontaneously; they also do not respond to stretch.
5. Most of the visceral smooth muscles generate action potentials inherently; any stimulus acting on it only alters the rate and pattern of action potentials formed.
6. The shapes of action potentials vary widely, which may be a spike, or action potential with a prolonged plateau, or multiple spikes, superimposed on the membrane potential (Fig. 29.4). Other forms of spikes or action potentials of smooth muscle have been described in GI system).
7. In some cells, in response to stimuli like hormones or mechanical stretch, the membrane potential shows a graded change that may culminate into an action potential.

**Action Potential**

The action potentials are generally of low amplitude, which is about 60 mV, and the duration is around 100 ms. 

The depolarization phase is caused by influx of calcium from ECF due to the opening of voltage-gated Ca$^{++}$ channels. Compared to the striated muscles, the upstroke of action potential is prolonged in smooth muscles, because the Ca$^{++}$ channels take more time to open than the Na$^+$ channels. The repolarization phase occurs due to closure of Ca$^{++}$ channels, which occurs slowly. Opening of voltage-gated K$^+$ channels contributes toward the later part of repolarization. Action potentials are generally observed in visceral smooth muscles. Some smooth muscle cells contract without any change in membrane potential.

**Pacemaker Potential**

In addition to action potentials, pacemaker potentials are recorded in visceral smooth muscle. However, unlike cardiac muscle, the pacemaker activity is not generated at a fixed location; rather it shifts from place to place. In visceral smooth muscles like intestine, pacemaker activities occur at several sites at the same time and then they travel for a short distance in the muscle.

**Mechanism of Contraction**

**Role of Calcium**

As in other muscle types, changes in sarcoplasmic calcium ion concentration plays a major role in smooth muscle contraction.

1. The strength of the stimulus (the degree of stretch or the amount of neurotransmitter/hormone reaching the cell membrane) acting on the smooth muscle fiber can be graded. Accordingly, the change in cytosolic calcium concentration may be minute, more or very high, producing different degrees of contraction.
2. The cytosolic calcium concentration is increased mainly by entry of calcium from the interstitial fluid (calcium influx) or to some extent by its release from cytoplasmic calcium stores (calcium release).
3. However, the concentration of calcium in cytosol decreases due to binding of calcium to calmodulin, pumping back of calcium to the SR and calcium efflux.

**Calcium Influx**

Calcium influx occurs through voltage-gated Ca$^{++}$ channels, ligand-gated Ca$^{++}$ channels and a few leaky channels. The ECF calcium concentration is about 12,000 times higher than that of the cytoplasm (1,200,000 nmol/L versus 100 nmol/L). This high inwardly directed gradient favors calcium entry into the smooth muscle as soon as calcium channels open.

**Calcium Release**

Calcium release from the SR takes place by two mechanisms.
1. $IP_3$-mediated pathway activated by second messengers.
2. Calcium-induced calcium release (CICR) mechanism (as described above) in which, some amount of calcium influx stimulates further calcium release from the SR.
Binding of Calcium to Calmodulin
Binding of calcium to calmodulin starts when cytoplasmic calcium concentration is above $10^{-7}$ M and is completed at $10^{-4}$ M.

Pumping Back of Calcium to the SR
Pumping back of calcium to SR is mediated via a Ca$^{++}$ ATPase present on the membrane of SR.

Calcium Efflux
Calcium efflux to the ECF occurs by Na$^+$-Ca$^{++}$ antiport, a process of secondary active transport and by Ca$^{++}$-ATPase, both the mechanisms being present on the cell membrane.

In smooth muscles, tension is generated in the same manner as in skeletal muscles, by the attachment of energized cross-bridges to actin, followed by detachment from and reattachment to actin.

Molecular Basis of Contraction
As described above, calcium concentration increases in the cell mainly by influx from ECF, and partly by release from SR. The following step-wise processes take place sequentially to culminate in muscle contraction.

1. Rise in cytosolic calcium mainly due to calcium influx from ECF.
2. Calcium binds to calmodulin following which activation of myosin light-chain kinase (MLCK) occurs. Calmodulin is a small protein associated with MLCK, which is a Ca$^{++}$-calmodulin dependent protein kinase. When calmodulin binds with four calcium ions, the calcium-calcmodulin complex activates MLCK.
3. Activated MLCK brings about phosphorylation of myosin head and stimulates myosin ATPase activity. MLCK utilizes one molecule of ATP and causes phosphorylation of the regulatory light chains of myosin, on serine at position 19. This phosphorylation process is critical for the activation of myosin ATPase.
4. Increased myosin ATPase activity and myosin-actin interaction initiates the cross-bridge cycle and shortening occurs due to the sliding-filament mechanism. The myosin ATPase enzyme is activated in the phosphorylated myosin head causing hydrolysis of one ATP molecule. The energized myosin head (Myosin-ADP-Pi complex) binds with actin producing the power stroke and pulls the thin filament toward the center of the thick filament. ADP and Pi are released during this process.
5. The cross-bridge detaches from actin when another ATP molecule attaches to myosin reducing its affinity for actin. Then, the myosin ATPase enzyme hydrolyses ATP resulting in the attachment of myosin head with actin.
6. Thus, the cross-bridge cycle continues, provided that the myosin head remains phosphorylated.
7. The cross-bridge cycle continues as long as the required cytoplasmic calcium concentration is maintained, because phosphorylation depends on cytosolic calcium level (Flowchart 29.1).

In skeletal muscles, contraction proceeds with activation of thin filament proteins (actin-linked regulation), whereas in smooth muscles, the process of contraction is myosin based (myosin-linked regulation).

Mechanism of Relaxation
Relaxation is brought about by dephosphorylation of myosin light-chain by the enzyme myosin light-chain phosphatase (MLCP). This enzyme is constantly active during the periods of relaxation or contraction.

1. During contraction, the rate of MLCK-induced phosphorylation exceeds the rate of MLCP-induced dephosphorylation and therefore, amount of phosphorylated myosin increases in the cell, which allows the contraction to proceed.
2. When the cytoplasmic calcium concentration decreases, calcium is detached from calmodulin resulting in decline in MLCK activity. Consequently, the activity of MLCP predominates causing dephosphorylation of myosin; the myosin ATPase enzyme remains inactive and relaxation ensues.
3. Thus, phosphorylation and dephosphorylation of the myosin light-chain is regulated by respective rise and fall of cytosolic calcium concentration.
Phasic and Tonic Contractions: Unlike the skeletal muscles that demonstrate either twitch or tetanic contraction waves on stimulation, the smooth muscles exhibit phasic or tonic type of contraction.

Phasic Contraction
In phasic type, the degree of phosphorylation, the rate of cross-bridge cycle and the cytoplasmic calcium concentration return to the resting value following the phase of contraction.

Tonic Contraction
During tonic contraction, the above-mentioned parameters do not return to the resting value, rather they remain elevated above the baseline. However, their activity remains less than their peak activity, producing a sustained tension in the muscle at a lower level of MLCK phosphorylation that occurs with less expenditure of energy. This is possible due to the operation of latch-bridge mechanism.

Latch-Bridge Mechanism
Muscle in this state is known as the latch-state, in which dephosphorylation of attached cross-bridges occurs in an environment of elevated cytosolic calcium level.
1. When MLCP-induced dephosphorylation of myosin light-chain takes place, it does not bring about dissociation of myosin from actin until the cytoplasmic calcium concentration falls below a critical level.
2. This attached cross-bridges following dephosphorylation are known as the latch-bridges. In this process the rate of cross-bridge cycle is decreased due to slower rate of detachment of cross-bridges. That means the cross-bridges spend more time in an attached state.
3. Therefore, the ATP utilization is less, which enables the visceral smooth muscles to have sustained contractions with less expenditure of energy.
4. The force of this sustained contraction can be graded over a wide range because the cytosolic calcium concentration can be finely regulated over a wide range. From the latch-state, the relaxation of the muscle occurs when the cytoplasmic calcium concentration falls below $10^{-7} \text{ M}$.

Properties of Smooth Muscle
The properties of visceral smooth muscles may be divided into 3 categories (Table 29.1):

Muscle Tone
Visceral smooth muscles are continuously in a state of spontaneous irregular contraction known as tonus, which occurs due to generation of basic slow wave rhythm. In blood vessels, especially the arterioles, this muscle tone helps to maintain the blood pressure without much expenditure of energy. The multiunit smooth muscles do not exhibit the inherent muscle tone.

Length–Tension Relationship
Unlike the skeletal and cardiac muscles, where the tension changes proportionately to the change in length, the length–tension relationship is variable in smooth muscles.
1. When a smooth muscle is stretched, it initially shortens and exerts tension. However, if the stretch is maintained, gradually the tension decreases and if the stretch is increased, the tension may not rise proportionately or at a particular length, the tension may increase considerably. Thus the relationship is highly inconsistent.
2. The adaptability of the smooth muscle to the new length with less increase in tension is known as plasticity, which is based on the latch-bridge phenomenon.
3. In blood vessels, this feature is also known as stress relaxation that helps to maintain BP within the normal range in spite of sudden rise in pressure.
4. In hollow viscera like stomach, large volume of food and fluid can be accommodated without an undue increase in internal pressure, called receptive relaxation.

Force–Velocity Relationship
Compared to the skeletal muscles, smooth muscles have a low myosin ATPase activity, less number of cross-bridges and a slower rate of cross-bridge cycling. These factors contribute to a slower contraction velocity. Moreover, a variety of force-velocity graphs can be obtained in response to different stimuli, which can alter the plasma...
Ca++ in a graded manner. Thus, the degree of phosphorylation of the cross-bridges changes over a wide range.

**Smooth Muscle Hypertrophy**

Growth and proliferation of vascular smooth muscles are stimulated by a variety of growth factors. This is typically seen during pregnancy and in hypertension.

In pregnancy: Toward term, estrogen stimulates the hypertrophy (increase in cell size) and hyperplasia (increase in cell number) of myometrium as well as the growth of the connective tissue mass. There is increase in the amount of contractile proteins and the number of gap junctions that helps for an effective and coordinated contraction. Stretch of the uterine wall by the growing fetus also induces expansion of the myometrium.

In hypertension: When blood pressure is chronically elevated, the pressure load acts as a stimulus and the walls of the blood vessels undergo hypertrophy and hyperplasia. In addition, if there is sympathetic hyperactivity, increased catecholamines also stimulate the vessel wall proliferation by trophic effect. Angiotensin II stimulates, whereas glucocorticoids inhibit growth of vascular smooth muscles. Some other factors like arachidonic acid derivatives, adenosine, serotonin and heparin like substances also affect smooth muscle hypertrophy.

Other examples: When a hollow viscus like small intestine gets obstructed, the prolonged elevation of the intraluminal pressure stimulates hypertrophy of its muscle layer. Another example is hypertrophy of urinary bladder in men due to enlargement of the prostate gland.

**Neural and Hormonal Influences**

**Autonomic Control**

The autonomic nervous system influences the intrinsic rhythmic or pacemaker activity of the visceral smooth muscles. The effect of sympathetic or parasympathetic stimulation depends on the type of receptor involved and the mechanisms of the second messenger(s) released subsequently.

**Parasympathetic control:** Parasympathetic stimulation is excitatory. It releases acetylcholine. In intestine, acetylcholine is stimulatory.
1. It decreases the membrane potential, which makes the tissue more excitable.
2. It also increases the frequency of action potentials. As a result, there is increase in the number of rhythmic contractions as well as the duration of tonic contractions.
3. Ach acts by increasing the cytoplasmic Ca++ through phospholipase C and IP3.

**Sympathetic control:** Sympathetic stimulation is inhibitory. It releases catecholamines. The effects of catecholamines on intestine are just opposite to that of Ach. Catecholamines increase the membrane potential and decrease the frequency of spikes producing relaxation of the muscle. Norepinephrine (NE) acts through both α and β receptors.

- **Action through α receptors:** Acting via α receptors, NE increases calcium efflux from the cell. This leads to decline in cytoplasmic Ca++ and relaxation of the muscle.
- **Action through β receptors:** Acting via β receptors, NE stimulates adenyl cyclase that increases formation of cAMP, which activates the enzyme cAMP-dependent protein kinase. This protein kinase as well as cAMP increase calcium uptake by the sarcoplasmic reticulum. This results in fall in cytoplasmic concentration of Ca++. Thus relaxation occurs. In addition, the cAMP-dependent protein kinase decreases the activity of MLCK. Therefore, the cross-bridge formation is reduced that also produces relaxation.

The multiunit smooth muscles do not exhibit the inherent muscle tone. In response to the stimulation of the autonomic nervous system, their contraction is regulated in a precise, graded fashion.

**Hormonal Control**

Nitric oxide (NO): In response to the shearing stress caused by flow of blood, NO is released from the endothelial cells lining the arteries. It diffuses to the vascular smooth muscle fibers and binds to the receptors present on the sarcolemma. The NO-receptor complex stimulates guanylyl cyclase and forms cGMP, which activates cGMP-dependent protein kinase. This protein kinase produces relaxation by increasing calcium reuptake by SR, opening of Ca++-activated K+ channels and decreasing IP3-induced Ca++ release by inhibiting phospholipases C.

Other hormones: Angiotensin II acting via AT II receptors, vasopressin and endothelin stimulate contraction of smooth muscles by releasing IP3. Adenosine causes relaxation by increasing the level of cAMP.

**CARDIAC MUSCLE**

Muscles present in heart are cardiac muscles. Though they are structurally close to skeletal muscle they demonstrate many properties of smooth muscles. The details of structure, properties and functions of cardiac muscles are given in “Heart” section of CVS. Here, salient features are given to differentiate it from skeletal muscles and smooth muscles (Table 29.2).

**General features of cardiac muscles are:**
1. Cardiac muscle is an involuntary, but striated muscle. The muscle cell is 100 µm long and 15 µm wide.
2. The fibers are branched and attached with each other closely.
3. Intercalated discs are present at the point of contact of two muscle fibers.
4. Numerous gap junctions are present in the intercalated disc that make cardiac tissue a functional syncytium. There are two such separate syncytia in the heart. The

CHAPTER SUMMARY

Key Concepts

1. Though smooth muscles do not have organized sarcomeres, they have myofilaments for muscle contraction.
2. Membrane potential fluctuates between −30 mV and −70 mV.
3. Cytosolic calcium concentration plays a great role in muscle contraction. Calcium from sarcoplasmic reticulum mainly determines to cytosolic level of calcium, though calcium influx by voltage-gated and ligand-gated channels contribute.
4. Phosphorylation of myosin and latch-bridge mechanism, are special characteristics.
5. There is no definitive length-tension relationship. Plasticity is the main feature.
6. Control of smooth muscle is by autonomic nerves (sympathetic inhibitory and parasympathetic excitatory), and hormones.

Important to Know (Must Read)

1. In examinations, “Mechanism of smooth muscle contraction, and properties of smooth muscle” may come as a Long Question.
2. Special morphological features of smooth muscle, Electrical properties of smooth muscle, Mechanism of smooth muscle contraction, Role of calcium in smooth muscle contraction, Latch bridge mechanism, Properties of smooth muscle, Plasticity, Regulation of smooth muscle activity, and Differences between skeletal muscle, cardiac muscle and smooth muscle, come as Short Questions in exams.

35. Heart Rate Variability
"A soul shall wake in the Inconscient's house:  
The mind shall be God-vision's tabernacle,  
The body intuition's instrument,  
And life a channel for God's visible power."

Sri Aurobindo (in 'SAVITRI')
The term ‘autonomic’ is derived from the words *auto* means ‘self’ and *nomos* means ‘control’. Emotional responses of the body and responses to environment occur without conscious knowledge of the individual. These responses are therefore, called autonomic responses that are executed by the autonomic part of the nervous system. The ANS controls functions of the involuntary organs of the body that include heart and blood vessels, exocrine and endocrine glands, and all visceral organs. Thus, ANS controls all major functions of the body such as circulation, respiration, digestion, excretion and reproduction. Circulating hormones and locally produced chemicals assist in mediating these autonomic functions.

The functions of ANS can be broadly categorized into five parts:
1. Maintenance of homeostatic conditions of the body.
2. Regulation of visceral activities.
3. Smoothening body’s responses to environmental changes.
4. Coordination of body’s responses to exercise and stress.
5. Assisting the endocrine system to regulate reproductive functions.

**Scientists contributed**

**WH Gaskell** (1847–1914)

Walter Holbrook Gaskell was the first scientist who thoroughly investigated the innervation of the cardiovascular system and viscera. He discovered the cardioaccelerator nerve and laid the foundation for an understanding of autonomic nervous system.

**Sources:**

**JN Langley** (1852–1925)

John Newport Langley analyzed the functional significance of autonomic nervous system (ANS) in vertebrates. He was the first scientist to classify ANS into the sympathetic and parasympathetic divisions, indicating their anatomical, physiological and pharmacological relations and characteristics.

**Source:** Heffer W. *The Autonomic Nervous System.* Cambridge Publication: Cambridge, 1921.
FUNCTIONAL OVERVIEW

Divisions of Autonomic Nervous System

Autonomic nervous system is traditionally divided into two subdivisions: sympathetic and parasympathetic, based on their anatomic, functional and neurochemical properties. Enteric nervous system is considered to be the third division of ANS.

Sympathetic System

When the body requires support to meet emergency conditions and stressful situations, sympathetic system provides the desirable assistance. For its sympathy to help the body to face and overcome such critical situations in life, this division of ANS is called sympathetic system. Sympathetic system also helps to control normal functions of the body such as regulation of blood pressure, respiration, metabolism, etc. The importance of sympathetic system is realized in its dysfunctions. For example, a person with sympathetic imbalance will not be able to stand up from sitting or supine posture and will not be able to maintain the standing posture. Thus, sympathetic system is a friend of the body not only in emergency needs but also in its routine deeds.

1. The cell bodies of sympathetic system are located in the thoracic and abdominal segments of the spinal cord and sympathetic ganglia are present as a chain close to the vertebral column.
2. This system is also termed as the thoracolumbar division of the ANS for the location of the ganglia and cell bodies of neurons at thoracic and lumbar segments of spinal cord (Fig. 30.1).

Parasympathetic System

The component of ANS that works by the side of the sympathetic system is the parasympathetic division of ANS. It has a reciprocal influence on organ functions to that of sympathetic influence. In fact, it checks the overactivity of sympathetic system and smoothens the autonomic responses.

1. The cell bodies are found in the brainstem cranial nerve nuclei (cranial component), and in the most caudal part of the spinal cord (spinal or sacral component).
2. Hence, it is also termed as craniosacral division of ANS (Fig. 30.1).

Enteric Nervous System

The enteric nervous system (ENS) is the local neural network in GI system which has strong anatomical and physiological link with ANS. Therefore, ENS is considered as the ‘Third division of ANS’. It is concerned with the regulation of gastrointestinal function.

FUNCTIONAL SPECIALIZATION

The neurochemical differences between two divisions of sympathetic system led to the description of the sympathetic system as adrenergic for adrenaline (or noradrenaline) like actions resulting from sympathetic activation; and the parasympathetic system as cholinergic for acetylcholine like actions from parasympathetic activation. Some of the important functional characteristics of sympathetic and parasympathetic divisions are as follows:

1. The sympathetic division is primarily meant for utilization of metabolic resources and emergency responses of the body, whereas the parasympathetic division helps in restoration and build-up of the body’s reserves and the elimination of waste products.
2. Almost all the organs are supplied by both sympathetic and parasympathetic nerves and usually they are activated in a reciprocal fashion. Therefore, when the discharge rate in one division is increased, the rate in the other division is decreased. For example, when sympathetic activation occurs during exercise to increase heart rate, simultaneous decrease vagal activity also contributes to achieve the target increase in heart rate.
3. In some organs, sympathetic and parasympathetic systems work synergistically. For example, to enhance gastrointestinal secretions, when parasympathetic stimulation increases volume and enzyme content, simultaneous sympathetic activation contributes to increased mucus content of the secretory product.
4. Also, few structures such as blood vessels and skin receive only sympathetic innervation and therefore, their functions are regulated by alteration in the rate of sympathetic discharge to these structures.

**Somatic vs Autonomic Nervous System**

The nervous system contacts all organs and tissues of the body via the sensory system (afferent innervation), motor system (efferent innervation) and the ANS.

**Central Connections**

For efferent innervation of somatic system (i.e. the motor pathway), axons originate from cell body of neurons in the motor cortex and terminate directly or indirectly on motor neurons in the ventral horn of the spinal cord or in the brainstem motor nuclei, and usually the second order neuron (or sometimes the third order neuron) innervates the skeletal muscle. Similarly, in ANS, efferent pathway consists of two or three-neuron tract with one or two synapses interposed between the center and the effector cells.

1. The cell bodies of autonomic motor neurons are located in the intermediolateral horn of spinal cord or in the specific brainstem cranial nerve nuclei.
2. The efferent fiber emerges from CNS as the preganglionic axon and then synapses with the cell bodies of neurons located in a peripheral ganglion. The neuron from the ganglion then projects as postganglionic axon to the effector cells (usually a visceral organ).

**Reflex Arc**

The somatic nervous system collects information from the external environment, whereas the ANS collects information usually from inside the body, i.e. the changes in visceral structures (Fig. 30.2).

**Receptors**

Receptors are located in the body surface or in the musculoskeletal system in somatic system. In ANS, the receptors are present in the visceral structures.

**Afferent Pathway**

The afferent neurons of somatic system enter spinal cord via dorsal root with their cell bodies in the dorsal root ganglion and terminate on interneurons in deeper layers of dorsal horn or on motor neurons in the ventral horn. The afferent neurons of ANS enter spinal cord in a similar fashion, but they terminate on autonomic efferent neurons having their cell bodies in intermediolateral horn (ILH) of spinal cord.

**Central Neurons**

Central component in somatic system consists of the cell body of a motor neuron in the ventral horn of the spinal cord on which the afferent neuron directly terminates monosynaptically. The afferent neuron may also contact motor neuron through interneurons via disynaptic or polysynaptic connections.

In ANS, the cell bodies of central neurons are located in intermediolateral horn of spinal cord on which the afferent neuron directly terminates.
Efferent Neurons

The efferent neurons in the somatic system are motor neurons that originate from ventral horn of spinal cord and directly terminate on effector organ, which is usually a skeletal muscle. Thus, there is a single efferent neuron between the CNS and the effector organ in the somatic system.

In ANS, there are two neurons between the CNS and the effector organ (Fig. 30.3).
1. The first efferent neuron is the preganglionic neuron that has its cell body in the intermediolateral horn of spinal cord or in the cranial nerve nuclei in brainstem.
2. The second efferent neuron is the postganglionic neuron that has its cell body in the ganglia outside the spinal cord or in the effector organ.

Effector Organs

Somatic motor nerves innervate skeletal muscles. The efferent neurons of ANS innervate visceral organs (smooth muscle, cardiac muscle, glandular tissues, etc.).

Types of Efferent Pathways in ANS

Sympathetic System

In sympathetic system, there are three types of efferent pathways (Fig. 30.4):
1. The preganglionic neurons leave spinal cord via white rami communicantes to the paravertebral sympathetic ganglion where they contact cell bodies of postganglionic neuron, the axons of which terminate on effector organ. The postganglionic sympathetic neurons to head originate from superior and middle cervical ganglia and stellate ganglion. These ganglia are in fact extension of sympathetic ganglion chain into the neck.
2. Axons of preganglionic neurons give collaterals to terminate on another set of cell bodies in the paravertebral ganglion chain. Axons of these postganglionic neurons enter gray rami communicantes and from there enter into the spinal nerve to finally innervate the effector organs.
3. Some of the preganglionic neurons do not relay in paravertebral ganglion chain, rather they come out directly of the ganglion chain to terminate on the cell bodies of postganglionic neurons located in collateral ganglion that are present close to the effector organ. In this efferent pathway of sympathetic system, the preganglionic fibers are longer than the postganglionic fibers. Thus, the postganglionic neurons in this system form short noradrenergic neurons.

Parasympathetic System

In parasympathetic system, the preganglionic neurons of cranial part originate from cell bodies in the cranial nerve......
nuclei (III, VII, IX and X) in the brainstem and terminate in
the postganglionic neuron located very close to or in the
visceral organ. The preganglionic neurons of sacral part
follow a similar route except that the fibers originate from
the cell bodies in the intermediolateral horn of spinal cord and
traverse in spinal nerve.

In general, in sympathetic system, the preganglionic
fibers are smaller than the postganglionic fibers (Application Box 30.1), whereas in parasympathetic system, the
preganglionic fibers are much longer than the postgangli-
onic fibers (Fig. 30.5).

Application Box 30.1

Intrinsic cardiac adrenergic cells: Evidences of recent research studies
indicate that few postganglionic sympathetic neurons are embedded in
the cardiac tissue like that of postganglionic neurons of parasympathetic
systems that are usually located in the visceral organs. These neurons
form intrinsic cardiac adrenergic cells (ICAC). Secretion from ICAC
accounts for about 15% of adrenaline and noradrenaline content of the
heart. It is believed that during fetal and early childhood, catecholamine
content of ICAC plays an essential role in development of the heart.

Neurotransmitters in ANS

In the somatic nervous system, the efferent fibers terminate
on motor end plate usually with one axon terminal to one
skeletal muscle fiber. The neurotransmitter is acetylcholine.
1. In ANS, postganglionic axons terminate in varicosities,
the swellings enriched in synaptic vesicles that release
the transmitter into the extracellular space surround-
ing the effector cells.
2. The electrical activity for discharge of autonomic fibers
originates in some of the effector cells and then propa-
gates to cells of rest of the tissue via gap junctions.
3. The neurotransmitters in ANS are acetylcholine,
noradrenaline and others (Fig. 30.6).

Acetylcholine

Acetylcholine is the neurotransmitter at the following
nerve terminals (cholinergic fibers) in ANS:
1. Preganglionic nerve terminals of both the sympathetic
and the parasympathetic divisions.
2. All parasympathetic postganglionic neurons.
3. Postganglionic sympathetic neurons to sweat glands
and blood vessels in skeletal muscle.

The synapse at preganglionic nerve terminals utilizes
nicotinic receptors similar to that found at neuromuscular
junction. The synapse between the postganglionic neuron
and the target tissues utilizes muscarinic receptors. The
receptor classification is based on the response of the syn-
apses to the alkaloids nicotine and muscarine at respec-
tive type of synapse.
1. The nicotinic receptor is blocked by hexamethonium in
autonomic ganglion, in contrast to blockade by curare
at neuromuscular junction. The nicotinic cholinergic
receptor is of direct ligand-gated type as it contains
ion channel in it.
2. The muscarinic receptor is blocked by atropine. The
muscarinic receptor is of indirect ligand-gated type
as it uses a G protein to mediate effector functions.
The action of acetylcholine is terminated by acetylcholinesterase, the enzyme present at the cholinergic synapses.

**Norepinephrine**

Noradrenaline (NA) or norepinephrine is the neurotransmitter at postganglionic sympathetic nerve terminals (adrenergic fibers). NA released from adrenergic synapses utilize adrenergic receptors that can also be activated by adrenaline or epinephrine released from adrenal medulla. Therefore, these receptors are designated as adrenergic.

1. **Adrenergic receptors** are broadly classified into two types: α and β. The α receptors respond more to NA and less to epinephrine, and least to isoproterenol, the synthetic catecholamine.
2. The β receptors respond best to isoproterenol and epinephrine and less to NA. Propranolol is the antagonist for β receptors. Each class of receptors is further classified as α₁ or α₂, and β₁, β₂ or β₃ (for details, refer ‘Adrenal Medulla’ in ‘Endocrine Physiology’).
3. The adrenergic receptors are of the indirect ligand-gated type as they utilize G protein for their effects. The α₁ receptors activate phospholipase C. The α₂ receptors inhibit adenyl cyclase, whereas β receptors stimulate it.

**Other Neurotransmitters**

In ANS, especially in the intrinsic plexuses of the gut many amines, amino acids and active peptides are widely distributed as co-neurotransmitters. For example, neuropeptide Y is co-released by vasoconstrictor nerve, vasoactive intestinal polypeptide (VIP) and calcitonin-gene-related peptide (CGRP) are released along with cholinergic nerve terminals. Nitric oxide is another neurotransmitter produced by autonomic fibers. The terms nonadrenergic noncholinergic fibers apply to such nerves.

**GENERAL ORGANIZATION OF ANS**

Organization of ANS occurs at five different levels: cortical organization, hypothalamic organization, brainstem organization, spinal organization and peripheral organization.

**Cortical Organization**

Cortical areas controlling functions of ANS are mainly limbic areas and prefrontal cortex.

1. The sympathetic responses to emotion originate in the limbic and prefrontal cortical areas.
2. These areas activate sympathetic system by stimulating hypothalamic and brainstem areas that have influence on the system.

**Hypothalamic Organization**

Hypothalamus considerably influences autonomic functions. Hypothalamus via hypothalamo-pituitary axis controls secretions of major endocrine glands.

1. Hypothalamus receives collaterals from ascending pathways, especially from spinothalamic tracts that transmit pain impulses.
2. Thus, hypothalamus integrates somatosensory, endocrine and autonomic responses that are essential components of homeostatic mechanisms during stressful situations like major surgical procedures, exposures to extreme weathers, trauma and hemorrhage.
3. For its profound influence on autonomic responses, Sherrington had correctly pointed out that hypothalamus is the head-ganglion of sympathetic nervous system.
Brainstem Organization

Brainstem areas contain major nuclei of ANS. These are broadly classified into two categories: parasympathetic nuclei and sympathetic nuclei.

Parasympathetic Nuclei

The cranial outflow of parasympathetic system originates from cranial nerve nuclei that are located in the brainstem.

1. The cranial nerves that carry parasympathetic fibers are oculomotor (III cranial nerve), facial (VII cranial nerve), glossopharyngeal (IX cranial nerve) and vagus (X cranial nerve).
2. Nucleus tractus solitarius (NTS) in the medulla receives general visceral sensation via IX and X cranial nerves. It is also closely connected with reticular formation containing cardio-respiratory centers. Therefore, NTS mediates respiratory and cardiovascular responses to autonomic activation. Special visceral sensations in VII, IX and X cranial nerves reach NTS.
3. Edinger-Westphal nucleus in the midbrain is the nucleus of III cranial nerve.
4. Salivary nucleus is located in pons and dorsal motor nucleus of vagus in medulla.

Sympathetic Nuclei

Sympathetic fibers originate from vasomotor center in the medulla and project to the intermediolateral horn of spinal cord via bulbospinal pathway.

1. Nucleus gigantocellularis and parvocellularis in the reticular formation on stimulation depress activity of vasomotor center.
2. Stimulation of NTS inhibits sympathetic outflow and stimulates vagal activity.

Spinal Organization

Cell bodies of autonomic efferent neurons are located in the intermediolateral column of the spinal cord.

Sympathetic Outflow

Sympathetic fibers originate from thoracic and lumbar segments (T1 to L2) of spinal cord. Hence, sympathetic system is called thoracolumbar outflow of ANS.

Parasympathetic Outflow

Spinal component of parasympathetic system originates from sacral segments (S2 to S4) of spinal cord. For its cranial and sacral origin, parasympathetic system is called craniosacral outflow of ANS.

Peripheral Organization

Ganglia

Autonomic fibers from CNS reach visceral organs in the cranial nerves and somatic nerves. They are distributed to target organs via various ganglia (Table 30.1). The ganglia of sympathetic system are close to spinal cord and the ganglia of parasympathetic system are close to the organs (Fig. 30.7). There are two sets of neurons in the efferent pathway: preganglionic and postganglionic neurons.
Preganglionic Neurons
Preganglionic neurons of sympathetic system originate from intermediolateral horn of thoracolumbar segments of spinal cord. They terminate in sympathetic chain of ganglion from where postganglionic fibers originate and innervate the viscera.
1. In sympathetic system, preganglionic neurons are shorter than postganglionic neurons. Preganglionic neurons of parasympathetic system originate from cranial nerve nuclei in brainstem and intermediolateral horn of sacral segments of spinal cord.

2. In parasympathetic system, preganglionic neurons are much longer than postganglionic neurons, as the ganglion is located either near the viscera or in the viscera.

Postganglionic Neurons
1. In sympathetic system, postganglionic fibers originate from sympathetic chain of ganglia and terminate in the viscera.
2. In parasympathetic system, postganglionic fibers are located close to or in the effector organs. Hence, postganglionic parasympathetic fibers are very small.

CHAPTER SUMMARY

Key Concepts
1. In sympathetic system, postganglionic fibers originate from sympathetic chain of ganglia close to spinal cord. Therefore, preganglionic fibers are small, whereas postganglionic fibers are long.
2. In parasympathetic system, ganglia are close to the viscera. Therefore, preganglionic fibers are long, whereas postganglionic fibers are very small.
3. Preganglionic fibers of both the division of ANS are cholinergic. Postganglionic parasympathetic is cholinergic, and postganglionic sympathetic is adrenergic.

Important to Know (Must Read)
1. In examinations, usually there will be no Long Question from this chapter.
2. Difference between spinal organization of somatic system and sympathetic system, Neurotransmitters of ANS, General organization of ANS, may come as Short Questions in exams.
3. In Viva, examiners usually ask… What the components of ANS, General organization of ANS, General functions of sympathetic and parasympathetic systems, Say the differences between spinal organization of somatic system and ANS Organization of pre-ganglionic and postganglionic fibers of sympathetic and parasympathetic systems, Location of ganglia in sympathetic and parasympathetic systems, List the neurotransmitters of sympathetic and parasympathetic systems.
Sympathetic System

CHAPTER 31

Sympathetic system is the system of energy utilization. At the time of activity, urgency, anxiety, emotion, excitement and combating stressful situations, sympathetic system is activated to provide energy to the body. Excessive and chronic stimulation of this system leads to leanness, degeneration ad decay, and underutilization of it leads to lethargy and adiposity.

FUNCTIONAL ANATOMY

Sympathetic Neurons

Preganglionic Neurons

Cell bodies of preganglionic neurons of the sympathetic division are located in the intermediolateral horn of the thoracic (T1 to T12) and upper lumbar (L1 to L3) segments of spinal cord. Hence, sympathetic division is known as thoracolumbar outflow of ANS. The preganglionic neurons come out of the spinal cord via ventral roots. After the merger of dorsal and ventral roots, spinal nerve emerges. Sympathetic preganglionic axons leave the spinal nerve via

Scientists contributed

Ernst Heinrich Weber (1795–1878)
Wilhelm Eduard Weber (1804–1891)
Eduard Friedrich Wilhelm Weber (1806–1871)

In 19th century, three Weber brothers (Ernst Heinrich Weber, Wilhelm Eduard Weber, and Eduard Friedrich Wilhelm Weber) had contributed greatly to Physiology, especially in the field of autonomous nervous system (ANS). Ernst Heinrich first made a comparative study of sympathetic nerves. With his younger brother, Eduard Friedrich measured the speed of pulse wave and correctly explained the nature of arterial pulse. Eduard Friedrich studied the hearing mechanism, Wilhelm and Eduard completed the full study of locomotion and demonstrated that vagal stimulation stops heart.

Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Understand the importance of sympathetic system in regulation of body functions.
2. Appreciate the anatomical and functional specializations of sympathetic divisions of autonomous nervous system (ANS).
3. Trace the course of pre- and postganglionic neurons of sympathetic system.
4. Name the sympathetic ganglia and give the segmental distribution of sympathetic fibers to various visceral organs.
5. Understand the importance of basal sympathetic tone.
6. List the widespread responses to sympathetic stimulation.
7. Give the effects of sympathetic stimulation to various organs and name the receptors that mediate these effects.
8. Comprehend the features, mechanism and importance of fight-or-flight responses.
9. List the differences between sympathetic and parasympathetic systems.

The student MAY also be able to:
1. Describe the detailed widespread responses to sympathetic stimulation.
2. Describe the effects of sympathetic stimulation to various organs.
3. Explain the basis of fight-or-flight responses.
the white rami communicantes and enter the paravertebral sympathetic ganglia, which is an interconnected chain located on both sides of the vertebral column.

Preganglionic fibers have any of the following destinations (refer to Fig. 30.4, Chapter 30):

1. Preganglionic fibers emerging from spinal cord synapse with cell bodies of postganglionic neuron located in the paravertebral sympathetic ganglion at the same spinal cord level. The postganglionic sympathetic axons then travel in the cervical and lumbar-sacral spinal nerves. However, few fibers of sympathetic ganglion chain extend above and below the spinal level.

2. The chain of sympathetic ganglia extends above and below the thoracolumbar spinal levels, in which branches of preganglionic fibers ascend to the cervical levels or descend to the sacral level. Thus, preganglionic axons may synapse with postganglionic neurons in the paravertebral ganglion at the same level, or ascend up or descend down to the several spinal segments and then synapse with the postganglionic neuron (Fig. 31.1).

   - **Preganglionic axons that ascend to cervical level** arise from T1 to T5 and form three major ganglia: superior, middle, and inferior cervical ganglia.
   - **Preganglionic axons descend below L3**, form two additional lumbar and at least four sacral ganglia. Preganglionic fibers **synapse with postganglionic neurons in these sympathetic ganglia** that are present beyond the thoracolumbar segments of spinal cord.

3. The preganglionic axons may pass through the paravertebral ganglia en route without synapsing there to terminate in a prevertebral ganglion (collateral ganglion), which is located close to the organ.

### Postganglionic Neurons

Postganglionic neurons for somatic structures such as sweat glands, piloerector muscles, cutaneous blood vessels and blood vessels of skeletal muscles leave the paravertebral ganglion in the gray rami communicantes and reenter the spinal nerve to supply the target tissues.

Postganglionic neurons to head, heart and lungs originate in the cervical or upper thoracic paravertebral ganglia and proceed to the organs as separate nerves, for example the cardiac nerve to the heart, or as perivascular plexuses of axons that accompany arteries.

### Sympathetic Ganglia

Sympathetic ganglia are of **three types**: paravertebral, prevertebral, and terminal.

### Paravertebral Ganglia

There are two paravertebral chains of ganglia on either side of the spinal cord. Each chain has 22 or 23 ganglia (Fig. 31.2).

### Cervical Ganglia

There are three cervical ganglia: superior, middle, and inferior.

1. The **superior cervical ganglion** provides sympathetic fibers that innervate the structures in the head. These sympathetic fibers travel in the perivascular plexus along the carotid arteries and innervate radial muscle of the iris that causes dilation of the pupil, supply Müller’s muscle that assists in elevating the eyelid, and innervate lacrimal and salivary glands. Therefore, diseases involving this pathway produce prominent ophthalmic signs.

2. The **middle and inferior cervical ganglia** innervate structures in the chest, including the trachea, esophagus, heart and lungs. Often, inferior cervical ganglion and first cervical ganglion fuse to form **stellate ganglion**.

### Thoracic Ganglia

There are about 12 thoracic ganglia. Fibers from these ganglia supply mainly thoracic structures. Preganglionic fibers from T1 and T2 supply structures in head and neck, from T3 and T4 supply thoracic viscera, from T5 to T9 supply structures in upper limb, and from T10 to T12 supply upper abdominal viscera (Table 31.1).

### Lumbar and Sacral Ganglia

There are three lumbar ganglia for three lumbar segments. However, there are **two additional lumbar** and at
least four sacral ganglia that are present below the lumbar segments. Preganglionic fibers from T10 to L2 supply structures in lower limbs, and from L1 and L2 supply lower abdominal viscera (Table 31.1).

**Prevertebral Ganglia**

Postsynaptic neurons for the abdominal and pelvic visceral organs arise from the prevertebral ganglia. They are also called collateral ganglia. There are three major prevertebral ganglia: celiac, superior mesenteric, and inferior mesenteric (Fig. 31.2). They are so named as they overlie the celiac, superior mesenteric and inferior mesenteric arteries at their origin from the aorta respectively.

1. **Celiac ganglion**: The preganglionic axons for celiac ganglion originate in the T5 to T12 spinal levels and provide innervation to the stomach, small intestine, liver, pancreas, gallbladder, spleen and kidneys.

2. **Superior mesenteric ganglion**: The preganglionic fibers for superior mesenteric ganglion originate primarily in T10 to T12 and innervate the small and large intestines.

3. **Inferior mesenteric ganglion**: The preganglionic fibers for inferior mesenteric ganglion originate from L1 to L3 and innervate the lower part of colon, rectum, urinary bladder, and reproductive organs.

**Terminal Ganglia**

These are located in the organ innervated by sympathetic fibers. Examples are adrenal medulla, heart, pancreas, and urinary bladder.

**Adrenal Medulla**

Adrenal medulla is a neuroendocrine structure. It forms the inner core of the adrenal gland.

1. Cells of the adrenal medulla are innervated by preganglionic sympathetic fibers originating in the lower thoracic spinal segments that travel in lesser splanchnic
nerve. Therefore, adrenal medulla is considered as a modified sympathetic ganglion that contains postganglionic cells.

2. Preganglionic fibers terminate on the chromaffin cells that represent modified ganglion cells. Chromaffin cells synthesize both epinephrine and norepinephrine. However, unlike neurons, these cells have no axons though they function as neuroendocrine cells and release hormone in response to preganglionic neuron activation.

**Other Terminal Ganglia**

Some of the cells in heart, pancreas and urinary bladder are modified postganglionic cells. The postganglionic cells in heart (intrinsic cardiac adrenergic cells) influence development of heart during fetal life.

**Neurotransmitters**

All preganglionic fibers are cholinergic and sympathetic postganglionic fibers are adrenergic that secrete either noradrenaline or adrenaline (for details, refer previous chapter). However, there are few sets of postganglionic sympathetic cholinergic fibers. These are postganglionic sympathetic fibers supplying sweat glands and blood vessels of skeletal muscles. Evidences suggest that blood vessels of heart, lungs, kidney and uterus also receive some cholinergic innervation.

**Scientists contributed**

The Nobel Prize in Physiology or Medicine 1936 was awarded jointly to neurophysiologist from UK Sir Henry Hallett Dale and neurophysiologist from USA Prof. Otto Loewi “for their discoveries relating to chemical transmission of nerve impulses”. Their pioneering works were in the field of neurotransmission in ANS. HH Dale had studied the details of neurotransmitters of sympathetic nervous system and sympathetic visceral responses.

**SYMPATHETIC RESPONSES**

Sympathetic activities are broadly two types: basal level activity at rest and widespread responses following activation.

**Basal Sympathetic Activity**

The sympathetic fibers impart a basal influence on many organs they innervate. This basal rate of discharge is called basal sympathetic tone.

1. Usually, functions of many viscera can be altered by changing the basal level of sympathetic discharge to the organs. Many such changes occur during normal physiological activities. For example, change in heart rate and blood pressure in response to change in posture.
2. But, if situations warrant for greater changes, basal firing rate in sympathetic nerves can be increased or decreased profoundly to achieve the target modulation in function. For example, to achieve a target increase in cardiac output during exercise, sympathetic stimulation considerably increases heart rate and myocardial contractility.

**Widespread Sympathetic Response**

Another characteristic of sympathetic stimulation is that it produces widespread organ responses. Example of a widespread response is fight or flight reaction (see below). The widespread response to sympathetic activation is due to two fundamental properties: divergence of sympathetic outflow and activation of adrenal medulla.

**Sympathetic Divergence**

The number of postganglionic axons emerging from the paravertebral chain of ganglia is greater than the number of preganglionic neurons originating from the spinal cord, the ratio of postganglionic to preganglionic neurons being 100:1. Therefore, effector tissues innervated by sympathetic fibers are more.

1. This basic principle of divergence enables the sympathetic system to produce widespread responses by simultaneously modulating functions of many effector organs.
2. The divergence is due to branching of the preganglionic sympathetic axons in the paravertebral chain of ganglia that makes synaptic connections with multiple postganglionic neurons both above and below their original level of emergence from the spinal cord.

**Role of Adrenal Medulla**

The adrenal medulla mediates many sympathetic responses. In addition to its anatomical divergence of postganglionic neurons, sympathetic system activates hormonal mechanism to achieve its widespread responses. These are mediated by catecholamine secreted from adrenal medulla.

1. The adrenal medulla is a neuroendocrine gland, which is basically a modified sympathetic ganglion.
2. The chromaffin cells of the adrenal medulla secrete both epinephrine and norepinephrine in a ratio of about 8:1 and store them in their secretory vesicles.
3. They release hormone directly into the bloodstream in response to activation by sympathetic preganglionic fibers. Catecholamines released from adrenal medulla by sympathetic stimulation modulate many organ functions and therefore, further promote sympathetic effects.
4. Thus, adrenomedullary secretion by sympathetic activation forms the physiological basis of divergence for widespread sympathetic responses. Circulating epinephrine plays a greater role than norepinephrine in physiologically mediating widespread responses for three reasons:
1. From adrenal medulla, epinephrine secretion is considerably more than norepinephrine.
2. Norepinephrine secretion is limited only to the axon terminals of sympathetic fibers, and therefore its effects are restricted only to the postsynaptic receptors in the target tissues, whereas circulating epinephrine reaches almost all tissues of the body.
3. Epinephrine potentiates sympathetic effects with greater efficacy than norepinephrine as it is more effective in stimulating both α and β-adrenergic receptors (though in general, epinephrine is a better β receptor agonist and norepinephrine is a better α receptor agonist).

### EFFECTS OF SYMPATHETIC STIMULATION

Effects of sympathetic stimulation are summarized in Table 31.2. Effects are mediated by release of noradrenaline from sympathetic nerve endings and adrenaline from adrenal medulla.

#### Effects via Adrenergic Receptors

Catecholamines elicit their effects by acting on adrenergic receptors. Adrenergic receptors are broadly divided into two types: α and β. The α receptor has two subtypes: α₁ and α₂; and β receptor has three subtypes: β₁, β₂, and β₃. Generally, β receptors are more sensitive to adrenaline and α receptors to noradrenaline.

#### Effects of α Receptor Stimulation

**Effects of α₁ Stimulation:** The α₁ receptors are present in vascular smooth muscles of cutaneous and splanchnic circulation, sphincters of bladder and GI tract and radial muscles of iris. Stimulation of these receptors causes contraction or constriction of the structures in which they are present. They are equally sensitive to adrenaline and noradrenaline. The effects are mediated by formation of intracellular IP₃.

**Effects of α₂ Stimulation:** α₂ receptors are present in presynaptic nerve endings, wall of GI tract, platelets and adipocytes. Stimulation of these receptors often causes relaxation or inhibition of the structure. The effects are mediated by decreased formation of intracellular cAMP.

#### Effects of β Receptor Stimulation

**Effects of β₁ Stimulation:** β₁ receptors are present in SA node, AV node and ventricular muscle. Stimulation of these receptors causes excitation of these structures. They are more sensitive to adrenaline than noradrenaline. The effects are mediated by increased formation of intracellular cAMP.

**Effects of β₂ Stimulation:** β₂ receptors are present in blood vessels of skeletal muscles, bronchial smooth muscles

and wall of GI tract. Stimulation of these receptors causes relaxation of these structures. They are more sensitive to adrenaline than noradrenaline. The effects are mediated by change in the level of intracellular cAMP.

**Effects of β3 Stimulation:** β3 receptors are present in adipose tissues. Stimulation of these receptors causes lipolysis. The effect is mediated by increase in the level of intracellular cAMP.

**Fight-or-Flight Response**

The fight-or-flight response is a typical widespread response of sympathetic activation. This occurs in critical situations of life when one has to either fight the situation or flee from the situation. Though many components of response are due to direct effects of sympathetic stimulation, secretion of catecholamine from adrenal medulla contributes considerably. The effects are as follows:

1. **Sympathetic stimulation of CVS increases blood pressure** due to increased cardiac output and vasoconstriction. Also, redistribution of the blood flow occurs to skeletal muscles and heart from splanchnic and cutaneous territories so that performance enhances.
2. In lungs, **increased exchange of blood gases** occurs due to stimulation of the respiratory rate and dilation of bronchiolar tree. This increases supply of oxygen to the tissues.
3. Sympathetic stimulation to salivary gland **decreases salivary secretion.** However, secretion of mucus increases proportionately, permitting lubrication of the mouth despite increased ventilation and reduced salivation.
4. **Supply of metabolic substrates increases,** which is an essential component of effective stress reaction. The demand for increased supply of substrates like glucose and fatty acids is met by the actions of circulating epinephrine on hepatocytes and adipocytes. **Glycogenolysis** increases plasma glucose concentration and lipolysis promotes plasma free fatty acid level.
5. **Sympathetic stimulation to sweat glands** causes secretion of a watery fluid, and evaporation of body heat. **Cutaneous vasoconstriction** with concurrent sweat gland activation causes cold, clammy skin of a frightened individual.
6. **Activation of piloerector muscles** of hair follicles causes hair-standing-on the skin. The hair erection helps in preservation of body temperature or gives a ferocious appearance to threaten the enemy.
7. **Pupillary dilation enhances visual acuity** and perception to make the individual environmentally maximal alert.
8. **Stimulation of brainstem reticular system** makes the individual maximally alert and mentally conscious to take appropriate decisions in quick successions.
9. Activity of **bowel and bladder temporarily ceases** due to constriction of sphincters.

### CHAPTER SUMMARY

**Key Concepts**

1. In sympathetic system (thoracolumbar outflow), preganglionic fibers in the paravertebral chain can ascend up or descend down to terminate in the postganglionic neurons of many segments in spinal cord, which can activate many visceral structures.
2. Sympathetic activation results in widespread sympathetic response that occurs due to divergence (more postganglionic fibers than preganglionic fibers), and secretion of catecholamines from adrenal medulla.
3. Generally, β receptors are more sensitive to adrenaline and α receptors to noradrenaline.

**Important to Know (Must Read)**

1. In examinations, usually there will be no Long Question from this chapter.
2. Sympathetic ganglia, Sympathetic neurons, Sympathetic neurotransmitters, Effects of sympathetic stimulation, Fight-or-flight response, may come as Short Questions in exams.
3. In Viva, examiners usually ask…Organization of sympathetic system, How preganglionic fibers come out of spinal cord, Sympathetic pre- and postganglionic neurons, Name the sympathetic ganglia, Specialities of sympathetic responses, Effects of sympathetic stimulation, Sympathetic neurotransmitters, Receptors for sympathetic neurotransmitters, Details of effects of sympathetic stimulation on each organ, What is Fight-or-flight response, and its features.
The parasympathetic system is the system of energy restoration. This system works when the body is at rest. It helps in generating and restoring the energy and recovering the body from energy loss. Thus, this helps in repair and renovation of the body systems. In general, parasympathetic activity is synonymous with the vagal activity, as vagus nerve controls most of the visceral functions.

Structural Organization

The parasympathetic system is the craniosacral outflow of autonomic nervous system.

1. The cranial component emanates from the brainstem, and the sacral component originates from intermediolateral gray column of sacral segments of spinal cord.

2. In contrast to the stimulation of sympathetic system that causes widespread responses, parasympathetic activation causes localized responses (Table 32.1). The divergence of parasympathetic outflow is minimal. The divergence ratio of the presynaptic output to postsynaptic output is about 1:15, in contrast to 1:100 in sympathetic system.

3. There is no circulating hormonal mechanism to aid to the divergence of parasympathetic activation. Hence, stimulation of parasympathetic nerve to an organ-system results in a limited activation of the concerned structures. For example, vagal stimulation to heart slows the heart rate without significantly altering the vagal influence on stomach.

Parasympathetic ganglia are located either close to the organ or embedded in the organ. Therefore, preganglionic neurons are much longer than postganglionic neurons. The differences between sympathetic and parasympathetic systems are summarized in Table 32.1.

Cranial Component

Cell bodies of preganglionic neurons of cranial component of parasympathetic system are located in the brainstem. Hence, this component is also called brainstem parasympathetic division. Brainstem parasympathetic neurons innervate structures in the head, neck, thorax and abdomen. Parasympathetic axons from brainstem travel in III, VII, IX, and X cranial nerves (Fig. 32.1). Nuclei of these cranial nerves are present in the midbrain in tegmentum, pons and medulla. Therefore, these nuclei serve as the centers for the integration of autonomic reflexes for the organ systems they innervate.

| **Gastrointestinal tract** | Decreases motility, contraction of sphincters and inhibition of secretion | Increases motility, relaxation of sphincters and stimulation of secretion |
| **Urinary bladder**      | Relaxation of detrusor and contraction of involuntary sphincter vesicae | Contraction of detrusor and relaxation of involuntary sphincter vesicae |
| **Male sex organs**      | Ejaculation | Erection |
| **Skin**                 | Contraction of erector pili and secretion of sweat glands | ------- |
| **Blood vessels**        | Vasoconstriction, dilation in some vessels | |
**Cranial Nerve III**

Cranial nerve III is the oculomotor nerve that originates from tectum of the midbrain. The cell bodies are located in the Edinger-Westphal nucleus.

1. The preganglionic axons travel in the III cranial nerve to terminate on the cell bodies of postganglionic neuron in ciliary ganglion, which is located inside the orbit of the eye.
2. The postganglionic axons enter eyeball near the optic nerve and innervate sphincter muscle of the iris (sphincter pupillae) that control the diameter of the pupil, the ciliary muscle that focuses the lens for accommodation for near vision, and the choroidal blood vessels.
3. The postganglionic fibers project mainly to the iris muscles. About 90% of fibers innervate ciliary muscle, 3 to 5% innervate sphincter pupillae and rest of the fibers terminates on blood vessels of choroid. Optic nerve projects to tectum and provides input for ocular reflexes.

**Cranial Nerve VII**

The preganglionic fibers in facial nerve emerge from the superior salivary nuclei in the rostral medulla and then pass from the facial nerve into the greater superficial petrosal nerve to synapse in the pterygopalatine ganglion.

1. The postganglionic fibers innervate the lacrimal gland and the glands of nasal and palatal mucosa. Another set of preganglionic fibers in the facial nerve travel via the chorda tympani nerve to synapse in the submandibular ganglion.
2. These postganglionic fibers from submandibular ganglion innervate submandibular and sublingual glands. Stimulation of this nerve increases saliva production.

**Cranial Nerve IX**

The preganglionic axons of the glossopharyngeal nerve originate form the inferior salivary nuclei in the medulla. The fibers take a tortuous course through the lesser petrosal nerve to terminate in otic ganglion.
1. The postganglionic axons join the auriculotemporal branch of 5th cranial nerve to innervate parotid gland, where they facilitate secretion of saliva.

2. Chemosensory information of blood gasses from carotid bodies and baroreceptor information of blood pressure from carotid sinuses are transmitted to the medullary cardiovascular centers via glossopharyngeal afferents.

Cranial Nerve X

Vagus nerve arises from the nucleus ambiguous and dorsal motor nucleus of vagus in the medulla. This nerve has an extensive autonomic component. It has been estimated that vagal output comprises up to 75% of total parasympathetic activity.

1. Preganglionic fibers travel in the vagus nerve to ganglia located in the organ, i.e. in the heart and lungs and in the intrinsic plexuses of the GI tract. Sympathetic postganglionic fibers intermingle and travel in the same nerve trunk with the parasympathetic preganglionic fibers to the target tissues. This forms the vago-sympathetic trunk.

2. The right vagus nerve has more influence on SA node and left vagus on AV node. Thus, vagal stimulation slows the heart rate.

3. The vagal efferents to the lung control bronchial smooth muscle (constriction of bronchioles), and secretory cell activity.

4. Vagal fibers innervate esophagus, stomach, small intestine and large intestine up to two-third of transverse colon.

5. On GI tract, vagus nerve stimulates motility and secretory functions. Acetylcholine and VIP are the transmitters of the postganglionic neurons.

6. There are vagal innervations of kidneys, liver, spleen and pancreas.

Sacral Component

Sacral parasympathetic neurons innervate structures in the pelvis.

1. Preganglionic fibers originate in the intermediolateral gray column of the sacral segments S₂, S₃, and S₄ of spinal cord.

2. The preganglionic fibers terminate in ganglia in or near the viscera that include descending colon, sigmoid colon, rectum, internal anal sphincter, urinary bladder and the reproductive organs.

PARASYMPATHETIC FUNCTIONS

Parasympathetic system restores body’s energy reserve. Favorable conditions in both external and internal environments herald parasympathetic activation. Except on cardiovascular system, most parasympathetic effects are stimulatory, especially for the processes that facilitate energy storage and growth. They stimulate intestinal motility, secretion, digestion and absorption. They promote reproductive functions (Application Box 32.1).

<table>
<thead>
<tr>
<th>Application Box 32.1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adequate parasympathetic tone ensures good health: Parasympathetic activity is more in resting conditions and sympathetic activity is more in active conditions. The energy lost during activities must be restored by adequate rest that stimulates parasympathetic system. It is not only the physical rest, but also the mental rest that promotes vagal activity. Therefore, both mental and physical relaxations as occurs by regular practice of yoga are advised for improving health in general, apart from achieving stable cardiac functions and blood pressure. People having hypersympathetic personality (always anxious and restless) are usually thin and do not maintain good health, and in the contrary, individuals with hyperparasympathetic personality (lazy and lethargic) develop obesity. Therefore, a balanced sympathetic and parasympathetic state (stable sympathovagal balance) is required to preserve good health.</td>
</tr>
</tbody>
</table>

Neurotransmitters and Receptors

Most of the parasympathetic fibers are cholinergic. Acetylcholine is the neurotransmitter in both pre- and post-ganglionic fibers. There are two sets of cholinergic receptors on the target cells: muscarinic and nicotinic.

Muscarinic Receptors

Cholinergic muscarinic receptors are present in heart, smooth muscles and glands. These receptors are activated by acetylcholine and muscarine.

1. Activation of these receptors produce inhibitory effects on heart, for example, decreased heart rate, and excitatory effects on smooth muscle and glands, for example, increased GI motility and secretion etc.

2. Effects are mediated by decreased cAMP formation in the cytosol of cardiac cells and direct opening of K⁺ channels in nodal tissues of heart.

3. In smooth muscles and glandular tissues, effects are mediated by intracellular IP₃ and Ca²⁺. Muscarinic receptors are blocked by atropine.

Nicotinic Receptors

Cholinergic nicotinic receptors are present in autonomic ganglia (both sympathetic and parasympathetic), neuromuscular junctions and adrenal medulla. These receptors are activated by acetylcholine and nicotine.

1. Activation of these receptors produces excitatory effects on target tissue. Effects are mediated by direct binding of acetylcholine to α subunits of the receptors.

2. Receptors also contain Na⁺ and K⁺ channels.

3. Nicotinic effects are blocked by ganglion blockers such as hexamethonium that prevent action of acetylcholine in the ganglia and at neuromuscular junction by curare drugs.
Chapter 32: Parasympathetic System

CHAPTER SUMMARY

**Key Concepts**

1. In parasympathetic system (craniosacral outflow), preganglionic fibers are very long as ganglions are located close to the organs.
2. Parasympathetic activation is considered to be similar with vagal activation, as 75% of parasympathetic functions are mediated by vagus nerve.
3. Greater vagal tone is essential for good health.

**Important to Know (Must Read)**

1. In examinations, usually there will be no Long Question from this chapter.
2. Parasympathetic ganglia, Parasympathetic cranial nerves, Parasympathetic neurotransmitters and receptors, Effects of parasympathetic stimulation, Parasympathetic functions, Vagal tone, may come as Short Questions in exams.
3. In Viva, examiners may ask… Name parasympathetic ganglia, Name parasympathetic cranial nerves, Parasympathetic neurotransmitters and receptors, Effects of parasympathetic stimulation on different organs, especially on CVS, Parasympathetic functions, Importance of vagal tone, and the differences between sympathetic and parasympathetic systems.
LEARNING OBJECTIVES

On completion of study of this chapter, the student MUST be able to:
1. List the control mechanisms of autonomic functions.
2. Understand the importance of regulation of autonomic functions.
3. Classify autonomic disorders.
4. Name the features of common autonomic disorders.

The student MAY also be able to:
1. Describe the regulation of autonomic functions.

CONTROL OF AUTONOMIC FUNCTIONS

Visceral organs are innervated by sympathetic and parasympathetic divisions of autonomic nervous system (ANS). Effects of stimulation of sympathetic and parasympathetic systems are usually opposite. But due to robust regulatory mechanisms, the process that activates one division of ANS usually inhibits and moderates the function of the other. Therefore, sympathetic and parasympathetic divisions are also reciprocal to each other. Consequently, under normal circumstances excessive stimulation or activation of both the systems, which might have deleterious effects, is avoided. Autonomic functions are regulated by various reflexes and supraspinal mechanisms.

Reflex Regulation

Previously, ANS was regarded as an efferent system, and the sensory neurons (afferents) that innervate autonomic structures were not considered as part of ANS. However, afferent fibers also constitute an important component of autonomic system and sensory input from visceral structures is part of autonomic organization.

1. The sensory innervation to the visceral organs including blood vessels and cutaneous structures forms the afferent limb of autonomic reflexes. The information from visceral organs reach the spinal cord through afferent fibers and, from there, the second order of neurons convey information to the higher centers via ascending pathways (Fig. 33.1).
2. Sensory information in the afferent pathways may not always reach higher center for finer integration and
conscious perception, but definitely reaches different levels of autonomic neuraxis up to the level of subcortical structures, especially the thalamus (Figs. 33.2A and B).

3. Thus, ANS integrates a hierarchy of reflexes to control organ functions. According to their level of integration, the autonomic reflexes are subjected to control by various part of CNS.

**Local Reflexes**

A sensory neuron (afferent autonomic fiber) has many terminal branches peripherally.

1. As a result, sensory action potential that propagates orthodromically in one of the afferent branch to CNS may also enter a branch of the same axon and then conduct antidromically to release neurotransmitters at the sensory terminals that end on other structure.

2. The process results in spreading initial reaction produced by the stimulus.

3. For example, when the branch of a sensory neuron innervates blood vessels, the response is the spread of reddening of skin as a result of arteriolar dilation (refer to the ‘Axon Reflex’ in ‘Cutaneous circulation’ in CVS), or if sensory neuron innervates sweat glands, the response will be local sweating as a result of sweat gland activation. This process is called ‘Local axon reflex’.

4. Persistent activation of such reflexes in nociceptive afferents following trauma can produce dramatic features.

---

**Role of Autonomic Ganglia**

Ganglia in ANS serves as relay stations for preganglionic and postganglionic neurons. Recent evidences suggest that synaptic activity in the ganglia may influence final efferent output.

1. Inputs arriving from many preganglionic neurons alter the activity in ganglia, which in turn alter the visceral activity. The best example is the regulation of GI functions by ganglia of GI tract (Fig. 33.3). Chemoreceptors
and mechanoreceptors in the gut generate afferent action potentials that pass to the spinal cord and then from there to the celiac and mesenteric ganglia. The output from these ganglia changes the GI motility and secretion required during digestion.

2. Also, ganglia serve as integrative centers for autonomic reflexes. The example for such integrative functions of ganglia is the parasympathetic ganglia in the wall of GI tract that finally control GI motility and secretion required during digestion.

3. The intrinsic plexuses in the wall of GI tract serve as the centers for integration of local or short reflex activities where input from parasympathetic preganglionic neurons, postganglionic sympathetic neurons and local sensory neurons converge and interact. The intrinsic plexuses also mediate the central or long gastrointestinal reflexes.

**Spinal Autonomic Reflexes**

Many autonomic reflexes are integrated in the spinal cord. The examples are micturition, defecation and sexual reflexes. These reflexes are coordinated by centers in the lumbar and sacral spinal cord.

1. Micturition reflex causes emptying of urinary bladder, defecation reflex causes emptying of rectum, and sexual responses in male cause erection and ejaculation and in female produce vaginal lubrication (Fig. 33.4). Sensory input from the wall of the bladder and bowel inform the degree of distension of these hollow viscera.

2. Coordination between sympathetic and parasympathetic systems is required for many of these responses.

3. Higher centers usually inhibit spinal cord reflex centers.

4. Therefore, following spinal injury, or in spinal preparation in animals, micturition first becomes involuntary and later becomes abnormal. Episodes of hypertension and piloerection in such patients are other examples.

**Supraspinal Regulation**

**Role of Brainstem**

Brainstem plays important role in autonomic functions.

1. The periaqueductal gray in midbrain coordinates autonomic responses to painful stimuli and induces endogenous analgesia system.

2. The nucleus parabrachialis in pons contribute to respiratory and cardiovascular control. The locus ceruleus influences micturition reflexes.

3. The medullary centers are the key areas for control of many visceral functions.

4. The nucleus tractus solitarius receives sensory information from cardiovascular, respiratory and gastrointestinal receptors. Vagal efferent fibers arise from this area in the medulla.

5. The vasomotor center in the ventrolateral medulla is the key center for sympathetic output as it directly controls preganglionic sympathetic neurons in the spinal cord.

Major autonomic reflexes integrated in the brainstem include:

1. Pupillary light reflex
2. Accommodation reflex
3. Reflex salivation
4. Reflex lacrimation
5. Deglutition reflex
6. Vomiting reflex
7. Reflexes for regulation of heart rate and blood pressure
8. Reflexes for regulation of respiration.

**Role of Hypothalamus and Cortex**

Hypothalamus and cortex provide the highest levels of autonomic control.

1. The periventricular hypothalamus, and medial and lateral hypothalamic areas control homeostatic functions such as thermoregulation, appetite behaviors etc.

2. Stimulation of lateral and posterior hypothalamus causes sympathetic activation, and stimulation of posterior hypothalamus causes parasympathetic activation.

3. Hypothalamus controls circadian rhythms that influence many autonomic functions.

4. Hypothalamus also contributes to the regulation of blood pressure and blood volume.

5. For its major role in autonomic functions, hypothalamus was designated (by Charles Sherrington) in the past as ‘head ganglion of the ANS’.
6. Hypothalamus, due to its close proximity and reciprocal interaction with limbic system, is influenced by limbic activities. Therefore, autonomic functions are easily affected by limbic functions and dysfunctions.
7. The **prefrontal cortex** is involved in the regulation of autonomic function.
8. The **amygdala** coordinates the autonomic components of emotional responses.
9. Cortex, limbic structures, brainstem and their spinal connections for control of autonomic functions are collectively referred to as **central network for autonomic control**.

### AUTONOMIC DYSFUNCTIONS

Following are the two fundamental types of lesion of autonomic nervous system
1. Diseases
2. Injury

#### Autonomic Diseases

Autonomic disorders are broadly termed as **autonomic failures**. Autonomic failures are of two types: primary and secondary.

**Primary Autonomic Failure**

Primary autonomic failure is **idiopathic autonomic dysfunction** that invariably manifests as **orthostatic hypotension**.

**Secondary Autonomic Failure**

Secondary autonomic failure occurs in various diseases.
1. Commonly seen in **diabetes**, amyloidosis, beriberi, syringomyelia, tabes dorsalis and subacute combined degeneration of spinal cord.
2. It also occurs in patients receiving **sympatholytic drugs** of those who have undergone surgical sympatheticomasty.
3. Autonomic imbalance also occurs in patients with **prolonged bed rest**.

#### Features of Autonomic Dysfunctions

Autonomic dysfunctions manifest as multiple organ dysfunctions as autonomic nerves innervate many visceral organs.

- **Cardiovascular features**: Usual manifestation is **orthostatic hypotension**. Tachycardia may also be seen.
- **Gastrointestinal features**: Either **constipation or diarrhea** can occur. Dysphagia is not uncommon. Dryness of mouth occurs frequently.
- **Renal features**: Increased **frequency of micturition** is the usual feature. Nocturia and incontinence may occur.
- **Reproductive features**: **Erectile dysfunction** is common in male. **Premature ejaculation** is also common. In females, decreased vaginal lubrication during sexual act is common.

**Sudomotor features**: **Anhydrosis** is common. Heat intolerance and hyperhidrosis may occur.

**Neurological symptoms**: Weakness, lethargy and giddiness.

#### Treatment

Treatment should start immediately for the cause of the disease, if it is of secondary variety of autonomic failure. Treatment otherwise is mostly symptomatic depending on the nature of the failure.

### Diseases affecting Sympathetic System

**Horner’s Syndrome**

This is a syndrome (described by Johan Horner) of autonomic dysfunction, characterized mainly by:

1. Presence of **ptosis** (drooping of the upper eyelid)
2. **Miosis** (constriction of pupil)
3. **Facial anhydrosis** (lack of sweating on the affected side of face and neck).

#### Etiology

Horner’s syndrome is a condition of **oculo-sympathetic paralysis**. Horner’s syndrome commonly occurs in malignancy of cervical lymph nodes that presses on cervical sympathetic chain, and **Pancoast tumor of lungs**.

#### Pathophysiology

Clinical manifestations of this syndrome occur due to interruption of sympathetic nerve supply to the head and neck.

1. Venter (connector neurons) for the sympathetic outflow to head and neck lies in lateral horn cells of first thoracic segment of spinal gray matter. Proximally, it gets supraspinal control through reticulospinal tract descending from brainstem reticular formation.
2. Preganglionic sympathetic fibres for head and neck arising from 1st thoracic segment ascend through cervical part of sympathetic chain.
3. After relay in cervical sympathetic ganglia, postganglionic fibres for head and neck arising from 1st thoracic segment ascend through cervical part of sympathetic chain.

A patient may suffer from Horner syndrome due to lesion of anyone of following three levels of sympathetic pathway for head and neck.
Physiological Basis of Clinical Features

Ptosis occurs due to paralysis of Muller’s muscle, and miosis occurs due to paralysis of dilator pupillae. Anhidrosis is due to decreased sympathetic activity.

1. **Miosis**: Constriction of pupil due to unopposed action of sphincter pupillae for non-functioning dilator pupillae.
2. **Ptosis**: Partial dropping of upper eyelid due to paralysis of levator palpebrae superioris.
3. **Anhidrosis**: Dryness of one half of the face with head and neck due to impaired secretion of sweat gland.
4. **Flushing or blanching of same half of face** due to loss of vasoconstrictor effect on skin.

<td><strong>Horner’s syndrome</strong>, a disorder of the sympathetic nervous system, was named after Johann Friedrich Horner, a 19th century Swiss ophthalmologist following his description of the condition in 1869. His name is also associated with “Horner’s muscle”, the lacrimal portion of the orbicularis oculi muscle that is sometimes referred to as the tensor tarsi muscle. With Alexis Trantas (1867–1960), the “Horner-Trantas spots” are named, being defined as small whitish-yellow chalky concretions of the conjunctiva around the corneal limbus.</td>
</tr>
</tbody>
</table>

Raynaud Disease

It is a vasospastic disease due to hyperactivity of vasoconstrictor sympathetic fibres affecting digital arteries of fingers. It is a bilateral disorder which is precipitated by exposure to cold and smoking. In case of smokers, nicotine aggravates vasospasm. Clinical manifestations are pain, pallor and cyanosis due to impaired vascular supply. Fingertips show black discoloration with formation of dry gangrene.

Buerger Disease

It is arterial occlusive disease of lower limb. Ischemia of muscle of leg causes pain due to muscular cramps intermittently. That is why the disorder is named as intermittent claudication.

Diseases affecting Parasympathetic System

1. **Argyll Robertson pupil**: It is a disorder in a patient of neurosyphilis due to lesion of pretectal nucleus of midbrain which is one of the cell stations in light reflex pathway. The disease is characterized by narrow pupil with no reaction to light due to interruption of light reflex pathway which is as follows:

   | Due to degeneration of diseases like |
   | Multiple myeloma, Syringomyelia |
   | Penetrating injury at root of neck |
   | Traction by cervical rib |

   - **Retina — optic nerve — optic chiasma — optic tract — lateral geniculate body — superior brachium — pretectal nucleus — Edinger-Westphal nucleus — ciliary ganglion — short ciliary nerve — sphincter pupillae.**

   In case of Argyll Robertson pupil, accommodation reflex is not disrupted as it is not passing through pretectal nucleus and its pathway id as follows.

   - **Retina — optic nerve — optic chiasma — optic tract — lateral geniculate body — optic radiation — primary visual cortex — superior — longitudinal fasciculus frontal eye lid — corticonuclear tract — occulomotor nucleus — (somatic as well as visceral efferent) — occulomotor nerve to supply medial rectus, sphincter pupillae and ciliaris for accommodation.**

   A simple formula mentioned below may be helpful to remember manifestation of Argyll Robertson pupil.

   - ARP (Pupillary reflex absent)
   - PRA (Pupillary reflex present)

2. **Adie tonic pupil**: This is a syndrome characterized by following clinical presentations.
   i. Diminished or absent light reflex due to disorder of function sphincter pupillae.
   ii. Slow or delayed dilation of pupil in the dark.
   iii. Slow or delayed accommodation to near vision because of ciliary muscle which is responsible for increase of curvature of lens.

   All the above features are supposed to be due to suppression of parasympathetic ocular function.

3. **Frey syndrome**: It is a clinical condition that is found to occur following healing of a penetrating wound of face over parotid gland. During healing process, injured nerves of this area of face communicate with one another, as done by auriculotemporal nerve supplying parasympathetic postganglionic secretomotor fibers to parotid gland with great auricular nerve supplying sweat glands of this area of face. So stimulation of salivary secretion during mastication of food causes sweating of area of face supplied by great auricular nerve.

4. **Hirschsprung disease**: This disease is also called ‘megalocolon’. It is a congenital disease characterized by failure of development of Auerbach (myenteric) plexus with absence of postganglionic parasympathetic neurons in the wall of distal part of colon. So, this part of colon does not show peristaltic activity.
for which part of the colon proximal to it presents huge dilation with stagnant fecal matter.

**Injuries to Autonomic Nervous System**

**Injury to Parasympathetic System**

It may be cranial or spinal. Causes of damage to the cranial component of parasympathetic system are head injury. Head injury may cause impairment of function of following components of parasympathetic system.

**Occulomotor Nerve Injury**

It is affected when head injury is associated with herniation of uncus of temporal lobe. Visceral afferent fibers of the nerve supply of sphincter papillae and ciliary muscles. So, damage of the nerve causes loss of light reflex with dilation of pupil due to non-functioning of sphincter papillae. Accommodation reflex is also affected due to non-functioning of ciliary muscle along with medial rectus and sphincter papillae.

**Facial Nerve Injury**

Facial nerve containing visceral efferent fibers with other functional components may be affected in fracture of base of skull affecting internal auditory meatus of petrous part of temporal lobe. Lesion of preganglionic secretomotor fibers to the lacrimal gland causes impaired lacrimation. Salivary secretion is not fully impaired, as parotid gland remains functioning, because it is supplied by visceral efferent fibers through glossopharyngeal nerve.

**Spinal Injury**

Spinal injury affecting the parasympathetic system alone with sympathetic system leads to disorders of bladder, bowel and sexual function.

**Injury to Sympathetic System**

It is the sympathetic trunk which is injured opposite the level of cervicothoracic (stellate) ganglion at the root of neck.

1. This injury may occur due to stab or gunshot wound.
2. It may also occur due to traction by cervical rib. Beside injury, metastatic lesion at the root of neck may affect stellate ganglion.

Clinical condition arising from this lesion is known as Horner syndrome which is described earlier.

### CHAPTER SUMMARY

#### Key Concepts

1. All visceral functions are controlled by both sympathetic and parasympathetic divisions of ANS. Though sympathetic and parasympathetic systems have opposite effects, they are reciprocal to each other.
2. Regulation of sympathetic and parasympathetic systems occurs at spinal cord, brainstem, hypothalamic, limbic and cortical levels.
3. As hypothalamus is the head ganglion of ANS, hypothalamic control is important. Nevertheless, all medullary visceral centers influence autonomic functions that could in turn be controlled by limbic-hypothalamic projections.
4. Autonomic functions are disturbed by metabolic diseases such as diabetes.

#### Important to Know (Must Read)

1. In examinations, Control of autonomic functions may sometimes come as a Long Question.
2. Control of autonomic functions, supraspinal control of autonomic functions, autonomic dysfunction, Horner syndrome, orthostatic hypotension may come as Short Questions in exams.
3. In Viva, examiners may ask… Name levels of control of autonomic functions, Name autonomic reflexes, Name supraspinal control mechanisms of autonomic functions, Classify autonomic dysfunction, Causes and features of Horner syndrome, Causes and features of orthostatic hypotension.
CHAPTER 34

Autonomic Function Tests

LEARNING OBJECTIVES

On completion of study of this chapter, the student **MUST** be able to:
1. Classify autonomic function tests (AFTs).
2. Appreciate the application of AFTs in clinical physiology.
3. List the AFTs for assessment of sympathetic and of parasympathetic functions.

The student **MAY** also be able to:
1. Describe the physiological basis, method and merits and demerits of AFTs.

Sympathetic and parasympathetic systems control all visceral functions. Neurons of sympathetic and parasympathetic systems are affected in metabolic diseases. Therefore, autonomic dysfunctions are common in metabolic diseases such as diabetes, obesity, hypertension, hyperlipidemia, hyper and hypothyroidism, etc. India is the epicenter of diabetes, hypertension and heart diseases. Therefore, assessment of sympathetic and parasympathetic functions by conventional **autonomic function tests** (AFTs) is now part of routine clinical management.

CLASSIFICATION OF AFTs

Autonomic function tests (AFTs) are performed to confirm the clinical diagnosis of autonomic dysfunctions and to assess the degree of sympathetic and parasympathetic involvement in the process of dysfunction.

AFTs are classified as:

A. Tests for cardiovascular autonomic functions
   1. Heart rate and Blood pressure (BP) response to standing
   2. Heart rate and BP response to passive tilting
   3. Assessing baroreceptor sensitivity (BRS)
   4. Heart rate response to deep breathing
   5. Valsalva ratio
   6. BP response to hand grip
   7. Cold pressure test
   8. Nor-epinephrine spillage technique
   10. Standing to lying ratio
   11. Spectral analysis of heart rate variability (HRV)

B. Tests for sudomotor functions
   1. Sympathetic skin response
   2. Thermoregulatory sweat test (TST)
   3. Quantitative sudomotor axon reflex test (QSART)

C. Vasomotor test
   1. Laser Doppler Velocimetry for skin blood flow measurement
   2. Cold pressor test

D. Tests for pupillary functions
   1. Cocaine test
   2. Adrenaline test

E. Other methods
   1. Muscle sympathetic nerve activity (MSNA)

Tests for Cardiovascular Autonomic Functions

Heart Rate Response to Standing

Changing the posture from supine to standing, heart rate increases immediately by about 10 to 20 beats per minute.
1. On standing, the heart rate increases until it reaches a maximum at about the 15th beat, after which it slows down to a stable state at about 30th beat.
2. The ratio of R-R intervals corresponding to the 30th and 15th heart beat is called the **30:15 ratio**.
3. The 30:15 ratio is a measure of parasympathetic function.
4. However, relative bradycardia at 30th beat depends also on the sympathetic reactivity.
5. The normal 30:15 ratio is 1.15–1.12 at 21 to 30 years and 1.12 to 1.10 at 31 to 40 years of age.
6. This ratio decreases with age. Ratio less than 1.04 is considered abnormal.

**Blood Pressure Response to Standing**
The changes in blood pressure on standing are studied to assess the integrity of the sympathetic system.
1. Immediately on standing, blood pressure falls, which activates baroreceptor reflex and blood pressure returns to normal within 15 seconds.
2. When there is a sustained fall in systolic pressure more than 20 mm Hg or diastolic fall more than 10 mm Hg within three minutes of standing, orthostatic hypotension is said to be present.

**Assessing Baroreceptor Reflex Sensitivity (BRS)**
Baroreceptor reflex sensitivity is a newer method of assessing autonomic reactivity to various stimuli, such as orthostatic challenge and injection of chemicals and drugs that change the blood pressure.
1. This is assessed by continuous blood pressure variability (BPV) measurement. Sensitivity of baroreceptors to change in dynamic component (fluctuations) of blood pressure is an important marker of sympathetic and parasympathetic systems. Thus, it is a reflection of integration of both the components.
2. BRS is expressed as ms/mm Hg.
3. BRS less than 20 ms/mm Hg reflect poor cardiovascular (CV) health, and BRS less than 15 ms/mm Hg is an indicator of increased CV risk.
4. BRS 25 ms/mm Hg or more indicates enhanced autonomic tone and improved CV health.

**Norepinephrine (NE) Spillage Technique**
Norepinephrine level in plasma is measured in supine position and after 5 minutes of standing. The difference in level of NE represents alteration in sympathetic-hormonal reactivity.

**Heart Rate Response to Tilting**
Heart rate response to head up tilt (HUT) is a useful tool in the diagnosis of autonomic dysfunctions. It is more accurate because the active change of position is avoided by passively tilting the subject on a tilt-table. Moreover, variation in time taken by individuals to stand and the manner in which they stand from supine position is avoided in this method.
1. On changing from recumbent to operate position on a tilt table to 60 to 80 degrees HUT, pooling of about 30% venous blood occurs in the peripheral vascular compartment, especially in lower limbs.
2. This decreases cardiac filling pressure and stroke volume by about 40%.
3. Heart rate rises immediately due to withdrawal of parasympathetic activity and afterward due to increased sympathetic activity.

**Standing to Lying Ratio (SLR)**
Heart rate (RR interval) response to lying down from standing posture is assessed by continuous recording of ECG.
1. Following lying from standing position, increase in venous return produces reflex bradycardia.
2. Longest RR interval in standing to shortest RR interval in lying down is calculated as SLR.
3. Value of SLR below 1 is considered as abnormal.

**Heart Rate Response to Deep Breathing**
The variation of heart rate with respiration is known as sinus arrhythmia. Inspiration increases and expiration decreases heart rate.
1. This is primarily mediated via parasympathetic innervation of heart. Pulmonary stretch receptor, and cardiac mechanoreceptors and baroreceptors contribute to sinus arrhythmia.
2. The difference between the maximum and minimum heart rate during a deep breathing is called deep breathing difference (DBD).
3. DBD is more than 15 beats per minute in normal individual. It assesses the parasympathetic activity. DBD decreases with age.
4. It is one of the best parasympathetic reactivity test. Normal values of DBD at different age group are:
   - 10 to 40 years: > 18 beats per minute
   - 41 to 50 years: > 16 beats per minute
   - 51 to 60 years: > 12 beats per minute
   - 61 to 70 years: > 8 beats per minute
   Usually, subject is asked to inhale deeply for five seconds and then exhale for five seconds for six cycles. The ratio of shortest RR interval in inspiration to longest RR interval in expiration is calculated for each, which is called expiration-inspiration ratio (E/I ratio). The average E/I ratio of six cycles in a normal young individual is about 1:20.
   The E/I ratio decreases with age (Table 34.1).
   Normally, instead of DBD expressed in terms of beats per minute, E/I ratio is usually considered for assessing parasympathetic reactivity to deep breathing.
   DBD is abnormal in multisystem atrophy, progressive autonomic failure, diabetes mellitus, autonomic neuropathy and CNS depression.

**Valsalva Ratio**
The Valsalva ratio is a measure of parasympathetic and sympathetic function.
1. In Valsalva maneuver (named after scientist A M Valsalva, who described it), parasympathetic is the afferent and the efferent, and sympathetic is the part
of the efferent pathway. Therefore, Valsalva ratio assesses more of parasympathetic (cardiovagal) than sympathetic functions.

2. The procedure is performed by closing both nostrils and then blowing into a tube connected to sphygmomanometer. By putting strain, blowing pressure is maintained at 40 mm Hg for 15 seconds.

Valsalva maneuver has four phases:

- **Phase I**: Phase I consists of the onset of strain. In this phase, there is transient increase in blood pressure that lasts for a few seconds. This occurs due to increased intrathoracic pressure and mechanical compression of the great vessels. However, heart rate does not change much.

- **Phase II**: This is the phase of straining. In the early part of this phase, venous return decreases, which in turn decreases cardiac output and blood pressure. This change persists for 4 seconds. In the later part of this phase, blood pressure returns towards normal, which occurs due to increased peripheral resistance as a result of sympathetic vasoconstriction. However, heart rate increases steadily throughout this phase due to vagal withdrawal (in the early phase) and sympathetic activation (in the later phase).

- **Phase III**: This phase occurs following the release of strain during which there is transient decrease in blood pressure lasting for a few seconds. This is caused by mechanical displacement of blood to pulmonary vascular bed, which was under increased intrathoracic pressure. There is little change in heart rate.

- **Phase IV**: This is the phase that occurs with further release of strain. The blood pressure slowly increases and heart rate proportionately decreases. It occurs following 15 to 20 seconds after release of strain and lasts for about 1 minute or more. The cardiovascular changes occur due to increase in venous return, stroke volume and cardiac output.

**Valsalva ratio** is the ratio of minimal heart rate in phase IV to maximum heart rate in phase II as depicted in terms of RR interval.

\[
\text{Valsalva ratio} = \frac{\text{Longest R-R interval during phase IV}}{\text{Shortest R-R interval during phase II}}
\]

**Clinical Correlation**

Valsalva ratio more than 1.45 is considered to be normal.
1. Ratio 1.2–1.45 is considered borderline, and ratio less than 1.2 is regarded abnormal.
2. The normal ratio is different at different age groups (Table 34.2).
3. Valsalva ratio is also affected by gender, posture of subject in which recording is done, expiratory pressure, duration of strain and level of yoga practice of the subject.

Changes in Valsalva ratio occur due to changes in cardiac vagal efferent and sympathetic vasomotor activity, which are stimulated by carotid sinus and aortic arch baroreceptors and other intrathoracic stretch receptors. Failure of heart rate to increase during strain suggests sympathetic dysfunction and failure of heart rate to slow down after the strain suggests parasympathetic dysfunction. If the cardiovascular response to Valsalva maneuver is abnormal but that to cold pressure test (see blow) is normal, the lesion is supposed to be present in the baroreceptors or their afferent nerves. Such types of abnormalities occur commonly in diabetes, other neuropathies, multisystem atrophy and autonomic failure.

**BP Response to Sustained Hand Grip**

In hand-grip test is an isometric exercise in which the subject is asked to maintain hand grip against resistance.
1. Resistance usually offered by using a hand grip dynamometer at a 30% of maximum voluntary contraction for 5 min. BP and heart (HR) are recorded before and after the hand grip.
2. In hand-grip test, heart rate and blood pressure increase.
3. These cardiovascular responses to isometric exercise are mediated partly by central motor command and partly by mechanical changes or both, in response to contraction of the muscles that activate small fibers in the afferent limb of the reflex arch.
4. The normal response is rise in diastolic pressure more than 15 mm Hg and rise in heart rate by about 30%.
5. The blood pressure rise is due to increased sympathetic activity and heart rate rise is due to decreased parasympathetic activity.
6. The responses to hand grip test are usually not dependent on age.
7. Isometric handgrip test is one of the best sympathetic reactivity tests.

Cold Pressure Test
This test is performed by submerging the upper limb of the subject in ice cold water at 4°C for 30 to 60 sec. and BP is recorded before and after the procedure. The submer- sion of hand in cold water increases systolic pressure by about 20 mm Hg and diastolic pressure by 10 mm Hg.
1. The afferent limb of the reflex pathway is somatic fibers whereas the efferent pathway is the sympathetic fibers.
2. Thus, it assesses sympathetic activity.
3. Cold pressor test is one of the best sympathetic reactivity tests.

Tests for Sudomotor Functions

Sympathetic Skin Response
Sympathetic skin response (SSR) helps in studying the functions of peripheral sympathetic cholinergic (sudomotor) fibers by evaluating the changes in resistance of skin in response to electrical stimuli.
1. SSR is age dependent and is present in both hands and feet till the age of 60.
2. Composition of surface electrodes, stimulus frequency, skin temperature, and mental state of the subject affect the parameters of SSR.
3. The latency and amplitude of SSR are measured.
4. The amplitude of SSR in hand is 1.6 mV and in feet is 2.1 mV. SSR is helpful in diagnosing multisystem atrophy, progressive autonomic failure, diabetes, uremic patients and alcoholic neuropathy.

Thermoregulatory Sweat Test (TST)
Assessment of sweating response to heat also assesses sudomotor functions.
1. The subject’s body temperature is raised to by 1°C by exposing to heat of the electric heater.
2. Sweating response is studied by demarcating the area of sweating with the help of iodide starch or quinizarin powder that changes the color of the moist skin.
3. Absence of sweating in TST indicates sympathetic pre- and post-ganglionic lesions.

Quantitative Sudomotor Axon Reflex Test
Quantitative sudomotor axon reflex test (QSART) is a measure of regional autonomic function by Ach-induced sweating.
1. In this test, Ach is injected intradermally and the sweat production rate is assessed.
2. Reduced or absence of sweating indicates post-ganglionic lesion of sudomotor fibers (sympathetic fibers concerned with sweating).

Tests for Pupillary Functions
Pupillary function tests assess the function of sympathetic nerve supplying iris. Two tests usually performed are: cocaine test and adrenaline test.

Cocaine Test
Dilation of pupil is observed following instillation of 4% cocaine on both eyes. Cocaine prevents reuptake of nor- epinephrine at adrenergic nerve endings. Therefore, pupils dilate in response to cocaine, but, Horner’s pupils do not.

Adrenaline Test
Instillation of 1:100 or 1% noradrenaline on eyes dilate Horner’s pupil more than normal pupil. This is due to the mechanism of denervation hypersensitivity of Horner’s pupil.

Tests for Bladder Function
Cystometrogram (CMG) is performed to detect autonomic dysfunctions of urinary bladder. CMG reveals decreased ability of bladder to accommodate urine. Absence of accommodation to filling indicates autonomic dysfunction. Also, contraction of bladder muscle is poor in response to the act of micturition (evacuation).

Spectral Analysis of HRV
Recently, spectral analysis of heart rate variability (HRV) has evolved as a sensitive tool for assessing integrity of sympathetic and parasympathetic functions and for determining the sympathovagal balance. (Details are given in the next chapter)

AFTs to Assess Sympathetic and Parasympathetic Functions
A. AFTs for assessment of sympathetic functions:
1. BP response to standing/tilt
2. Cold pressor test
3. Isometric hand grip
4. Galvanic/sympathetic skin response
5. Thermoregulatory sweat test
6. Tachycardia ratio
7. Valsalva ratio
8. NE spillage test
9. LF and LFnu of HRV
B. AFTs for assessment of parasympathetic functions:
1. Resting heart rate: Basal heart rate is a good index of parasympathetic functions as heart rate in resting conditions is a measure of vagal tone. Resting HR more 75 indicates poor vagal tone and is presently considered as a CV risk.
2. 30:15 ratio
3. E/I ratio
4. Valsalva ratio
5. Bradycardia ratio
6. Baroreceptor sensitivity
7. Standing to lying ratio
8. HF and HFnu of HRV

**Concept of Reactivity and Activity Tests and CAFTs**

**Reactivity Tests**
Tests that are based on stimuli or disturbances such as change in position (standing, lying, dipping finger in cold water, hand grip against resistance, Valsalva maneuver etc.) are called reactivity tests. Accordingly, they are grouped as sympathetic and parasympathetic reactivity tests.

**Activity Tests**
Tests that are performed without disturbing the subject (subject at rest usually lying on couch in a comfortable room for 15 to 20 min) are called activity tests.
1. Recording of Resting HR and BP, and HRV analysis are examples.
2. Accordingly, they are grouped as sympathetic and parasympathetic activity tests.
3. Resting heart rate is parasympathetic test and resting BP is sympathetic test.

**CAFTs**
CAFTs refer to conventional autonomic function tests. HR and BP response to standing, HR response to deep breathing, isometric hand grip, cold pressor test and Valsalva maneuver are CAFTs.
Heart Rate Variability

Learning Objectives

On completion of study of this chapter, the student MUST be able to:

1. Define and explain the term heart rate variability (HRV).
2. List different spectral components (time domain and frequency domain) of HRV.
3. Mention physiological significance of each HRV component.
4. Understand the principle of short-term HRV measurement.
5. Comprehend the concept of sympathovagal balance and understand the importance of HRV recording in assessing sympathovagal balance.
6. Explain the importance of HRV analysis and its clinical utility in health and diseases.

The student MAY also be able to:

1. Describe different methods of measurement of HRV indices.
2. Explain the technical aspects of HRV components.
3. Describe the clinical application of HRV in health and disease.

Physiological Aspects

Heart rate variability (HRV) is the cardiac beat-to-beat variation (variation in cardiac cycle length), a physiological phenomenon that occurs mainly due to variation in cardiac activity during the respiratory cycle (respiratory sinus arrhythmia) at rest, though the circadian rhythm, environmental factors and exercise also contribute to it. Resting heart rates can vary; some have rates of 100 beats/min while others beat at only 60 beats/min for no obvious reason.

1. The rate of the heart and its beat-to-beat variations are dependent on the rate of discharge of the primary pacemaker, the SA node, which is influenced by autonomic activities that are controlled in a complex way by a variety of reflexes, central irradiations and cortical factors.
2. As SA nodal discharge is largely controlled by parasympathetic (vagal) influence, and sinus arrhythmia is primarily due to alteration in vagal tone in inspiration and expiration, HRV is mainly influenced by vagal activity, though both the divisions of ANS influence it.
3. Recently, HRV has been proposed as the most sensitive indicator of autonomic function, especially for the assessment of sympathovagal balance, the balance between the sympathetic and parasympathetic activity of the individual at any given time.
4. The state of sympathovagal balance is used for the prediction of many cardiovascular (CV) dysfunctions and other dysfunctions affecting cardiovascular function, its main use is in the CV risk stratification. However, the use of HRV analysis is limited in the diagnosis and management of CV and other diseases.

Technical Terms

Heart rate variability can be quantified in time and frequency domains.

1. Time domain measures include the usual tools of assessment of variations, as done in statistics. Time domain is easier to assess but finer aspects of variations are not appreciated. Shortly, the overall magnitude of HRV is assessed well but the individual contribution of various factors is not elucidated.
2. On the other hand, the variations in the instantaneous heart rate can be assessed spectrally. That is, an RR tachogram is plotted using the RR intervals in the five-minute lead II ECG.
3. The RR tachogram is considered as a non-periodic signal which is transformed to its frequency spectrum using fast-Fourier transformation algorithm or autoregressive modeling.

4. The biggest advantage of this complex mathematical transformation is that the distribution of magnitude of variations in different frequency bands corresponds to the activity of different physiological systems. The entire frequency spectrum 0 to 0.4 Hz is divided as follows:

**HRV Components**

The power spectrum of HRV in mammals usually reveals three spectral components. These components are (Fig. 35.1):

1. A high frequency band (HF) 0.15–0.4 Hz
2. A low-frequency band (LF) 0.04–0.15 Hz
3. A very low-frequency band (VLF) 0–0.04 Hz

**HF Component**

HF component is caused by vagal tone during the respiratory cycle.

1. The inspiratory inhibition of vagal activity is evoked centrally in the cardiovascular center and explains why heart rate fluctuates with the respiratory frequency.
2. In addition, peripheral reflexes arising from thoracic stretch receptors also contribute to this so-called respiratory sinus arrhythmia (RSA).
3. As RSA is clearly abolished by atropine or vagotomy, the power of the HF component has been used as an index of the vagal drive.

**LF Component**

LF component of HRV is usually characterized by an oscillatory pattern with a period of 10 seconds.

1. This rhythm originates from self-oscillation in the vasomotor part (sympathetic component) of the baroreflex loop as a result of negative feedback and it is commonly associated with synchronous fluctuations in blood pressure, the so-called Mayer waves.
2. Thus, LF component mainly represents sympathetic power. However, parasympathetic drive also contributes to it.

**VLF Component**

VLF component accounts for all other heart rate changes, including those associated with thermoregulation and humoral (especially, rennin-angiotensin mechanism) and local factors.

**Power Spectrum Analysis of HRV**

Power spectrum of HRV is analyzed by two methods: Fast-Fourier transform and autoregressive modeling.

**Fast Fourier Transform**

Any electrophysiological signal can be described as a sum of sine waves and this decomposition is called the Fast Fourier Transform (FFT). An efficient algorithm to carry out this transformation is the FFT, which, with some improvements and modifications, is still in use in many applications, such as voice analysis or vibration studies.

1. The analysis of short-term HRV (SHRV) is another one of these applications.
2. FFT algorithms impose some constraints on the signal to analyze because an evenly sampled, infinite and stationary time series is required.

**Autoregressive Modeling**

An alternative method to the FFT is the autoregressive (AR) identification algorithm combined with power spectral estimation for the assessment of SHRV. This method fits the data to a prior defined model and estimates the parameters of the model. The power spectrum implied by the model is then computed.

1. FFT or AR modeling methods share a common goal: the estimation of the power spectrum of a signal.
2. FFT-based methods are also called nonparametric methods because the time domain prior to spectral analysis is greatly simplified.

**Physiological basis**:

The FFT and autoregressive algorithms are the most commonly used tools to study the SHRV.

1. The final step in SHRV analysis includes the application of power spectrum estimation methods to characterize the frequency components associated with vagal and/or sympathetic outflow.
2. AR methods are parametric because they require prior information of the system under study. Thus, it was suggested that FFT-based methods are still the best
choice for the assessment of SHRV in comparative studies, where no previous knowledge of the system is available.
3. In addition, FFT algorithms are readily available in many different languages, even in commercial statistical packages.
4. Once the basic spectral content of the system is known and an initial model of the signal can be formulated, AR algorithms should be a better choice because they provide better frequency resolution and avoid the problems of spectral leakage.
5. The electrocardiogram (ECG) is the most appropriate signal to study SHRV because it offers the most accurate representation of the electrical cardiac events.
6. In particular, the QRS complex of the ECG sharply defines the onset of ventricular electrical depolarization and is the closest approach to time the occurrence of pacemaker potentials, which, in turn, are modulated by the autonomic outflow.

HRV Indices

Analysis of HRV has two parts: time-domain and frequency-domain.
1. HRV assessed by calculation of indices is based on statistical operations on R-R intervals (time domain analysis) or by spectral analysis of an array of R-R intervals (frequency domain analysis).
2. Both methods require accurate timing of R waves.
3. The analysis can be performed on short electrocardiogram (ECG) segments (lasting from 0.5 to 5 minutes) or on 24-hour ECG recordings.
4. The analysis of 5 min ECG recording is called short-term HRV and of 24 h ECG recording is called long-term HRV.

Time Domain Analysis

Two types of heart rate variability indices are distinguished in time domain analysis. Beat-to-beat or short-term variability (STV) indices represent fast changes in heart rate. Long-term variability (LTV) indices are slower fluctuations (fewer than 6 per minute). Both types of indices are calculated from the R-R intervals occurring in a chosen time window (usually between 0.5 and 5 minutes).
1. An example of a simple STV index is the standard deviation (SD) of beat-to-beat R-R interval differences within the time window.
2. Examples of LTV indices are the SD of all the R-R intervals, or the difference between the maximum and minimum R-R interval length, within the window.
3. With calculated heart rate variability indices, respiratory sinus arrhythmia contributes to STV, and baroreflex- and thermoregulation-related heart rate variabilities contributes to LTV.

Frequency Domain Analysis

Ever since spectral analysis was introduced as a method to study heart rate variability, an increasing number of investigators have preferred this method to time domain analysis for the calculation of heart rate variability indices.
1. The main advantage of spectral analysis of signals is the possibility to study their frequency-specific oscillations.
2. Thus, not only the amount of variability but also the oscillation frequency (number of heart rate fluctuations per second) can be obtained.
3. Spectral analysis involves decomposing the series of sequential R-R intervals into a sum of sinusoidal functions of different amplitudes and frequencies by the Fourier transform algorithm.
4. The result can be displayed (power spectrum) with the magnitude of variability as a function of frequency. Thus, the power spectrum reflects the amplitude of the heart rate fluctuations present at different oscillation frequencies.

Measurement of HRV Indices

Time Domain Methods

The variations in heart rate may be evaluated by a number of methods. Perhaps the simplest to perform are the time domain measures.
1. In these methods, either the heart rate at any point in time or the intervals between successive normal complexes are determined.
2. In a continuous ECG record, each QRS complex is detected, and the so-called normal-to-normal (NN) intervals, i.e. all intervals between adjacent QRS complexes resulting from sinus node depolarization or in the instantaneous heart rate are determined.
3. Simple time domain variables that can be calculated include the mean NN interval, the mean heart rate, the difference between the longest and shortest NN interval, the difference between night and day heart rate and so forth.

Statistical Methods

From a series of instantaneous heart rates or cycle intervals, particularly those recorded over longer periods, traditionally 24 hours, more complex statistical time domain measures can be calculated.
1. These may be divided into two classes: (a) Those derived from direct measurements of the NN intervals or instantaneous heart rate, and (b) those derived from the differences between NN intervals.
2. These variables may be derived from analysis of the total ECG recording or may be calculated using smaller segments of the recording period.
3. The most commonly used measures derived from interval differences include RMSSD, the square root of
the mean squared differences of successive NN intervals; NN50, the number of interval differences of successive NN intervals greater than 50 ms; and pNN50, the proportion derived by dividing NN50 by the total number of NN intervals (Table 35.1).

4. All of these measurements of the short-term variation estimate high-frequency variations in heart rate and, thus, are highly correlated.

### Geometrical Methods

A series of NN intervals also can be converted into a geometric pattern, such as the sample density distribution of NN interval durations, sample density distribution of difference between adjacent NN intervals, Lorenz plot of NN or RR intervals and so forth.

1. A simple formula is used that judges the variability on the basis of the geometric and/or graphics properties of the resulting pattern.
2. The HRV triangular index measurement is the integral of the density distribution (that is, the number of all NN intervals) divided by the maximum of the density distribution.
3. The major advantage of the geometric methods lies in their relative insensitivity to the analytical quality of the series of NN intervals.
4. The major disadvantage of the geometric methods is the need for a reasonable number of NN intervals to construct the geometric pattern.

The methods expressing overall HRV and its long-and short-term components cannot replace each other. The selection of method used should correspond to the aim of each particular study.

### Frequency Domain Methods

Various spectral methods for the analysis of the tachogram have been applied since the late 1960s.

1. **Power spectral density (PSD)** analysis provides the basic information of how power (variance) distributes as a function of frequency.
2. Independent of the method used, only an estimate of the true PSD of the signal can be obtained by proper mathematical algorithms.

### Nonparametric and Parametric Methods

Methods for the calculation of PSD may be generally classified as nonparametric and parametric. In most instances, both methods provide comparable results.

**The advantages of nonparametric methods** are:

1. The simplicity of the algorithm used [fast Fourier transform (FFT)] in most of the cases.
2. The high processing speed.

**The advantages of parametric methods** are:

1. Smoother spectral components that can be distinguished independent of preselected frequency bands.
2. Easy post processing of the spectrum with an automatic calculation of low- and high-frequency power components with easy identification of the central frequency of each components.
3. An accurate estimation of PSD even on a small number of samples on which the signal is supposed to remain stationary.

The basic disadvantage of parametric methods is the need for verification of the suitability of the chosen model and of its complexity (that is, the order of the model).

### Spectral Components of Frequency Domain

#### Short-term Recordings

Three main spectral components are distinguished in a spectrum calculated from short term recordings of 2 to 5 minutes: VLF, LF and HF components (Table 35.2). The distribution of the power and the central frequency of LF and HF are not fixed but may vary in relation to changes in autonomic modulations of heart period. The physiological explanation of the VLF component is much less defined and the existence of a specific process attributable to these changes might even be questioned. The non-harmonic component, which does not have coherent properties and is affected by algorithms of baseline or trend removal, is commonly accepted as a major constituent of VLF. Thus VLF assessed from short-term recordings (≤ 5 minutes) is a dubious measure and should be avoided when the PSD of short-term ECG is interpreted.

1. The measurement of VLF, LF and HF power components is usually made in absolute values of power (milliseconds squared).
2. LF and HF may also be measured in normalized units, which represent the relative value of each power component in proportion to the total power minus the VLF component.

3. The representation of LF and HF in normalized units (LFnu and HFnu) emphasizes the controlled and balanced behavior of the two branches of the autonomic nervous system. Moreover, the normalization tends to minimize the effect of the changes in total power on the values of LF and HF components.

4. Nevertheless, normalized units should always be quoted with absolute values of LF and HF power in order to describe completely the distribution of power in spectral components.

5. LF-HF ratio provides a better indicator of spectral powers.

**Long-term Recordings**

Spectral analysis also may be used to analyze the sequence of NN intervals of the entire 24-hour period. The result then includes an ultra-low frequency (ULF) component, in addition to VLF, LF and HF components. The slope of the 24-hour spectrum also can be assessed on a log-log scale by linear fitting the spectral values. Frequency domain measures are summarized below.

**Technical Aspects**

The basic principle is that beat-to-beat variation in SA nodal discharge as recorded by ECG is computed and analyzed by the software for determination of spectral indices of HRV.

**Brief methodology:** There are two types of HRV recordings: the short-term 5 min HRV recording and day-night long-term HRV recording. Though long-term HRV recording is the ideal one, **short-term HRV recording** is usually performed for research and clinical investigations. We shall briefly describe the procedure of short-term recording as depicted in the **Task Force Report on HRV**.

1. The subject is asked to lie down comfortably in supine position in the laboratory, and ECG electrodes are connected for Lead II ECG recording.

2. After 5 minutes of supine rest, ECG signals are acquired at a rate of 1000 samples/second during supine rest using data acquisition system, such as BIOPAC MP 100 (BIOPAC Inc., USA) (minimum 250 Hz sampling rate). The raw ECG signal and the RR intervals are acquired on a moving time base.

3. Data from BIOPAC are transferred to a windows-based PC loaded with software for HRV analysis, such as Acknowledge software version 3.8.2. Ectopics and artifacts are removed from the recorded ECG.

4. **RR tachogram** is extracted from the edited 256 sec ECG using the R wave detector in the Acknowledge software and saved in ASC-II format, which is later used offline for short-term HRV analysis (RR tachogram should have minimum 288 RR intervals) (Fig. 35.2).

5. HRV analysis is performed by using the HRV analysis software version 1.1 (Bio-signal Analysis group, Finland).

**Calculation of Time Domain Indices**

In a continuous ECG record, each QRS complex is detected, and the so-called normal to-normal (NN) intervals (i.e. all intervals between adjacent QRS complexes resulting from sinus node depolarizations) or instantaneous heart rate is
determined. Simple time domain variables that are calculated include:
1. The mean RR
2. Standard deviation of normal-to-normal interval (SDNN)
3. Square root of the mean squared differences of successive normal-to-normal intervals (RMSSD) of HRV.
4. NN50
5. pNN50

**Calculation of Frequency Domain Indices**

Frequency domain variables that are usually calculated include **total power** (TP), **low frequency** (LF) component, LF component expressed as **normalized unit** (LFnu), **high frequency** (HF) component, HF component expressed as **normalized unit** (HFnu) and **LF/HF ratio** (Table 35.2).

Normalizing spectral powers are calculated by the formula as follows:
1. LF nu = LF x 100 (TP – VLF)
2. HF nu = HF x 100 (TP – VLF)
3. LF/ HF ratio = Ratio of LF to HF spectral powers

**Importance of HRV Analysis**

**Physiological Significance**

HRV analysis is used to precisely assess the efficiency of vagal control of the individual, as it reflects the heart rate variability that occurs mainly due to sinus arrhythmia.
1. Due to inspiratory inhibition of the vagal tone, the heart rate shows fluctuations with a frequency similar to the respiratory rate.
2. The inspiratory inhibition is evoked primarily by central irradiation of impulses from the medullary respiratory to the cardiovascular center.
3. Respiratory sinus arrhythmia can be abolished by atropine or vagotomy as it is parasympathetically mediated.

**HRV Analysis for Assessment of Sympathovagal Balance**

HRV, that is, the degree of heart rate fluctuations around the mean heart rate, can be used as a mirror of the cardiorespiratory control system. It is a valuable tool to investigate the sympathetic and parasympathetic function of the autonomic nervous system. SA nodal activity at any particular time is determined by the balance between vagal activity, which slows it, and sympathetic activity, which accelerates it. Generally, if the rate is lower than the intrinsic rate of the pacemaker, it implies predominant vagal activity, while high heart rates are achieved by increased sympathetic drive.

1. The **HF component of HRV indicates the cardiac vagal drive** of the individual. Increased HF power (or more specifically, increased HFnu) represents increased vagal drive and decreased HF power (decreased HF nu) represents decreased vagal drive to the heart.
2. The **LF component of HRV mainly indicates the cardiac sympathetic drive** of the individual. Increased LF power (or more specifically, increased LFnu) represents increased sympathetic drive while decreased LF power (decreased LFnu) represents decreased sympathetic drive.
3. The **sympathovagal balance** is assessed by the LF–HF ratio. Increased LF–HF ratio reflects increased sympathetic activity, while decreased LF–HF ratio indicates increased parasympathetic and decreased sympathetic activity.

**Physiological basis:** The relationship between vagal stimulation frequency and the resulting change in heart rate is hyperbolic, with changes in frequency at low heart rates having a much greater effect that does not directly control the heart rate, but which regulates the interval between successive beats.

1. The effect of vagal stimulation is rapid. Vagal stimulation releases the neurotransmitter acetylcholine, which inhibits the pacemaker potentials.
2. **Sympathetic responses** differ from vagal effects in that they develop much more slowly. Hence, responses with longer latency are likely to be mainly sympathetic.
3. **Peripheral vascular resistance** exhibits intrinsic oscillations with a low frequency. These oscillations can be influenced by thermal skin stimulation and are thought to arise from thermoregulatory peripheral blood flow adjustments.
4. The fluctuations in peripheral vascular resistance are accompanied by fluctuations with the same frequency in blood pressure and heart rate and are mediated by the sympathetic nervous system.
5. Hence, analysis of HRV also indicates the tone of sympathetic outflow and, therefore, reflects the individual’s state of sympathetic function and susceptibility to sympathetic dysfunction.

**Importance of LF-HF Ratio and Sympathovagal Balance**

1. The **HF component** of HRV, which indicates the cardiac vagal drive to the heart, represents parasympathetic activity. The **LF component** of HRV, which mainly indicates the cardiac sympathetic drive, represents sympathetic activity, though parasympathetic drive also contributes to it.
2. In healthy individuals, **HF constitutes about 60%, and LF constitutes about 40%** of the total power (TP) of HRV.
3. Therefore, **LF-HF ratio less than 1 indicates good cardiovascular health.** However, LF-HF ratio in normal population varies from 0.5 to 1.5.
4. The sympathovagal balance is assessed by the LF-HF ratio.
5. Increased LF-HF ratio reflects increased sympathetic activity (Figs. 35.3A and B) that is invariably associated with decreased TP.

6. Decreased LF-HF ratio indicates increased parasympathetic and decreased sympathetic activity that is invariably associated with increased TP (Fig. 35.4).

**Clinical Application**

Though there is considerable discussion regarding the physiology of HRV, it is well correlated and studied in many physiological and pathological conditions:

1. Total power (TP) of HRV indicates the magnitude of heart rate variability.
2. Decreased TP (decreased overall cardiac vagal modulation) has been implicated with future adverse cardiovascular (CV) morbidities and mortalities.
3. Decreased HRV (decreased total power of HRV) is observed in many cardiovascular disease conditions and generally indicated poor prognosis in these conditions.
4. Much before the onset of clinical symptoms of the cardiovascular disease, alterations are observed in HRV, indicating that HRV could be used as sensitive tool in the prediction of CV risks. However, more research is required to establish the predictive value of HRV in CV dysfunctions.
5. Presently, HRV is used as a prognostic tool in conditions like postmyocardial infarction and cardiac transplantation.
6. The most important application of HRV analysis is the surveillance of postinfarction and diabetic patients.
7. HRV gives information about the sympathetic-parasympathetic autonomic drives, and used as tool for assessment of autonomic imbalance.
8. As HRV analysis is used to assess the state of sympathovagal balance of the individual, it can be used to determine the individual’s susceptibility to developing autonomic dysfunctions in conditions like prehypertension and hypertension.

9. Decreased HRV is well correlated with the risk of sudden cardiac death in patients with heart disease.

10. Improvement in HRV and CV health is observed in interventions, like exercise, yoga and relaxation exercises. Hence, this can be used in future research works for improvement of holistic health.

The clinical applicability is still limited for lack of established normative data of HRV for different ages, genders and ethnic groups due to its demanding technical and mathematical comprehensibility. However, with increasing use of automation and computers in medicine, the clinical applicability of HRV is bound to be appreciated by researchers and clinicians.

CHAPTER SUMMARY

**Key Concepts**

1. Though HRV is a sensitive tool for assessing autonomic functions and dysfunctions, due to lack of wide range of normative data, its application in clinical medicine is limited.

2. HRV has less diagnostic application, though it is widely used in assessing prognosis of the diseases and in prediction of CV risks for morbidity and mortality.

3. TP of HRV depicts overall vagal modulation of heart. HF and HFnu indicate cardiac vagal drive, and LF and LFnu indicate sympathetic drive in general.

4. LF-HF ratio more than 1.5 indicates less vagal and more cardiac sympathetic drive, LF-HF ratio less than 0.5 indicates more vagal and less cardiac sympathetic drives. Less LF-HF ratio and more TP are indicators of good CV health.

**Important to Know (Must Read)**

1. In examinations, ‘Physiological basis, procedure, clinical application and merits and demerits of HRV’ may come as a Long Question.

3. In Viva, examiner may ask……. What is power spectral density, What are the HRV indices and how are they measured, Name Time-domain indices and mention their significance, What are the normalized units and how are they calculated, What LFnu and HFnu represent, Name frequency-domain indices and mention their significance, What is normal LH-HF ratio and what it indicates, What is the importance of sympathovagal balance, What are clinical utilities of HRV.
SECTION–5
Gastrointestinal System

**Part A: Introduction to GI System**
36. Functional Organization of GI System and Principles of GI Regulations
37. Gastrointestinal Hormones

**Part B: GI Secretions**
38. Principles of GI Secretion and Secretion of Saliva
39. Gastric Secretion
40. Pancreatic Secretion
41. Physiology of Liver, Liver Function Tests and Pathophysiology of Jaundice
42. Biliary Secretion
43. Intestinal Secretion
44. Secretion of Large Intestine

“Where ignorance is, there suffering too must come.  
...Your grief is a cry of darkness to the Light above;  
Pain was the first-born of the Inconscience  
Which was the body’s dumb original base”

Sri Aurobindo (in ‘SAVITRI’)
CHAPTER 36

Functional Organization of GI System and Principles of GI Regulations

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:
1. Appreciate the importance of GI physiology in learning medicine.
2. List the functions of GI tract and correlate the functional anatomy with functions of GI tract.
3. Name the layers of wall of GI tract, and give their functional importance.
4. Understand the difference in sympathetic and parasympathetic stimulation on GI functions.
5. Appreciate the organization of enteric nervous system.
6. Learn the principles of GI regulations.

The student **MAY** also be able to:
1. Describe the innervation of GI tract
2. Describe the principle of GI regulations

Gastrointestinal (GI) system is a fundamental design of the nature to provide nutrition to the individual by ingestion. The food particles that enter GI tract as larger molecules like polysaccharides, proteins and fats must be broken down into smaller absorbable molecules in the lumen of stomach and intestine to cross the GI epithelium and enter blood. Though, a person can survive on parenteral (usually, intravenous) nutrition, this restricts the mobil- ity of the individual and requires assistance for connecting intravenous infusion. Therefore, parenteral nutrition is advocated temporarily in patients who cannot eat, or in whom oral feeding is prohibited due to some other cause. It is also difficult to provide all nutritional ingredients for a longer duration through parenteral route. Therefore, gastrointestinal dysfunctions invariably lead to malnutrition.

1. When food enters GI system, starting from the mouth cavity, exocrine secretions (GI secretions) pour into the tract.
2. GI secretions (mainly salivary, gastric, pancreatic, biliary and intestinal) contain enzymes that split various food materials into their absorbable form. This is called digestion of food.
3. For adequate enzymatic digestion to take place, food should be thoroughly grinded and then mixed with GI secretions.
4. The process of grinding and mixing is initiated when food is present in oral cavity. Contraction of smooth muscle in the wall of the gastrointestinal tract produces various movement of the tract. This is called GI motility.
5. Chewing, and gastric and intestinal motilities help in grinding food particles and facilitate their mixing with the digestive juices.
6. GI motility also exposes chyme (digested food) to the epithelial surface of the intestine for their transfer into general circulation. This is called absorption of food.
7. GI motility is essential for propulsion of food in aboral direction.

Keeping the sequence of GI activities in mind, while describing GI physiology, we shall first discuss GI secretions, followed by GI motility and finally, the digestion and absorption of food.

**Scientist contributed**

RENÉ ANTONIE FERCHAULT DE REAUMUR, the French entomologist explored the comparative physiology in insects and birds. He studied the digestive process in birds and isolated gastric juice. He demonstrated the solvent action of gastric juice on food. His pioneering works in comparative physiology included regeneration in crustacean, electric organs of torpedo, star-fish movement, marine phosphorescence, formation of silk from silkworms and digestion in birds.

FUNCTIONAL ORGANIZATION

Functions of GI Tract

Gastrointestinal system, in addition to its principal functions of digestion and absorption of nutrients, carry out many other functions of the body. The GI functions may be listed as follows:

1. **Digestion and absorption of food**: The primary functions of GI system are to digest food materials and absorb essential nutrients of digestive products into the bloodstream.

2. **Excretion of waste materials**: Digestive tract excretes waste materials in the form of feces. Fecal matter includes mainly the excretory products of digestion and undigested food particles.

3. **Fluid and electrolyte balance**: On average, an adult consumes 1 kg of food and 1.5 liters of water per day. An additional amount of 7 liters of fluid is secreted into GI tract in the form of secretions from various exocrine glands. Thus, intestine is presented with about 8.5 liters of fluid per day. About 99% of this fluid and 90% of solids are absorbed in small and large intestines along with absorption of various electrolytes, so that only about 100 ml of liquid and 100 g of solids are excreted in feces per day. Decreased absorption of this water content results in dehydration. **Diarrhea occurs when capacity of intestine to absorb fluid is decreased or secretion of fluid is increased.**

4. **Immunity**: The GI tract is approximately a 15 feet long tube, which is open at both the ends. Therefore, anatomically it is continuous with the external environment. Consequently, it provides a fine channel for organisms from external world to pass through it. However, the gut associated lymphoid tissues (GALTs) protect the body from pathogenic organisms. GALTs are of two types: Peyer’s patches (aggregates of lymphoid tissue in the submucosa) and diffuse population of immune cells (discussed below). GALTs prevent entry of organisms from gut into the body. **Acidic secretion of stomach** also prevents entry of organisms through oral route.

5. **Intestinal bacterial flora**: Many nonpathogenic bacteria inhabit intestine. They form the normal bacterial flora of intestine. This normal flora is essential for many intestinal functions like epithelial cell permeability to electrolytes and water, synthesis and absorption of vitamins, stimulation of enzymatic activity, peristalsis and mucus secretion. Decreased flora impairs intestinal functions and increased flora increases the susceptibility to diarrhea and steatorrhea. These bacteria also **detoxify many toxins** present in the chyme and prevent their absorption into the bloodstream.

---

Parts of GI System

Gastrointestinal system consists of gastrointestinal tract (GIT) and its associated glandular structures that produce exocrine secretions essential for digestion and absorption of various nutrients. The parts of GIT include **mouth, pharynx, esophagus, stomach, small intestine (duodenum, jejunum, and ileum), colon (ascending, transverse, descending and sigmoid colons), rectum, and anus** (Fig. 36.1). The major associated glandular structures are salivary glands, liver, exocrine pancreas and intestinal glands.

1. GI tract begins with the **mouth** (oral cavity). Digestion of food starts in mouth with chewing. **Salivary glands** open into the oral cavity and pour their secretion (saliva) into it. Salivary amylase helps in partial digestion of complex sugars (polysaccharides).

2. Oral cavity opens into **pharynx** which in turn is continuous with the esophagus.

3. **Esophagus** transmits food from oropharynx into stomach.

4. **Stomach** is a bag like structure that stores and grinds food, and mixes food with gastric juice. HCl and pepsin secreted in stomach help in partial digestion of proteins and stomach converts food into chyme. Chyme from stomach enters intestine through pyloric sphincter by controlled gastric emptying.

5. **Small intestine** is a 9 feet tube that extends from pyloric sphincter to the ileocecal valve. It consists of three parts: duodenum, jejunum and ileum.

6. **Biliary and pancreatic secretions** are poured into duodenum.

7. Intestinal glands secrete **sucus entericus**.

8. **Pancreatic and intestinal secretions** are rich in various enzymes that cause digestion of carbohydrates, fat and proteins.

9. Absorption of most of the nutrients takes place in jejunum and ileum.
10. Small intestinal motility propels food into large intestine through ileocecal sphincter.
11. Large intestine absorbs water and electrolyte and temporarily stores the concentrated and undigested material, which then enters the rectum.
12. Rectum, the final segment of large intestine stores fecal matter and contracts when distended. Defecation reflex relaxes the anal sphincters and expels feces from rectum to outside through anal canal.

**Structure of the Wall of GI Tract**
The basic nature of arrangement of tissues in the wall of GI tract starting from esophagus to the rectum is similar. In general, there are four layers from interior to exterior: mucosa, submucosa, muscle layer, and serosa (Fig. 36.2).

**Mucosa**
The innermost layer of GI tract is the mucosa, which has an epithelium, lamina propria and muscularis mucosa (Fig. 36.3).

**Epithelium**
A single layer of epithelial cells line the mucosa. The cells are tightly bound to each other at their edges by tight junctions.
1. The epithelium is mainly a stratified squamous epithelium.
2. In stomach and intestine, the mucosa is lined by simple columnar epithelium that facilitates secretion and absorption.
3. At places, the epithelium contains endocrine cells (enterochromaffin cells) that secrete local hormones.

**Lamina Propria**
Just below the epithelium is the lamina propria consisting of mainly loose connective tissue that contains collagen and elastin fibers.
1. This sub-layer is rich in blood vessels, lymph nodes and lymphatic ducts, nerve fibers, and capillaries. This layer supports the epithelium and also binds epithelium to the muscularis mucosa.
2. The lymphatic tissues present in this layer form the local immune system and prevent the entry of pathogens that try to penetrate mucous membrane to enter into the body.

**Muscularis Mucosa**
This is the innermost layer of the intestinal smooth muscle present in the mucosa. The muscle fibers are arranged in two layers: an inner circular and outer longitudinal layer.
1. Contraction of muscularis mucosa in the stomach and intestine throws the mucous membrane into folds and ridges.
2. In the intestine, these mucosal folds called plica increase the surface area for absorption (Fig. 36.4).
3. Contraction of muscularis mucosa in small intestine produces local movements that facilitate the process of digestion and absorption.

**Submucosa**
Next to the mucosa is the submucosa. It consists mainly of loose connective tissue and is highly vascular.
1. The submucosal layer contains a network of nerve fibers known as submucosal plexus or plexus of Meissner.
2. Autonomic nerve fibers supplying muscles and blood vessels of GI tract closely interact with Meissner’s plexus.
3. In some regions, especially in intestine, submucosa contains lymphatic tissue.

**Muscular Layer**
This is called muscularis externa. It consists of two layers of smooth muscles: the inner circular and the outer longitudinal layers.
1. A nerve plexus is located between the muscle layers, called as myenteric plexus or plexus of Auerbach.
2. Auerbach’s plexus contains fibers from both divisions of ANS.
3. Muscularis externa primarily controls the motility of GI tract that mixes and circulates the gastrointestinal contents and propels them along the lumen of the tract.
Fig. 36.4: Differences in the layers of the wall in different parts of GIT. Note that mucosa is simple columnar in stomach and intestine. In jejunum, the muscularis mucosa is folded to form plica that increases the surface area for absorption.

Courtesy: Figure 13.1, Basic Histology, by V Subhadra Devi, 1st edition, 2016; Jaypee Brothers Medical Publishers (P) Ltd.
Serous

This is the outermost layer of the GIT. It consists mainly of a thin layer of connective tissue covered with a layer of squamous mesothelial cells. It provides external protection to the GIT.

Intestinal Modifications

Villi

In small intestine, from the luminal surface, finger like projections extend into the lumen. These are called villi. Surface of each villus is covered with an epithelial cell layer.
1. Small projections arise from the surface of these epithelial cells, known as microvilli (Fig. 36.5).
2. Microvilli are collectively called as brush border.
3. Folded mucosa, villi and microvilli increase the surface area of the intestinal luminal epithelium by 600 fold.
4. The total luminal surface area of human intestine is about 300 m², which is about the area of a tennis court.
5. Intestinal epithelial cells are continuously replaced by new cells. About 17 billions of epithelial cells are replaced every day and the entire intestinal epithelium is replaced almost every five days.
6. Center of each villus is occupied by lymphatics called lacteals, and capillaries, venules and nerve fibers.

Peyer’s Patches

These are the aggregates of lymphoid tissue in the mucosal-submucosal regions of the intestinal wall.
1. They serve local immune functions in the intestine. They prevent organisms to enter blood stream from the intestinal lumen.
2. They also secrete mediators of inflammation (cytokines) that alter motility. These cytokines play role in genesis of inflammatory bowel disease and Crohn’s disease.

Innervation of GI Tract

Gastrointestinal tract is innervated by sympathetic and parasympathetic fibers. Also, it has its own neural circuits (enteric nervous system).

Sympathetic Innervation

Stimulation of sympathetic fibers to GI tract is generally inhibitory. Sympathetic innervation is via noradrenergic fibers having their cell bodies in the prevertebral and paravertebral chain of ganglia. The postganglionic fibers mainly originate from celiac, superior and inferior mesenteric ganglia (Refer to Fig. 31.2; Chapter 31).

Usually, sympathetic fibers do not directly innervate the target GI tissues. Instead, they terminate on neurons of intrinsic nerve plexuses that in turn contact the target structures (Fig. 36.6). However, the vasoconstrictor fibers directly innervate blood vessels of GI tract.

Sympathetic stimulation results in:
1. Inhibition of motor activity resulting in relaxation of GI smooth muscles.
2. Stimulation or contraction of sphincters.
3. Inhibition of GI secretions.

Parasympathetic Innervation

Parasympathetic innervation is mainly via vagus nerve, which innervates GI tract from oral cavity upto transverse colon. Remaining parts (descending and sigmoid colons, rectum, and anal canal) receive parasympathetic fibers from pelvic nerves (see Fig. 32.1; Chapter 32).

1. Parasympathetic fibers are cholinergic and generally excitatory.
2. They terminate mainly on the intrinsic nerve plexuses.
3. Parasympathetic stimulation leads to increased motility and exocrine secretions of GI tract.

Enteric Nervous System

Enteric nervous system (ENS) is the intrinsic nervous system of the GI tract.

1. This includes myenteric and submucosal nerve plexuses in the GI tract (Fig. 36.6). These two plexuses are the network of nerve fibers and ganglion cells.
2. The neurons of these plexuses are small interneurons that connect afferent neurons and efferent neurons to smooth muscles, secretory cells and epithelial cells (Flowchart 36.1), and they form the anatomical basis of local GI reflexes. Therefore, the reflex arc for local GI reflexes is located within the GI tract. Hence, ENS is capable of coordinating GI activity in the absence of external innervation.
3. The neurons of ENS closely interact with the autonomic nervous system. The sympathetic and parasympathetic fibers project to the neurons of the myenteric and submucosal plexuses, and control GI activities via these neurons.
4. Therefore, ENS is also known as **third division of ANS**. However, it should be remembered that **regulation of GI functions by ENS is independent of autonomic control**.

**ENS as the Mini-brain of gut**: ENS consists approximately of 100 million neurons, the number of neurons that are roughly present in spinal cord or in entire ANS. These neurons are clustered exclusively in the gut.

1. They have sensory neurons, interneurons and motor neurons. Therefore, ENS is loosely called the ‘**mini brain**’ for the gut.

2. The ENS afferent neurons monitor changes in luminal activity like distension, alteration in osmolality, pH etc. and activate gut interneurons.

3. The interneurons signal the changes in ENS motor fibers that alter the activities of effector tissues like smooth muscle cells, glandular cells, epithelial cells and vascular cells.

**Neurotransmitters in the ENS**: Many neurotransmitters in the ENS have been recently identified.

1. **Acetylcholine** (ACh) is the primary neurotransmitter in preganglionic and postganglionic neurons that regulate secretory and motor activities of GI tract.

2. **VIP, serotonin, enkephalins, substance P, norepinephrine, GABA, ATP, NO and CO** have also been described as neurotransmitters in ENS, and these chemicals play important role in regulation of GI functions.

**GI Sphincters**

Sphincters are **specialized circular muscles** that are present at the **beginning or at the end of a gut structure**. Sphincters regulate antegrade (forward) movement of food and prevent retrograde (reverse) expulsion of the same. There are **six sphincters** in GI tract:

1. Upper esophageal sphincter
2. Lower esophageal sphincter
3. Pyloric sphincter
4. Ileocecal sphincter
5. Internal anal sphincter
6. External anal sphincter

There is another sphincter located in the wall of the duodenum called **Sphincter of Oddi** that regulates secretion of bile and pancreatic juice into the intestine.

**GI Immune System**

An extensive immune mechanism is developed in GI system, which is called **gastrointestinal immune system**. This system includes:

1. **Mesenteric lymph nodes**
2. **Peyer’s patches** (aggregation of lymphatic tissues in the submucosa)
3. **Phagocytic cells and immunocytes** present in the mucosa and submucosa throughout the GI tract (For details, refer to Chapter 18).

**Immunological Cells in GI System**

The immunological cells in GI system constitute about **50% of the total immunocytes in the body**.

1. Immunocytes in GI tract are **B and T cells**, **epithelial lymphocytes**, **plasma cells**, mast cells and macrophages.
2. These cells **secrete chemicals** that mediate immunological and inflammatory responses in GI tract.
3. They secrete **antibodies** locally in response to antigens that enter through GI tract.
4. **Other chemicals** secreted by immunocytes are **leukotrienes, cytokines, prostaglandins and histamine**. These chemicals not only mediate immunological responses, but also influence activities of smooth muscles of GI tract.
5. GI immune system plays an important role in the pathogenesis of inflammatory bowel diseases like ulcerative colitis.

**PRINCIPLES OF GI REGULATIONS**

The functions of GI tract are regulated mainly by neural and hormonal influences. Interestingly, the hormonal and neural control systems of GI functions are mostly intrinsic to GI tract.

**Neural Regulation**

The digestive system is regulated by the nerves arising locally in the GI tract (intrinsic neural control) and the nerves innervating the gut (extrinsic neural control). The GI reflexes modify activities of GI system depending on the state of digestion and absorption taking place in the tract.

**Intrinsic Neural Regulation**

The intrinsic nerves of the GI system form the enteric nervous system, sometimes called as third component of ANS.

1. The nerves are arranged in the submucosal layer as Meissner’s plexus and in the muscle layer as Auerbach’s plexus.

2. These nerve plexuses control local secretion and movement of GI tract.
3. The Meissner’s plexus performs sensory functions and Auerbach’s plexus performs motor functions.
4. The intrinsic neurons mediate local or short reflexes.
5. The intrinsic nerve plexuses are connected and controlled by extrinsic nerves.

**Extrinsic Neural Regulation**

Extrinsic nerves regulating GI functions belong to sympathetic and parasympathetic systems.

1. In general, the sympathetic system to the GI tract is inhibitory and the parasympathetic system is stimulatory.
2. The autonomic innervations also control GI functions by altering the activity of neurons in the enteric nervous system.
3. Extrinsic nerves mediate long reflexes.

**Reflex Control**

There are two types of neural reflexes that operate in GI system: short or local reflexes and long or central reflexes (Flowchart 36.2).

1. Afferent pathway in the GIT forms afferent limb for both local and central reflexes.
2. There are many chemoreceptors and mechanoreceptors in the mucosa and muscularis mucosa that are extensively connected to intrinsic plexuses. Actions of these receptors mediate local reflex activity.
3. Enterogastric reflex is an example of a short reflex. Receptors also provide signals to the CNS that control GI functions via central reflexes. The efferent fibers for central reflexes are present in the autonomic fibers that terminate in enteric nerve plexuses. Reflex secretion of saliva in response to smell of food is an example of a long reflex.

**Hormonal Regulation**

The hormones controlling GI functions are also of two types: intrinsic hormones, and extrinsic hormones.

### Intrinsic Hormones

Many hormones are secreted from endocrine cells of GI tract. These hormones are called GI hormones (for details, refer next chapter). They mainly act in a paracrine fashion. For example, histamine secreted from neuroendocrine cells of the stomach greatly influences gastric acid secretion. However, many hormones also have systemic functions. Therefore, GI tract is sometimes designated as an endocrine organ.

### Extrinsic Hormones

GI functions are also influenced by hormones secreted from other endocrine glands like thyroxine and cortisol. Thyroxine stimulates intestinal motility, whereas cortisol stimulates acid secretion from parietal cells of stomach.

---

**CHAPTER SUMMARY**

**Key Concepts**

1. The layers in the wall of GI tract are modified at parts to suit the functions of that part.
2. Interneurons from sympathetic and parasympathetic system (form extensive neural plexuses in muscle layer and mucosal layer) innervate and control the epithelial cells, smooth muscle cell and secretory cell in GIT.
3. Immunocytes in the GIT (Peyer’s patches, Gut associated lymphatic tissues, and other lymphocytes) provide local immunity.
4. Short and long reflexes control GI functions.

**Important to Know (Must Read)**

1. In examinations, usually Long Questions are not asked from this chapter.
2. Layers of GIT, Innervation of GIT, Immune system of GIT, Enteric nervous system, and Reflex control of GI functions, may come as Short Questions in exams.
3. In Viva, examiner may ask… What are the parts of GIT and what are their main functions, What the layers of GIT and what are their functions, What is the system of innervation of GIT, What are the effects of stimulation of sympathetic and parasympathetic system to GIT, Name the immune mechanisms in GIT, How is enteric nervous system formed and how it works, What are neurotransmitters secreted by GI neurons, What are short and long reflexes and how they work.
4. If a student fails to answer the part of GIT, their organization and functions, it becomes difficult for examiner to give pass mark.
The hormones secreted from the endocrine cells of the GI tract are collectively known as gastrointestinal hormones (GI hormones). Endocrine cells are scattered throughout epithelium of GI tract, especially in stomach and small intestine. The apical surface of epithelial endocrine cells is continuously exposed to chemical changes in the luminal contents of the gut, which directly stimulates the release of hormones from these cells.

1. Endocrine cells that secrete GI hormones are called enteroendocrine cells.
2. Cells that secrete serotonin are called enterochromaffin cells, and cells that secrete amines and polypeptides are called APUD cells (amine precursor uptake and decarboxylation).
3. APUD cells are also found in other organs like lungs. They are also called neuroendocrine cells. Carcinoid tumors originate from these neuroendocrine cells.

Families of GI Hormones: GI hormones are broadly divided into three categories:

1. **Gastrin family** that includes cholecystokinin and gastrin.
2. **Secretin family** that includes GIP, glucagon, secretin, and VIP.
3. **Other polypeptides**.

**GI Hormones of Gastrin Family**

**Gastrin**

**Source**

Gastrin is produced by G cells in the stomach that are located mainly in the antral region.

1. G cells are conical cells with apex projecting toward the lumen. Apical surface of G cells contains numerous microvilli. Microvilli of G cells contain receptors for chemicals that mediate gastrin release.
2. **Gastrin producing cells are also present** in hypothalamus, anterior pituitary, medulla, and fetal pancreas.
3. Gastrin as a neurotransmitter is also secreted from vagus and sciatic nerve.

**Structure**

Gastrin is a polypeptide hormone. Gastrin has marked heterogeneity; but its physiological significance is not clearly known.

1. Gastrin exhibits both macroheterogeneity (gastrins having different polypeptide lengths) and microheterogeneity (gastrins having different molecular structures).
2. Though different types of gastrins have been described, three types of gastrin are physiologically important. Depending on the number of amino acids they possess, they are named as G 34, G 17, and G 14. Other types of gastrins are C-tetrapeptide (carboxyl terminal tetrapeptide, which is also called minigastrin), and gastrin containing 45 amino acids (megagastrin).

3. However, G 17 is the principal gastrin secreted from the stomach and is the major stimulator of gastric acid secretion.

4. Though C-tetrapeptide executes all the actions of G-17, it has only 10% of its physiological strength.

**Metabolism**

Gastrin secreted from G cells enters general circulation. In blood, half-life of gastrin is less. Half-life of G 14 and G 17 is 2–5 min and of G 34 is about 15 min. Gastrin is inactivated in the intestine and degraded in the kidney.

**Functions**

1. Primary function of gastrin is the stimulation of gastric acid and pepsin secretion. In fact, gastrin is the most potent natural stimulator of HCl secretion from parietal cells of stomach. Therefore, hypergastrinemia causes peptic ulcer.

2. Gastrin stimulates growth of gastric mucosa and mucosa of intestine. This is called trophic action of gastrin.

3. It stimulates gastric motility.

4. It causes contraction of muscles at the gastroesophageal junction (lower esophageal sphincter). Therefore, it prevents reflux esophagitis.

5. It stimulates exocrine pancreatic secretion.

6. It also stimulates insulin secretion.

7. It stimulates mass movement of large intestine.

8. It causes colonic contraction that initiates gastrocolic reflex after a meal. Therefore, usually defecation is activated after a meal.

9. It stimulates histamine secretion from ECL (enterochromaffin like cells) in GI mucosa.

**Mechanism of Action**

The primary function of gastrin is to stimulate acid secretion from parietal cells of the stomach. Gastrin acts on gastrin or CCK receptors on parietal cells and increases intracellular calcium concentration via second messenger, IP3. Increased cytosolic calcium activates protein kinase that stimulates H⁺–K⁺ ATPase to promote acid secretion.

**Control of Gastrin Secretion**

1. Stimuli that increase gastrin secretion: Gastric distention, products of protein digestion (peptides and amino acids) in the stomach, increased vagal discharge via GRP (non-cholinergic), epinephrine and calcium (Flowchart 37.1). Hypergastrinemia occurs in ZE syndrome (Clinical Box 37.1). Gastrin secretion is also elevated in pernicious anemia, in which acid secretion in the stomach is less as parietal cells are damaged. This causes feedback release of gastrin from G cells.

2. Stimuli that decrease gastrin release: Acid in the stomach, somatostatin, secretin, GIP, VIP, calcitonin, and glucagon. Acid in the antrum inhibits gastric secretion by negative feedback mechanism, which is partly by direct action of acid on G cells and partly by release of somatostatin.

**Cholecystokinin**

**Source**

Secreted from I cells in the mucosa of upper small intestine. CCK is present as neurotransmitter in cerebral cortex, in somatic nerves and in nerves of distal ileum and colon.

**Structure**

Cholecystokinin (CCK) is a polypeptide hormone. There are different forms of CCK depending on the number of amino acids present, like CCK 58, CCK 39, CCK 33, CCK 12, CCK 8, and CCK 4 (carboxyl terminal tetrapeptide). CCK secreted from duodenum and jejunum are usually CCK 12 and CCK 8. CCK in the enteric and pancreatic nerves is mainly CCK 4. The forms of CCK in brain are primarily CCK 58 and 8. Half-life of CCK is about 5 minutes.
**Chapter 37: Gastrointestinal Hormones**

**Functions**
1. CCK causes contraction of gallbladder. Therefore, CCK increases bile release into the intestine following a meal.
2. It stimulates pancreatic secretion rich in enzymes. Therefore, CCK is also called *cholecystokinin-pancreozymin* (CCK-PZ).
3. It also augments the action of secretin to produce alkaline pancreatic secretion.
4. It inhibits gastric acid secretion.
5. It inhibits gastric motility, thereby delays gastric emptying.
6. Causes relaxation of sphincter of Oddi that allows both bile and pancreatic juice to enter duodenum.
7. Stimulates growth of pancreas.
8. Increases secretion of enterokinase.
10. Stimulates colonic movements.
11. Causes contraction of pyloric sphincter. Therefore, prevents reflux of duodenal contents into the stomach.
12. Stimulates glucagon secretion.
13. In brain, it acts as an anorexigenic neurotransmitter. It inhibits food intake.
14. It also produces analgesia and anxiety.

**GI HORMONES OF SECRETIN FAMILY**

**Secretin**
Secretin has an important place in the history of endocrine physiology, as it was the *first hormone to be discovered* (Bayliss and Starling; 1902).

**Source**
Secretin is secreted from S cells located in the mucosa of upper part of small intestine.

**Structure**
Secretin is a polypeptide hormone containing 27 amino acids.

**Functions**
1. Secretin increases secretion of pancreatic juice rich in bicarbonate (watery and alkaline pancreatic secretion).
2. It also increases alkaline bile secretion.
3. Augments the action of CCK to produce pancreatic secretion rich in enzymes.
4. Decreases gastric acid secretion and motility.
5. Causes contraction of pyloric sphincter.

**Mechanism of Action**
Secretin acts on adenylate cyclase on the cell membrane and increases cytosolic formation of cAMP.

**Regulation of Secretion**
Secretion of secretin is increased by acidic chyme and products of protein digestion entering the upper part of intestine. Secretin stimulates watery and alkaline pancreatic secretion. When watery and alkaline pancreatic juice enters intestine, the acidic content of upper small intestine is neutralized. The increased pH of duodenal and upper jejunal content decreases secretin secretion by feedback mechanism (Flowchart 37.3).

**Flowchart 37.2:** Regulation of cholecystokinin secretion.

**Flowchart 37.3:** Regulation of secretin secretion.
Scientists contributed

Ernest Henry Starling (1866–1927) an English physiologist worked with his brother-in-law, Sir William Maddock Bayliss. Both of them had discovered the first hormone, Secretin. Starling is most famous for developing the “Frank–Starling law of the heart”, presented in 1915 and modified in 1919. In 1891, when he was 25, Starling married Florence Amelia Wooldridge, the widow of Leonard Charles Wooldridge, who had been his physiology teacher at Guy’s and died at the age of 32. She was a great support to Starling as a sounding board, secretary, and manager of his affairs as well as mother of their four children. To be noted, Bayliss was born on 2nd May and Starling died on 2nd May.

GIP

Structure

Glucose-dependent insulinotropic polypeptide (GIP) is a polypeptide hormone containing 42 amino acids. This is also called gastric inhibitory peptide (GIP).

Source

GIP is produced by K cells present in the mucosa of duodenum and jejunum.

Functions

1. It inhibits gastric secretion and motility.
2. It stimulates insulin secretion. For this function, GIP is considered as an important physiological regulator of insulin secretion. Though other hormones like gastrin, CCK, secretin and glucagon also stimulate insulin secretion, plasma insulin level of insulin in response to GIP resembles the concentration of insulin attained following oral glucose ingestion.
   - Therefore, GIP is called glucose-like insulinotropic polypeptide.
   - However, GLP-1, derived from glucagon appears to be more potent than GIP in promoting insulin secretion.
   - Hence, both GIP and GLP-1 are among the important physiological regulator of insulin secretion from beta cells of pancreas.

Regulation of Secretion

Secretion of GIP is increased by glucose and fat in the duodenum.

VIP

Structure

VIP is a polypeptide containing 28 amino acids. It is formed from prepro-VIP that contains both VIP and PHM-27, a closely related peptide.

Source

VIP is secreted from mucosal cells of entire GIT, starting from stomach to colon. However, the secretion is more in the colon. It is found in the nerves of GIT, other autonomic nerves, blood and also in brain. Its half-life is 2 minutes.

Functions

1. It markedly increases intestinal secretion rich in electrolytes and water. Therefore, in excess it produces watery diarrhea.
2. It causes vasodilation. Therefore, it decreases blood pressure.
3. It decreases GI motility. It causes relaxation of intestinal smooth muscle including sphincters.
4. It potentiates the action of acetylcholine on salivary glands.
5. It inhibits gastric acid secretion.

Clinical Significance

The tumor of VIP secreting cells is called VIPoma. Profuse watery diarrhea and hypotension are major features of VIPoma.

Glucagon

This is structurally similar with glucagon secreted from A cells of pancreas. In GIT, it is secreted from A cells in the stomach and L cells in intestine, where it is known as enteroglucagon. This produces hyperglycemia.

Glucagon-like Polypeptides

Glucagon is mainly produced from A cells in pancreas and L cells in intestine.

1. In A cells, preproglucagon is processed to form glucagon and major proglucagon fragments (MPGF), whereas in L cells it is processed to form glucagon, glicentin and glucagon-like peptides (GLP).
2. There are two GLPs: GLP 1 and GLP 2, and both are also produced in brain.
3. GLP 1 is a potent stimulator of insulin secretion.
4. GLP 2 does not have definitive biological activity.
5. However, GLP 2 produced in the brain inhibits food intake and acts as a neurotransmitter in the neurons that project from NTS to dorsomedial nucleus of hypothalamus.
6. Both A and L cells also produce oxyntomodulin and glicentin related polypeptide (GRPP).
7. Oxyntomodulin inhibits gastric acid secretion. Exact function of GRPP is not known.
MISCELLANEOUS FAMILY

Motilin

Structure and Source
This is a polypeptide hormone containing 22 amino acids. It is secreted from enterochromaffin cells and Mo cells present in the mucosa of all parts of GIT, except esophagus and rectum. It acts on G-protein coupled receptors on enteric neurons.

Functions
1. It causes contraction of intestinal smooth muscle and therefore, increases GI motility, especially in the interdigestive phase.
2. It is a major regulator of migrating motor complex (MMC), that regulates GI motility between meals.
3. Secretion of motilin is decreased following ingestion of a meal and its concentration remains low until the digestion and absorption of that meal is complete. Then the concentration increases and activates MMC that sweeps and cleans the intestine. Thus, it prepares the intestine for next meal.

Applied Physiology
Erythromycin can be used in patients having hypomotility of GI tract, as this antibiotic and its derivative bind to motilin receptors and facilitate intestinal motility.

Other Hormones

Neurotensin
This is a polypeptide hormone containing 13 amino acids. It is produced by neurons and mucosal cells of intestinal epithelium, mainly in ileum. It inhibits GI motility but increases ileal blood flow.

GRP
Gastrin releasing polypeptide (GRP) is a polypeptide containing 27 amino acids.
1. It is secreted from non-cholinergic vagal fibers.
2. It mediates gastrin release via non-cholinergic vagal stimulation.
3. The 10 amino acid residues at the carboxyl terminal of GRP is almost similar to the bombesin of amphibians.

Somatostatin
This is a polypeptide containing either 14 (SS 14) or 28 (SS 28) amino acids.
1. Somatostatin is secreted from GIT (starting from stomach to colon), hypothalamus and D cells of pancreas.
2. It inhibits gastrin secretion.
3. It also inhibits secretion of VIP, GIP, secretin, and motilin.
4. It is an inhibitory neurotransmitter in many parts of brain, especially in hypothalamus and pituitary.

Guanylin

Structure and Source
This is a polypeptide hormone containing 15 amino acids. It is secreted from the cells of intestinal mucosa. In human, it is produced by Paneth cells (endocrine cells located in the crypts of Lieberkuhn of small intestine).

Mechanism of Action
It acts by stimulating the activity of guanylyl cyclase (hence called guanylin) which increases the concentration of cGMP. The cGMP in turn increases activity of chloride channels and increases chloride secretion into the intestine.

Functions
Guanylin increases secretion of chloride ions into the intestinal lumen and therefore regulates fluid movement across intestinal tract. Guanylin receptors are present in kidney, liver and female reproductive tract. In these organs, guanylin appears to control fluid movement and particularly integrates the actions of intestine and kidneys.

Applied Physiology
Enterotoxins of some strains of E. coli that cause diarrhea have structural similarity with guanylin. They activate guanylin receptors in intestine and produce fluid secretion into the intestinal lumen.

TRH
This is structurally similar to the hypothalamic TRH. But, as it does not enter circulation, it does not produce any effect on thyroid. However, it is involved in the regulation of secretory immunity of intestine.

ACTH
Structurally, it is similar to the ACTH of anterior-pituitary. The function of intestinal ACTH is not clearly known.

Ghrelin
It is a 28 amino acid polypeptide secreted mainly from stomach. It has more systemic effects than local actions. It is a strong orexigenic agent that increases food intake by acting on arcuate nucleus of hypothalamus. It stimulates secretion of growth hormone from anterior pituitary.

Peptide YY
It is a polypeptide hormone secreted from small intestine and colon. It inhibits gastric secretion and motility.
Hence, it is proposed to be an effective gastric inhibitory peptide. Its secretion is stimulated by presence of fat in jejunum. Though, structurally it resembles neuropeptide Y that stimulates food intake, peptide YY inhibits feeding.

**Substance P**
Substance P is secreted from endocrine cells and neurons of entire GIT starting from stomach to colon. It increases intestinal motility. Its role in modulation of pain is discussed in “Physiology of Pain” in Sensory System.

---

### CHAPTER SUMMARY

#### Key Concepts
1. Though of GI hormones have local effects, and they are called local hormones, many of them have systemic effects.
2. In addition to influence on GI secretion and motility, they affect food intake, metabolic functions, insulin and glucagon secretion, cardiovascular function and many brain functions.

**Important to Know (Must Read)**
1. In examinations, “Classify GI hormones and describe their functions” may come as a Long Question.
2. GI hormones of Gastrin family, GI hormones of secretin family, Gastrin, Cholecystokinin, Secretin, VIP, GIP, Enteroglucagon, Guanylin, Motilin, may come as Short Questions in exams.
3. In Viva, examiner may ask... Classification of GI hormones, structure and functions of any GI hormone, Applied aspect of any GI hormone.
4. GI hormones are usually asked in oral examination.
Secretions from exocrine glands associated with GI tract are called GI secretions. The major GI secretions include secretion from:
1. Salivary glands (salivary secretion)
2. Gastric glands (gastric secretion)
3. Exocrine pancreas (pancreatic secretion)
4. Liver (bile secretion)
5. Intestinal glands (intestinal secretion).

The major objectives of GI secretions are to facilitate digestion of food in the gut lumen, promote absorption of nutrients from the GI tract, and to assist in passage of luminal contents in aboral direction.

**PRINCIPLES OF GI SECRETION**

**Phases of GI Secretions**

Most of the GI secretions occur in three phases: cephalic, gastric, and intestinal. These phases are classified based on stimulus location.

**Cephalic Phase**

When stimuli activate the brain mechanisms (cephalic means “head”) to alter GI secretions, the phase is called cephalic phase.
1. **Sight, smell, and thought** of food initiates cephalic phase of secretion. **Taste of food** (food in mouth) and chewing of food that increase GI secretions are also stimuli for cephalic phase.
2. Various **emotional states** also activate cephalic phase of secretions.
3. The efferent pathway is the **vagus nerve** that activates neurons in the ENS, which in turn influence gastric secretion and motility.

**Physiological Importance of Cephalic Phase**

Cephalic phase is important for salivary, gastric, pancreatic, and bile secretions.
1. It accounts for about 90% of volume of salivary secretion. It contributes to about 40% of gastric and pancreatic secretions. This simply indicates that GI tract prepares for digestion even before food enters into stomach and intestine.
2. In fact, sufficient GI secretions **accumulate in advance** in this phase so that the process of digestion starts as soon as food arrives in the gut, especially in the intestine.
3. Therefore, **it is desirable to spend some time in taking soup and starters before taking a major meal.**
Physiological Importance of Gastric Phase
Distension of stomach is the major mechanical event of the gastric phase.
1. **Gastric distension** is the primary regulator of satiety.
2. It also greatly influences digestion of food by controlling GI secretions.
3. Gastric distension along with acidic chyme in the stomach and gastrin secreted from stomach, activate short and long GI reflexes to influence gastric, pancreatic, biliary, and intestinal secretions.
4. These secretions control the processes of digestion and absorption.

Intestinal Phase
Intestinal phase is initiated when chyme enters duodenum.
1. Products of digestion (fatty acids, peptides, etc.), presence of acidic chyme, intestinal distension and osmolality of intestinal contents are important stimuli in the intestinal phase of GI secretions.
2. They activate various intestinal reflexes to alter GI secretions.
3. CCK, secretin, GIP, VIP, and many other hormones are secreted during this phase.

Physiological Importance of Intestinal Phase
Chyme in the intestine requires enzymes for digestion of food particles in which the first step is to hydrolyze macromolecules into their smaller absorbable forms. This is achieved mainly by pancreatic and intestinal secretions.
1. Acidic chyme in duodenum stimulates secretion of CCK and secretin from upper part of small intestine that profoundly influence pancreatic and bile secretions.
2. Through reflex mechanisms, food in intestine inhibits gastric secretion and motility.

Principles of Regulation
Regulation of GI secretions occurs mainly by neural and hormonal factors. However, mechanisms specifically controlling these regulations depend on the phase of GI secretion.
1. For example, cephalic phase is predominantly regulated by neural mechanisms, whereas gastric and intestinal phases are regulated by both hormonal and neural mechanisms.
2. Accordingly, tests detecting the integrity of GI secretions are different for different phases.

General Functions of GI Secretion
1. **Digestion:** Enzymes in GI secretion are key elements for digestion of food particles in the GI tract. Broadly, these enzymes are amylases that digest carbohydrates, peptidases that digest proteins and lipases that digest lipids.
2. **Protection from infections:** Chemicals present in GI secretions protect the body from infections. For example, lysozyme in secretions is antibacterial, IgA in saliva provides local immunity and HCl in gastric secretion kills all types of organisms.
3. **Mixing:** The aqueous part of secretions help in mixing of food with chemicals and enzymes in the secretions. This is essential for thorough exposure of food particles with chemicals for proper digestion of each ingredient in the food.
4. **Lubrication:** Mucus secretions facilitates passage of bolus of food or chyme along the GI tract in aboral direction. This especially helps in propulsion of food.
5. **Protection of mucosa:** The mucus and alkaline pH of secretions protect mucosal epithelium of gut from the harmful effects of HCl, bile acids, and toxins in the food.
6. **Absorption:** GI secretions present digested food materials to the epithelium of GI tract for absorption. Many food particles are dissolved and carried in GI secretions to the absorptive surface of the GI tract for absorption into blood and lymph.
7. **Appetite regulation:** Chemicals in GI secretions stimulate appetite. For example, bile acids and HCl are appetitizers in physiological concentration. Therefore, patients with achlorohydria (gastric atrophy) and bile deficiency (liver disease) develop anorexia. However, in high concentration these chemicals may also inhibit appetite.

**SALIVARY SECRETION**
The secretion from the salivary glands is called salivary secretion. It is secreted from a heterogeneous group of salivary glands located in and around the mouth cavity. Salivary secretion is distinctive for its exclusive neural regulation.

**Scientists contributed**

*Niels Stensen (1638–1686)* was a prominent Danish scientist who laid the foundations of paleontology, geology, and crystallography. Though he is known eponymously for the discovery of the duct of the parotid gland (Stensen’s duct) and study of salivary secretion, he researched more on the anatomy of the brain, and did seminal investigation on methods in neuroscience. His scientific letter on a hydrocephalic calf represents an early pathophysiological investigation on hydrocephalus. Source: Perrini P, Lanzino G, Parenti GF. Niels Stensen (1638–1686): scientist, neuroanatomist, and saint. Neurosurgery. 2010 Jul;67(1):3-9; doi: 10.1227/01.NEU.0000379610.79429.2B.

*Thomas Wharton (1614–1673)*, a great physician from Cambridge, received fellowship of Royal College of Physicians for his extensive studies on salivary and pancreatic secretions. Wharton described the glands more accurately relying on his dissection and experiment. He was the discoverer of the duct of the sub-mandibulary gland for the conveyance of the saliva into the mouth, which bears his name (Wharton’s duct). He made a special study of the minute anatomy of the pancreas.
Salivary Glands

Types
There are major and minor salivary glands.
1. Major salivary glands are three pairs: parotid, sublingual and submandibular glands.
2. There are many minor salivary glands located in the mucosa of oral cavity, at the pharyngeal outlet, in the palates and in buccal pouches.

Based on nature of secretion: Salivary glands may be serous that exclusively release watery secretions, mucous that secrete viscous secretion mainly containing mucus and mixed that secrete moderately viscous secretions.

Parotid Glands
Parotid glands are the largest salivary glands.
1. They are entirely serous glands. Serous cells are usually arranged in the form of rounded acini.
2. The parotid secretion is rich in water and electrolytes, and lacks mucins.
3. They pour their secretion into the mouth cavity by means of parotid duct (duct of Stensen), which opens into the oral cavity at the level of second molar tooth (Fig. 38.1).

Sublingual Glands
These glands are situated below the tongue in the floor of the mouth.
1. Secretions from these glands drain directly into the mouth by means of sublingual ducts (ducts of Rivinus).
2. There are about 10 sublingual ducts. Sublingual glands are predominantly mucous glands.
3. They secrete thick viscous saliva.

Submandibular Glands
Submandibular, also called submaxillary glands are situated below the inner ramus of mandible on both sides.
1. They pour their secretion into the mouth cavity by means of submandibular ducts (ducts of Wharton).
2. These glands are mixed type (both serous and mucous).

Histology of Salivary Glands
Salivary gland consists of base units called salivon. Each salivon consists of acinus, intercalated duct and striated duct (Fig. 38.2).

Acinus
Acinus is a sac like structure containing many pyramidal cells. Myoepithelial cells are present at places surrounding the pyramidal cells.
1. Serous cells of acinus contain many endoplasmic reticulum and zymogen granules, and secrete digestive enzyme, whereas mucous cells contain mucin droplets and secrete mucin (Fig. 38.3).
2. The secretion in the acinus is called primary secretion. Electrolyte composition of primary secretion is similar to that of plasma.
Intercalated and Striated Ducts

These ducts are lined by cuboidal cells. Secretion from these duct epithelial cells modifies the ionic composition of secretion from acinus and determines the final composition of saliva. Secretion coming out of duct is called modified or final secretion.

Innervation of Salivary Glands

Salivary glands are innervated by both the divisions of autonomic nervous system. In normal situation, parasympathetic innervation is the major neural factor for salivary secretion.

Parasympathetic Innervation

The centers for parasympathetic fibers are located in medulla. 1. Preganglionic fibers for parotid gland are present in 9th cranial nerve that originate in inferior salivary nucleus and terminate in otic ganglion from where postganglionic fibers originate and innervate the gland (Fig. 38.4).
2. Fibers for submandibular and sublingual glands are present in the 7th cranial nerve that originate from superior salivary nucleus and terminate in submandibular ganglion from where postganglionic fibers come out and supply the glands (Fig. 38.5).
3. In general, parasympathetic stimulation is excitatory.

Sympathetic Innervation

Sympathetic fibers originate from upper cervical segments and terminate in superior cervical ganglion. Postganglionic fibers leave the ganglion and innervate acini, duct and blood vessels. In general, sympathetic stimulation is inhibitory.
**Salivary Blood Flow**

Salivary glands have a high rate of metabolism and a high blood flow. Blood flow and metabolism are proportionate to the rate of saliva formation.

1. The rate of salivary secretion in human is about 50 mL/min/100 g of salivary tissue.
2. Blood flow to salivary glands is about 10 times the blood flow to that of active skeletal muscles.
3. Stimulation of parasympathetic nerve to salivary gland increases blood flow by about 10 times by causing vasodilation, which occurs due to secretion of VIP, bradykinin, and acetylcholine at nerve terminals.
4. Sympathetic stimulation decreases blood flow.

**Salivary Secretion**

**Rate of Secretion**

About 1.5 liters (1,000–1,800 mL) of saliva is secreted every day. Normally, we never realize the amount of saliva secreted as it is a continuous and slow process. Salivary secretion even continues in minimum amount during sleep. However, an orexigenic stimulus, especially sight, smell or thought of food causes immediate and profuse salivation. We realize the importance of salivation when the secretion becomes less and mouth becomes dry. Salivary secretion increases in response to feeding.

**Composition of Saliva**

Saliva contains mainly water (99.5%) and some solids (0.5%). Solids are organic and inorganic.

**Organic Solids**

Organic solids are mainly enzymes such as ptyalin, lysozyme, lactoperoxidase, carbonic anhydrase, lingual lipase, RNAase, and DNAase. Other organic solids include kallikrein, blood group substances, secretory immunoglobulin (IgA), and nerve growth factor.

**Inorganic Solids**

Cations like sodium, calcium, potassium, and magnesium ions, and anions like chloride, bicarbonate, phosphate, sulfate, and bromide ions constitute the inorganic solids.

**Tonicity of Saliva**

In human beings, saliva is always hypotonic to plasma. The concentration of sodium and chloride ions in saliva is less than that of plasma. The tonicity of saliva depends on the rate at which saliva is produced. Greater the rate of secretion, higher is the tonicity. The tonicity of saliva is about 70% of that of plasma.

**The pH and K+ Content of Saliva**

The pH of saliva is alkaline (about 8).

1. The pH of the original secretion in the salivary gland is slightly acidic. But as saliva flows down the salivary ducts, it becomes alkaline because of secretion of bicarbonate from the duct epithelium.
2. The decrease in flow rate in duct increases bicarbonate concentration as time to add more bicarbonate increases, and therefore, this increases pH.
3. However, if the increase in flow is due to parasympathetic stimulation, secretion of bicarbonate from duct cells is more that increases salivary content of bicarbonate.
4. Therefore, invariably with increased flow rate, bicarbonate content becomes high.
5. The concentration of K+ in saliva is always greater than that in plasma, but with increase in flow rate, K+ concentration decreases.

**Functions of Saliva**

Saliva performs many important digestive and non-digestive functions.

1. Saliva contains ptyalin. This is an enzyme called salivary amylase, which causes splitting of starch. Salivary amylase reduces starch to oligosaccharide molecules. However, digestion of starch is not impaired in the absence of salivary amylase (if pancreas is intact). Action of salivary amylase is maximum at pH 6.8. But, digestion by ptyalin takes place in the stomach, as food remains for a short duration in mouth. In the stomach, digestion occurs at the center of food bolus which is still alkaline, until the food is thoroughly mixed with the acidic gastric secretion of the stomach.
2. Saliva has many protective functions. Saliva keeps the mouth clean and therefore prevents oral infection. Saliva contains lysozyme, which is anti-bacterial. IgA in saliva provides local immunity and lactoferrin in saliva is bacteriostatic.
3. Saliva keeps the mouth cavity and tongue moist, which facilitates speech. The importance of this function of saliva is realized when mouth becomes dry due to decreased salivary secretion that impairs speech. Dryness of mouth is usually felt before appearing for an interview, especially for learners.
4. Saliva increases the taste of food. Taste is perceived by the taste buds present in the tongue. For taste of food to be well appreciated, food particles should better be present in solution. Saliva dissolves the food and makes the solution of food.
5. Saliva helps in mastication and swallowing. This is due to lubricant property of saliva. The mucin in saliva lubricates food. In the absence of saliva, deglutition becomes impossible, especially for dry foods.
6. Saliva contains bicarbonate which buffers gastric acid to some extent in the stomach, and therefore reduces heart burn.
7. Proline rich protein in saliva prevents enamel of the teeth and thus provides them strength. Proline also binds with tannin & reduces its toxicity.
8. Saliva prevents injury to buccal mucosa by diluting the hot and irritant food materials.
9. In animals, salivation (panting) is an important process of dissipation of heat and therefore, has contribution in temperature regulation.

10. Saliva excretes certain heavy metals, thiocyanate and morphine from the body.

**Mechanism of Secretion**

Salivary secretion occurs in two stages: secretion in the acinus and secretion in the duct.

**Secretion in Acinus of Gland**

In the gland acini, the secretion is called primary secretion in which amylase concentration is more.

1. The enzyme is produced and stored in the zymogen granules.
2. On stimulation, granules are exocytosed and the enzyme is released.
3. The electrolytes secreted from the epithelial cells of the end pieces are Na\(^+\), K\(^+\), HCO\(_3\)\(^-\), and Cl\(^-\).
4. The fluid of primary secretion is almost isotonic to that of plasma.

**Secretion in Ducts**

The composition of secretion in the ducts when the fluid passes through the intercalated and striated ducts, is modified. This is called modified or final secretion.

1. This is because Na\(^+\) and Cl\(^-\) are extracted from the fluid and K\(^+\) and HCO\(_3\)\(^-\) are added to the fluid.
2. The ducts do not change the volume of saliva but only modify the composition of the primary secretion (Fig. 38.6).

**Stimuli for Salivary Secretion**

Saliva is continuously secreted. However, a large number of stimuli increase the secretion. The important stimuli are anticipation, thought, sight and smell of food, discussion on food, and presence of food in the mouth cavity. Chewing is also an important stimulus for salivary secretion.

**Control of Salivary Secretion**

Salivary secretion is controlled exclusively by the neural mechanisms. Both sympathetic and parasympathetic stimuli influence salivary secretion.

**Neural Control**

**Parasympathetic Stimulation**

Parasympathetic stimulation occurs by sight, smell, and taste of food.

1. Chewing of food is a potent stimulus for salivary secretion. These factors act through salivary nucleus in the medulla (Flowchart 38.1).

Flowchart 38.1: Mechanism of increased salivary secretion by parasympathetic stimulation.

(CN: Cranial nerve).
2. Parasympathetic activation increases salivary secretion rich in enzymes, and mucin.
3. It increases secretion by causing vasodilation (via bradykinin, VIP, and acetylcholine), and stimulation of glandular tissue.

**Sympathetic Stimulation**
Stimulation of sympathetic fibers (sympathetic fibers to salivary gland originate from superior cervical ganglion) temporarily increases secretion but finally decreases it.
1. The *transient increase* is due to contraction of myoepithelial cells of the glandular tissue.
2. However, sympathetic stimulation causes vasoconstriction that decreases salivation and makes the secretion thick.

**Reflex Secretion**
Saliva is secreted reflexly by contact of food with the mouth cavity. This reflex secretion is *unconditioned* as this is present since birth (does not need learning). However, salivary secretion due to smell or thought of food is a *condition reflex* as these are learnt by social and environmental factors. Conditioned salivary secretion was described by Pavlov.

Salivary secretion exclusively occurs in the **cephalic phase** (sight, smell and thought of food, presence of food in mouth, chewing food, etc.). Secretion is almost nil in gastric and intestinal phase of digestion of food. Hormonal regulation of saliva is negligible.

**CHAPTER SUMMARY**

**Key Concepts**
1. Though salivary secretion does not help much in digestion, it is very essential for chewing, deglutition, speech and oral and dental hygiene.
2. Parasympathetic stimulates and sympathetic inhibits salivary secretion.
3. Xerostomia (dryness of mouth) is a common in acute stressful situation that happens due to sympathetic stimulation.

**Important to Know (Must Read)**
1. In examinations, “Composition, mechanism and regulation of salivary secretion” may sometimes come as a Long Question.
2. Phases of GI secretions, Salivary secretion, Composition and function of salivary secretion, Mechanism of salivary secretion, Regulation of salivary secretion.
3. In Viva, examiner may ask… What are the Phases of GI secretions and how are they generally controlled, Amount of salivary secretion/day, Name of salivary glands, Histologic types of salivary glands, Innervation of salivary glands by parasympathetic and sympathetic fibers, Composition and function of salivary secretion, Function of each constituent of saliva, Mechanism of salivary secretion, What are the differences between primary and secondary salivary secretion, Regulation of salivary secretion, What are the effects of parasympathetic and sympathetic stimulation, What is Xerostomia, silaorrhea and sialolithiasis.
4. Composition and functions of saliva are usually asked in oral examination. A student is expected to answer this; otherwise it may be difficult for him to pass.

**Applied Physiology**

**Xerostomia**
This is a condition in which there is consistent decreased secretion of saliva. This causes dryness of mouth, and predisposes to oral infections. Xerostomia (dryness of mouth) is a common in acute stressful situation that happens due to sympathetic stimulation.

**Sialorrhea**
In this condition, salivary secretion is increased persistently.

**Sialolithiasis**
This is the condition in which stone is formed in the ducts of salivary gland.

**Infections**
Viral infection of parotid gland is seen commonly in children (mumps).
Stomach is an important part of GI system. Though the major function of stomach is the storage of food, it regulates controlled emptying of food into the duodenum and prepares the chyme for digestion and absorption in the small intestine. Chyme results from grinding of food into smaller particles and mixing of food with gastric secretion.

FUNCTIONS AND FUNCTIONAL ANATOMY OF STOMACH

**Functions of Stomach**

1. **Temporary storage of food:** The primary function of stomach is the temporary storage of food. It serves as a **reservoir for food** so that ingestion of a large meal at a time becomes possible.
2. **Grinding and mixing of food:** Stomach causes grinding and mixing of food. It churns the food and breaks larger food particles (macromolecules) into smaller molecules. It also mixes food with gastric juice. The content of stomach after proper mixing with gastric juice is called **chyme.**
3. **Controlled emptying of food:** Stomach performs its **own controlled emptying (gastric emptying).** It allows food to enter into duodenum and jejunum at a lesser but controlled rate so that load on the upper part of the small intestine is not more than the amount that it can handle. This allows intestine to digest and absorb nutrients slowly, steadily and adequately.
4. **Secretion of hydrochloric acid:** Stomach secretes hydrochloric acid (HCl), which is essential for digestion of food. Though the exact nature of digestion by HCl is not clearly known, hypochlorohydria decreases the process of digestion and impairs appetite.
5. **HCl in the stomach converts ferric form of iron into ferrous form.** Iron is absorbed from gut only in the ferrous form. Therefore, **HCl deficiency in the stomach results in iron deficiency anemia.**
6. **Kills the microorganism:** Gastric HCl kills the bacteria and other ingested microorganisms. Therefore, entry of microbes into body through GI system is prevented in the stomach.
7. **Activates pepsinogen to pepsin:** HCl activates pepsinogen to pepsin, an **endopeptidase.** Pepsin cleaves protein molecules to form smaller peptides. The optimal pH
for endopeptidase activity is 1.8 to 3.5. Thus, HCl not only activates pepsin, but also provides acidic environment for action of pepsin.

8. **Secretes intrinsic factor:** Stomach secretes intrinsic factor (IF) which is essential for reabsorption of vitamin B\(_{12}\) (the extrinsic factor) in the terminal ileum. Vitamin B\(_{12}\) binds with intrinsic factor to form IF-B\(_{12}\) complex, which is taken up by cubilin, a lipoprotein present in the terminal part of ileum and then absorbed by endocytosis. Therefore, gastrectomy or chronic gastric atrophy results in megaloblastic anemia (Clinical Box 39.1).

9. Stomach helps in absorption of water and lipid soluble substances, such as alcohol and few drugs.

**Clinical Box 39.1**

**Dimorphic anemia:** When red cell morphologies in an anemia have both microcytic and macrocytic features, the type of anemia is called dimorphic anemia. Anemia following gastrectomy or chronic gastric atrophy results in such type of anemia, as HCl deficiency causes microcytic hypochromic anemia due to iron deficiency and intrinsic factor deficiency causes megaloblastic anemia due to B\(_{12}\) deficiency.

**Functional Anatomy**

Anatomically, stomach is divided into three major parts: fundus, body and antrum (Fig. 39.1). Esophagus opens into stomach through gastro-esophageal junction that contains lower esophageal sphincter (LES). The initial portion of the stomach close to gastroesophageal junction is called cardia. The proximal part of stomach is called fundus, the middle and major part of stomach is the body or corpus, and the distal portion of the stomach is the antrum. Antrum opens into the duodenum through pylorus which contains pyloric sphincter:

1. The capacity of the stomach depends on age, gender and eating habit. On average, it is about 1.5 liter in adults, though it varies from 1 to 4 liters.
2. The mucous membrane of stomach is thick and thrown into large folds, called gastric rugae. These rugae are more prominent in empty stomach (Fig. 39.2).
3. The mucosal epithelium is formed by simple columnar epithelial cells that secrete mucous and alkaline fluid. These mucous and alkaline fluids protect gastric epithelium from acidic content and mechanical injury.
4. The gastric glands are situated deep in the mucosal infoldings that open into the pits.

**Gastric Glands**

The mucosal lining of the stomach is a glandular mucosa that contains surface mucous cells in the gastric pit and glands deep in the mucosal infoldings. There are three types of gastric glands:

1. **The cardiac glands:** Located below the lower esophageal sphincter and contain mainly mucous secreting cells. They secrete mucous and bicarbonate ions.
2. **The oxyntic glands:** Located in the fundus and body of the stomach and contain mainly the oxyntic cells.
3. **Pyloric glands:** Present in the pyloric-antral region and consist mainly of mucous neck cells that secrete mucous and G cells that secrete gastrin.

**Oxyntic Gland**

The acid secreting oxyntic gland is typically a tubular and straight gland (Fig. 39.4). It consists of neck, body and base. The cells in the neck are mainly mucous secreting cell. The oxyntic cells are present mainly in the body of the gland. Chief or peptic cells are present at the base.
Different cell types in the oxyntic glands are:

1. **Mucous cells**: They are present in the neck region of the gland. The mucous and bicarbonate ions secreted by them protect the stomach epithelium from acidic gastric secretion.

2. **Oxyntic or Parietal cells**: Oxyntic cells are present mainly in the body part of the gland. They secrete hydrochloric acid and intrinsic factor.

3. **Chief or Peptic cells**: Chief cells are present towards the base of the gland. They secrete pepsinogen.

4. **Endocrine cells**: The endocrine cells are also called enterochromaffin cells. The major endocrine cells in oxyntic glands are enterochromaffin-like cells (ECL) or mast-like cells that secrete histamine. There are also other endocrine cells that secrete somatostatin, VIP, glucagon, and enkephalin. **G cells** are present in antral region that secrete gastrin. Antrum also contains **D cells** that secrete somatostatin.

**Structure of Oxyntic Cells**

Oxyntic cells or parietal cells are present in the body and neck of the oxyntic glands. They secrete hydrochloric acid and intrinsic factor:

1. They have extensive **tubulovesicular system** and open **canalicular system**.

2. The apex of the parietal cells faces towards the lumen of the gastric glands. The canaliculi extend from apical surface into the cell. The tubules and vesicles open into the canaliculi.

3. **In resting cells**, tubules and vesicles are present abundantly (Fig. 39.5) and microvilli are rudimentary. The membrane of these tubulovesicular structures contains $H^+\cdot K^+\text{ATPase}$.

4. **On activation**, the tubulovesicular membranes fuse with the cell membrane and microvilli that project into the canaliculi (Fig. 39.6), so that the **area of cell membrane in contact with gastric lumen is greatly increased**.

5. Fusion of tubules and vesicle with microvillar or canalicular membrane ensures **increased $H^+\cdot K^+\text{ATPase}$ activity of the membrane** in the active state.

**Nerve Supply of Stomach**

Stomach is supplied by both divisions of ANS:

1. **Parasympathetic innervation** is by vagus nerve.

2. **Vagal stimulation facilitates** and sympathetic stimulation inhibits gastric secretion and motility.

**Gastric Juice**

**Composition of Gastric Juice**

The amount of gastric secretion per day varies from 1 to 2.5 liters. The gastric juice is **highly acidic**, having pH 0.7–4. It has following constituents:
1. Water (99.5%)
2. Solids (0.5%)
   Solids contain inorganic and organic substances.
   **Inorganic constituents:** Anions are Cl\(^-\), PO\(_4\)\(^3-\), SO\(_4\)\(^2-\), and HCO\(_3\)\(^-\); and cations are H\(^+\), Na\(^+\), K\(^+\), Ca\(^{2+}\), and Mg\(^{2+}\).
   **Organic constituents:** Pepsinogen, intrinsic factor, mucin, rennin, gastric lipase, gelatinase, carbonic anhydrase, and lysozyme.

**Functions of Constituents**

Normal concentration of HCl is 40–60 mEq/L. The maximum concentration can increase up to 150 mEq/L:

1. **Pepsinogen** is secreted from the peptic cells. There are two types of pepsinogens:
   - **Type-I pepsinogen** is found in chief cells in fundus and body.
   - **Type-II pepsinogen** is found in the chief cells throughout the stomach.

2. Pepsinogen is converted into pepsin by HCl. Pepsin is a proteolytic enzyme that breaks down protein molecules into peptones. Pepsin acts best at pH of 2–4.

3. The **mucin** secreted by mucous cells is of two types: the insoluble mucin, and the soluble mucin. Mucin forms a protective layer on the gastric epithelium. It retains bicarbonate and has alkaline pH. Thus, it protects the stomach from acid peptic digestion, as it buffers HCl.

4. **Intrinsic factor helps in vitamin B\(_{12}\) absorption** from terminal ileum.

**GASTRIC SECRETION**

**Mechanism of HCl Secretion**

HCl is secreted from **parietal cells** that are located in the fundus and body of the stomach. H\(^+\) secretion is possible in stomach due to the presence of numerous **H\(^+\)-K\(^+\) ATPases** in apical membrane of the parietal cells:

1. H\(^+\)-K\(^+\) pump actively pumps H\(^+\) (against its concentration gradient) out of the cell into the gastric lumen. In exchange for H\(^+\), the K\(^+\) enters the cell (Fig. 39.7). As this is an active transport, energy is provided for the process by hydrolysis of ATP.

2. In the cytosol of parietal cell, H\(^+\) is derived from the breakdown of carbonic acid (H\(_2\)CO\(_3\)). H\(_2\)CO\(_3\) is formed by combination of CO\(_2\) and H\(_2\)O in a reaction catalyzed by **carbonic anhydrase**. This step can be blocked by acetazolamide, the carbonic anhydrase inhibitor.

3. CO\(_2\) utilized for formation of H\(_2\)CO\(_3\) is derived from intracellular metabolisms and plasma.

4. HCO\(_3\)\(^-\) formed by break down of H\(_2\)CO\(_3\) is exchanged for Cl\(^-\) on the basolateral membrane of the cell by **HCO\(_3\)\(^-\)-Cl\(^-\) exchanger**.

5. The Cl\(^-\) that enters parietal cell is transported into the gastric lumen.

6. In the lumen, Cl\(^-\) combines with H\(^+\) to form HCl.

7. The **HCO\(_3\)\(^-\) enters blood stream** from the interstitial fluid.

   Thus, for each H\(^+\) secreted into the gastric lumen, one HCO\(_3\)\(^-\) is reabsorbed into the plasma. Therefore, with **increase in the rate of HCl secretion**, HCO\(_3\)\(^-\) level increases in the blood. Consequently, following a meal that stimulates gastric acid secretion, pH of blood increases. As blood becomes alkaline, the urine becomes alkaline. This is called **post-prandial alkaline tide**.

K\(^+\) that enters the oxyntic cell by H\(^+\)-K\(^+\) ATPase is transported back into the gastric lumen, which is **reutilized** for further H\(^+\) secretion (recycling of K\(^+\)). K\(^+\) entering the
Secretion of Other Constituents

Pepsinogen Secretion

Pepsinogen is secreted from chief cells. It is synthesized in the cell like other proteins and stored in the zymogen granules:

1. There are two types of pepsinogens: **type-I pepsinogen**, found in chief cells in fundus and body and **type-II pepsinogen** found in the chief cells throughout the stomach.
2. Pepsinogen is converted into pepsin by HCl.
3. Pepsin is a strong proteolytic enzyme.
4. Pepsinogen secretion is stimulated by gastrin and histamine.

Mucus Secretion

Mucus is secreted by mucus secreting cells that are plentiful available in the neck region of gastric glands:

1. The **mucin** secreted by mucous cells is of two types: the **insoluble mucin**, which is secreted by mucus secreting cells of entire gastric mucosa and the **soluble mucin**, secreted from mainly cardiac and pyloric mucosal cells.
2. Mucin forms a protective layer on the gastric epithelium. It retains bicarbonate and has alkaline pH. Thus, it protects the stomach from acid peptic digestion, as it buffers HCl.
3. Mucus secretion is stimulated by increased blood flow to the stomach.

Intrinsic Factor Secretion

Intrinsic factor (IF) is secreted from parietal cells along with HCl. It is a glycoprotein:

1. It is synthesized like other glycoproteins and its secretion is stimulated by factors that stimulate HCl secretion like histamine and gastrin.
2. IF helps in vitamin B₁₂ absorption from terminal ileum.

Factors that Influence HCl Secretion

Factors that Stimulate Gastric Acid Secretion

Factors that increase HCl secretion from the parietal cells of stomach mainly act through locally altering the concentration of three hormones: acetylcholine, gastrin and histamine. In the parietal cells, there are specific receptors for these hormones and other hormones. Hormones bind with the receptors and change the intracellular second messenger concentration that finally stimulate HCl secretion (Fig. 39.9).

Acetylcholine

Acetylcholine is an effective stimulator of gastric acid secretion. It is released at the nerve endings of **vagal cholinergic fibers** that innervate parietal cells:

1. Acetylcholine acts on the **M₃ cholinergic receptors** on the parietal cells and increases intracellular Ca²⁺.
2. It acts directly on the parietal cell to increase HCl secretion and acts indirectly by secreting histamine and gastrin from ECL cells and G cells respectively that in turn stimulate parietal cells.

Gastrin

Gastrin is the **most potent stimulus for HCl secretion**:

1. Gastrin acts on **gastrin receptors** on the parietal cells and increases HCl secretion by **increasing intracellular Ca²⁺** (Fig. 39.8).
2. Gastrin is secreted from G cells that are present in the antral mucosa of the stomach.
3. Vagal fibers innervate G cells and vagal stimulation increases gastrin release. However, vagal fibers that mediate gastrin release are **non-cholinergic** (Fig. 39.9) as the neurotransmitter is GRP (**gastrin releasing peptide**).
4. Gastrin also stimulates histamine release from ECL cells that in turn increases secretion of HCl from parietal cells. Gastrin secretion from stomach is increased by gastric distension, noncholinergic vagal stimulation, protein rich food, and catecholamines. **Pentagastrin** is used for assessing gastric acid output (Application Box 39.1).
Application Box 39.1

Pentagastrin test; and Gastrectomy: As gastrin is the most potent stimulator of HCl secretion, exogenously administered synthetic gastrin (pentagastrin) assesses the degree of acid output from parietal cell mass of the stomach. This forms the physiological basis of pentagastrin test. As G cells are present in antral part of stomach and gastrin is the strong stimulus for parietal cells, antrectomy (partial antral gastrectomy) is performed for surgical treatment for protracted peptic ulcer. It is useful in patients with protracted peptic ulcer.

Histamine

Histamine is a powerful stimulator of HCl secretion from stomach:
1. It acts on H2 receptors on the parietal cells and increases intracellular cyclic AMP as second messenger. Cyclic AMP stimulates protein kinase, which increases the activity of H+–K+ ATPase and HCl secretion.
2. Histamine is secreted from enterochromaffin-like (ECL) cells.
3. Histamine release is stimulated by both acetylcholine and gastrin.
4. Thus, histamine is considered as a major mediator of HCl secretion. Therefore, patients with peptic ulcer are usually first treated with histamine type-2 receptor antagonists.

Mechanical and Chemical Factors

Accumulation of food in the stomach increases acid secretion. This mainly occurs due to mechanical distension that stretches G cells and stimulates gastrin release. Also, products of protein digestion (peptides and amino acids) increase gastrin secretion, and hot and spicy foods facilitate HCl secretion from the stomach (Table 39.1).

Factors that Inhibit Gastric Acid Secretion

Increased acid output, somatostatin and acidic content of duodenum decrease gastric acid secretion.

pH of Gastric Luminal Content

Decreased pH of gastric content is an important and natural inhibitor of HCl secretion:
1. When secretion of acid is high enough to decrease pH of gastric content to below 2, secretion of HCl is inhibited by negative feedback mechanism. Hence, this is called as autoregulation of acid secretion.
2. The highly acidic gastric pH does not inhibit parietal cell directly; rather inhibition of acid secretion is mediated by gastrin and somatostatin.
3. The highly acidic chyme directly inhibits gastrin secretion from G cells, and stimulates somatostatin secretion from D cells of stomach.
4. Somatostatin inhibits secretion of gastrin from G cells that decreases acid secretion.

Somatostatin

Somatostatin is secreted from the D cells of the gastric mucosa:
1. Decreased pH of gastric content (pH less than 2) increases the secretion of somatostatin, which inhibits gastrin release.
2. As gastrin is the most potent stimulator of acid secretion, decreased gastrin release decreases HCl secretion from the stomach.
**Chyme in the Duodenum**

When acidic chyme enters duodenum, **secretin** is secreted from upper intestinal mucosa:

1. **Secretin inhibits gastric secretion** and motility, and gastrin release from G cells.
2. Products of carbohydrate and lipid digestion in the duodenum, and hyperosmolality of duodenal content inhibit acid secretion by increasing the release of an **enterogastrone** called GIP (**gastric inhibitory peptide**).
3. There are other enterogastrones also that inhibit gastric secretion.

**Regulation of Gastric Secretion**

Gastric secretion is regulated by neural and humoral mechanisms. The mechanism of regulation depends on the phase of gastric acid secretion. The **neural mechanisms** are autonomic influences, short and long GI reflexes, and central influences mediated by vagus nerve. The **hormonal mechanisms** regulating gastric secretion are discussed above.

Gastric secretion occurs in **three phases** (cephalic, gastric and intestinal) and the mechanisms regulating secretion are different for each phase of secretion.

**Cephalic Phase**

The cephalic phase of gastric secretion is elicited by smell, sight, thought, taste and chewing of food. This is called cephalic phase as impulses to increase acid secretion originate mainly in the brain:

1. The sensory stimuli activate dorsal motor nucleus of vagus in the medulla. Therefore, cephalic phase of gastric secretion is **entirely mediated by vagus nerve** and the fibers are both **cholinergic and noncholinergic** (see Fig. 39.9).
2. The vagal fibers that directly contact parietal cells are cholinergic and fibers that contact G cells are **noncholinergic** (**neurotransmitter is GRP**).
3. As noncholinergic effects are stronger than cholinergic effects, **atropine can not effectively prevent vagally mediated acid secretion**. Therefore, atropine is not prescribed in the management of peptic ulcer.

The gastric juice secreted in the cephalic phase occurs before food reaches the stomach. Therefore, this is also called **pregastric phase**. This phase accounts for 40–50% of total gastric secretion (Application Box 39.2).

**Experimental Design to Study Cephalic Phase**

The usual experimental design to assess the integrity of the cephalic phase is the **sham feeding**. In this procedure, a dog is taken as the experimental animal:

1. A fistula is made in the esophagus of the dog; so that when animal eats the food comes out of the neck **through the fistula** (food is not allowed to reach stomach). Simultaneously, the gastric juice is collected from the stomach by placing a cannula into it (Fig. 39.10). Gastric juice obtained during the cephalic phase is analyzed for volume and composition.
2. Then, **bilateral vagotomy** is performed and the gastric juice is collected following vagotomy for analysis.
3. **Vagotomy abolishes gastric secretion during cephalic phase**, which proves that this phase is primarily vagally mediated.

**Application Box 39.2**

**Appetite juice**: The gastric juice secreted during cephalic phase stimulates the appetite, and therefore, this is called **appetite juice**, as it occurs in anticipation of food. Usually in parties and special dinners, enough time is spent initially in taking soup and appetizers before actual dinner is served. This is meant to stimulate appetite for food and to collect enough gastric juice in stomach before food enters the stomach, so that digestion becomes easier.

**Gastric Phase**

The gastric phase of gastric secretion starts when food enters the stomach:

1. The primary stimulus for secretion in this phase is the **distension of the stomach**.
2. Also, products of digestion like peptides and amino acids produced by pepsin action that breaks proteins stimulate gastric secretion.
3. The distension of the stomach elicits acid secretion by both local as well as central reflexes (Fig. 39.11). The **central reflex** is mediated by vagus nerve (**vagovagal reflex**), and is both cholinergic and noncholinergic. The **local reflex** releases acetylcholine that directly stimulates parietal cell. Distension of stomach per se also increases gastrin release from the antral G cells that in turn increases HCl secretion.
4. Amino acid and peptides stimulate G cells to release gastrin.
5. Therefore, mechanisms of acid secretion in the gastric phase are **mechanical, neural, and chemical**.
6. Gastric phase accounts for 50–60% of gastric secretion.
HCl secretion in this phase is decreased by the acidic pH of the chyme bathing in the gastric mucosa. When pH of gastric content becomes less than 2, HCl secretion is effectively reduced. This is called autoregulation of gastric acid secretion (discussed above). HCl inhibits both G cells and parietal cells.

**Experimental Designs to Study Gastric Phase**

Gastric phase of gastric secretion is studied by making five different types of pouches: Pavlov pouch, Heidenhain pouch, Bickel pouch, Farrell pouch and Ivy pouch. However, the pouch experiment to study gastric secretion is not performed nowadays. This is mainly of academic and historical importance.

1. **Pavlov pouch** is a small pouch separated from the main body of the stomach by a double layer of mucous membrane. This gastric pouch of mucous membrane has intact nerve and blood supply. Therefore, it helps to study both neural and chemical factors of gastric acid secretion.

2. **Heidenhain pouch** is a denervated pouch, which helps to study the influence of neural factors on gastric secretion.

**Scientist contributed**

Rudolf Peter Heinrich Heidenhain (1834–1897) pioneered in the study of salivary and gastric secretions. He developed experimental designs to study secretion of salivary and gastric juices. The pouch made in experimental animals to study gastric secretion is named as Heidenhain’s pouch. He also studied the functions of secretory and trophic nerves of glands and promoted the intracellular theory of secretory phenomena.

**Intestinal Phase**

When chyme enters the intestine, intestinal phase of gastric secretion starts. This is also called postgastric phase. Initial part of intestinal phase is stimulatory to gastric secretion, but later part is inhibitory.

**Stimulation of Secretion**

1. Distension of duodenum increases gastric acid secretion by activating vagovagal reflex.

2. The chemical composition of chyme, especially the products of protein digestion like amino acids and peptide stimulate G and other endocrine cells in the duodenum and upper jejunum to secrete entero-oxynin, which in turn stimulates gastric acid secretion (Fig. 39.12).

**Inhibition of Secretion**

1. Acidic chyme in the duodenum (decreased pH of duodenal content) inhibits gastric secretion via enterogastric reflex.

2. Acid also stimulates release of secretin, which inhibits gastrin secretion from G cells. Secretin also decreases the response of parietal cells to gastrin and histamine.

3. Acid in the duodenum and hyperosmolality of duodenal content also secrete a hormone called bulbogastrone that inhibits acid secretion from parietal cells of the stomach.

4. Products of fat digestion especially fatty acids and triglycerides stimulate secretion of GIP and CCK from upper part of small intestine. These hormones inhibit secretion of acid from parietal cells.

Thus, the net effect of intestinal phase is the inhibition of gastric secretion. Hence, intestinal phase accounts for about 10% of gastric secretion.

The differences between cephalic, gastric and intestinal phase of gastric secretion are summarized in Table 39.2.
GASTRIC FUNCTION TESTS

To diagnose various diseases of stomach, the laboratory tests measuring gastric secretion, serum gastrin, etc carry much importance. Therefore, gastric function tests (GFTs) are performed to diagnose various gastric and duodenal anomalies and to monitor the effectiveness of the therapy. It includes:

1. Examination of gastric contents
2. Test for gastric acid secretion
3. Tests for pepsin, mucous, intrinsic factor
4. Tests for gastrin
5. Visualization of the interior of stomach
6. Tests for gastric motility and electrical activities (gastrography)
7. Obtaining biopsy from the suspected tissue.

Classification

Gastric content is examined for the normal and abnormal constituents. The following parameters are looked for in the gastric content sample: Volume of acid (acid output), pH, colour, acidity (total and free), and presence of blood, mucous and food particles.

Examination of gastric contents can be divided into three types according to the time of examination:

1. At rest: Gastric juice is collected after the patient awakes in the morning, but still lying on the bed.
2. After a meal in the post absorptive phase: A specific diet is provided, which has a fixed composition (also known as fractional test meal analysis) followed by that gastric content is collected for analysis.
3. After a specific stimulus: A specific stimulus for induction of acid secretion is applied following which the gastric content is withdrawn. Mainly the maximum amount of acid output is checked in these type of tests.

Measurement of Acid Output

Two types of acid outputs are assessed: basal acid output (BAO), and maximal acid output (MAO). Acid output is measured to assess the size of parietal cell mass or the ability of parietal cells to secrete HCl.

BAO

Usually, it is measured in the interdigestive phase (between two meals, when stomach is supposed to be at rest). The gastric juice is collected for about 60 minutes through a Ryle’s tube introduced into patient’s empty stomach following an overnight fast and complete sleep.

Normal value: Usually, it is 10–40 mEq/L or 0.5–2 mEq/hour.

Significance: Increased BAO indicates high gastrin activity as occurs in Zollinger-Ellison syndrome. A pH more than 2.5 for the acid, rules out this syndrome.

MAO

This is the maximum quantity of acid that can be secreted by the stomach. Usually, estimation of MAO is performed by a stimulation test in which a stimulant is injected to increase acid secretion. The chemical is injected and gastric juice is collected by Ryle’s tube. Usual tests performed are given below.

Normal value: The MAO is usually 12–60 mEq/hour.

Special Test to Detect Acid Output

Histamine Test

Historically, histamine was the first standard stimulant used for gastric acid secretion test. 0.01 mg/kg bodyweight of histamine phosphate is injected subcutaneously with simultaneous administration of antihistaminic agent to prevent the untoward side effects. Then the acid output is measured, every 10 minutes for 1 hour. Upto 10 ml of gastric content is aspirated and analyzed. It is helpful in the diagnosis of pernicious anemia, subacute combined degeneration of spinal cord and assessing the maximum acid output following duodenal surgery.

Histalog (Betazole) Test

Histalog, is a better replacement for histamine as it does not require the simultaneous administration of antihistaminic agent due to its fewer side effects. 1-15 mg/kg of
Radioimmunoassay (RIA) is the diagnosis of gastric malignancy (Achlorhydria in the presence of normal or slightly below normal. Higher values are found in:

- Duodenal ulcer
- Zollinger-Ellison syndrome (gastrinoma)
- Anastomotic ulcer
  Higher values are found:
  - Pernicious anemia (atrophic gastritis)
  - Gastric malignancy (Achlorhydria in the presence of gastric ulcer is highly suggestive of gastric malignancy)

Tests for other Gastric Secretory Products

Test for Pepsin

Pepsin inhibitors are used for analysis of pepsin derived from pepsinogen for research purposes. The level of pepsin is low in atrophic gastritis.

Test for Mucous

Protein content of gastric mucous is measured, normal value being 1.8 mg/ml. The level is increased in chronic hypertrophic gastritis (Menetrier disease).

Test for Intrinsic factor

Intrinsic factor (IF) is essential for vitamin B₁₂ absorption from the small intestine. In its absence, the absorption of vitamin B₁₂ is impaired as occurs in chronic atrophic gastritis and gastric atrophy. Schilling test is used for evaluation of patients with suspected pernicious anemia but can also be used as diagnostic test for pancreatic efficiency resulting in impaired absorption of vitamin B₁₂ since gastric R binder protein is not cleared from intrinsic factor due to reduced pancreatic proteolytic activity.

Test for Gastrin

Gastrin is secreted by G cells present in the antralpyloric and proximal duodenal mucosa. The circulating gastrin level is normally 0-200 pg/mL. It can be tested by following methods:

1. Serum gastrin level: Radioimmunoassay (RIA) is the commonly used method for gastrin measurement. Normal fasting level of gastrin is 20-150 pg/mL. Its levels are higher in:
   - Atrophic gastritis (with low gastric acid secretion)
   - Zollinger-Ellison syndrome or gastrinoma (with high gastric acid secretion)
   - Following surgery of the stomach
2. Gastrin provocative tests: These tests are used to differentiate between hypergastrinaemia and gastric acid hypersecretion as follows:
   - Secretin test: an intravenous injection of secretin (1 U/kg body weight) is given. If the serum level rises by more than 50% of basal value in 5-15 minutes, it is diagnostic of Zollinger-Ellison syndrome (gastrinoma).
     - This rise does not occur in other conditions.
   - Calcium infusion test: Intravenous infusion of calcium (5 mg/kg per hour) is given for 3 hours. Rise in serum gastrin levels by more than 50% of basal value is diagnostic of Zollinger-Ellison syndrome (gastrinoma).

Other Tests

Barium-Meal X-Ray

A barium-mixed food is swallowed by the subject following which X-rays of upper GI tract are obtained. This gives
the details of the contour of the lower esophagus, stomach and upper small intestine. The **location and size of the ulcer and tumor** can be delineated.

**Endoscopy (Gastroscopy)**

A fiber-optic gastroscope is introduced into the stomach to study the details of the ulcer or other pathologies. The advantages are:

1. It gives an opportunity to visualize the lumen of the stomach, so that the ulcer details can be seen.
2. A **biopsy of the ulcer** can be taken to study the type of ulcer (to exclude malignancy).
3. The tissue is also cultured to study the organism (to confirm *H. pylori* infection).
4. The gastroscope can be introduced into the duodenum and biliary tract to study further details.
5. **Urease test** is performed from the biopsy sample for *H. pylori* confirmation.

The major tests for analysis of gastric secretory functions are summarized in Table 39.3.

### Applied Aspects

The common diseases related to gastric secretion are gastritis and peptic ulcer.

**Gastritis**

The term gastritis is commonly employed for any clinical condition with upper abdominal discomfort like indigestion or dyspepsia in which the specific clinical signs and radiological abnormalities are absent. The condition is of great importance due to its relationship with peptic ulcer and gastric cancer. Broadly, gastritis is of 2 types: acute and chronic. Chronic gastritis can further be of various types.

A simple classification of various types of gastritis is presented in Table 39.4.

### Etiopathogenesis

A variety of etiologic agents have been implicated in the cause of acute gastritis. These are as follows:

1. **Diet and personal habits**
2. **Infections**
3. **Drugs**
4. **Chemical and physical agents**
5. **Severe stress**

Chronic gastritis, if untreated leads to peptic ulcer.

**Peptic Ulcers**

Peptic ulcer means ulcer in the stomach (**gastric ulcer**) or duodenum (**duodenal ulcer**). Acid of the gastric juice or pepsin in the gastric secretion produces damage to the gastroduodenal mucosa in abnormal conditions. Therefore, peptic ulcer is called **acid-peptic disease**.

### Pathophysiology

Peptic ulcer is caused either by decreased mucosal defense, or by hypersecretion of acid or infection.

**A. Diminished Effectiveness of Mucosal Barrier**

The defense barrier of the stomach is the mucous coat on the gastric epithelium. This is called **mucosal defense barrier**:

1. The mucus is secreted by mucous cells. Mucus is a viscous gel that contains mucin, phospholipid, electrolytes (mainly HCO₃⁻) and water.
2. The **mucous gel layer** is about 0.2 mm thick and effectively separates the bicarbonate rich secretion of epithelial cells from the acidic content of the stomach (Fig. 39.13).
3. This allows the **pH of the epithelial cells to remain alkaline** despite acidic pH of gastric content. It protects mucosal epithelium from injury caused by acidic chyme.
4. However, when secretion of mucus is impaired, or bicarbonate production is decreased or when the mucosal coat is mechanically damaged, acid and pepsin cause ulcer formation.
5. Therefore, antibiotic therapy to kill *H. pylori* is frequently successful in the treatment of peptic ulcer.

**B. Hypersecretion of Acid**

Gastric acid secretion increases in chronic anxiety. Peptic ulcer is common in business executives as most of them lead a life either in hurry or in worry. Intake of *more spicy food* is known to increase acid secretion. Therefore, it is generally believed that *hurry, worry, and curry* are the causes of peptic ulcer. Chronically increased secretion of acid (hyperchlorhydria) produces peptic ulcer by damaging the mucosal barrier.

Conditions that cause hyperchlorhydria are:

- Zollinger-Ellison syndrome
- Gastric outlet obstruction syndrome (as occurs in pyloric stenosis)
- Systemic mastocytosis (histamine secreted from mast cell increases HCl secretion)

**Zollinger-Ellison syndrome** is a non-α non-β *gastrin secreting tumor of pancreas*.

**C. Helicobacter Pylori Infection**

Recently it is observed that infection by *H. pylori* is the major cause of peptic ulcer:

1. This is a *Gram-negative bacillus* that secretes an enzyme called *urease* that converts urea into carbon dioxide and ammonia. Ammonia buffers the acid surrounding the bacteria.

2. *H. pylori* colonizes the antral mucosa, where it causes *local inflammation* and disrupts immune responses. It also *inhibits somatostatin secretion* from D cells that facilitates gastrin release and consequently increased HCl secretion.

3. Therefore, serum gastrin level is moderately elevated in duodenal ulcer.

4. *H. pylori* causes gastritis initially, but later, ulcer is produced.

**Features**

In most of the cases ulcer is located in the duodenum (Fig. 39.14), usually above the ampulla of Vater, as in this area acidic chyme is not neutralized by alkaline pancreatic juice. The main feature of peptic ulcer is *upper abdominal pain* (*epigastric pain*). Typically, pain is experienced in empty stomach and is relieved by taking water, food or antacid. If disease is untreated, *hematemesis* (vomiting of blood) or *malena* (dark, tarry stool), *vomiting* (due to pyloric obstruction), and peritonitis due to perforation of ulcer into the peritoneal cavity occurs.

**Treatment**

**Specific Treatment**

The specific treatment includes use of following drugs:

1. **H₂ receptor antagonists**: Ranitidine, cimetidine, famotidine, and nizatidine are different generations of H₂ receptor blockers. These drugs block the H₂ receptor and inhibit histamine secretion. As histamine is a potent stimulator of HCl release from parietal cells, H₂ receptor blockers inhibit HCl secretion.
2. Proton-pump blocker (H⁺-K⁺ATPase inhibitor): This drug inhibits the activity of proton-pump, i.e., the activity of H⁺-K⁺ATPase. Therefore, the final step of acid secretion is inhibited. This is the most effective medicine for the treatment of peptic ulcer. The usual proton-pump blocker used is omeprazole.

3. Sucralfate: This is a sucrose octasulfate. It provides a protective layer on the ulcer. Therefore, it promotes ulcer healing.

4. Muscarinic blockers: Atropine and pirenzepine are used to block the M₁ and M₃ receptors. Therefore, acetylcholine does not act on parietal cells. However, as the noncholinergic vagal innervation dominates over the cholinergic innervation for acid secretion, atropine does not produce encouraging results. Therefore, muscarinic blockers are not used in peptic ulcer treatment.

5. Gastrin blockers: As gastrin is the most potent stimulator of acid secretion, effort has been made to discover gastrin antagonists. However, a successful gastrin blocker has not yet been discovered. Proglumide, a gastrin blocker is used recently for the purpose.

6. Antibiotics: Recently, high dose of antibiotics such as amoxicillin to kill H. pylori has provided promising result.

Nonspecific Measures

Antacids
Antacids give immediate and temporary relief from pain. As the disease is mostly due to stress, measures to reduce the stress level are very helpful.

Yoga Therapy and Other Measures

Yoga therapy like practice of relaxation techniques, adequate sleep and rest, regulation of diet, and withdrawal of drugs like aspirin and NSAID improve the condition. Use of cold milk and avoidance of spicy food & alcohol also help in curing the disease.

Surgical Treatment

Sometimes inspite of effective use of medicines, the disease is not cured. In such patients, surgery is advocated. The usual surgical procedures performed are:

1. Vagotomy: There are different types of vagotomy such as truncal vagotomy (cutting the trunk of vagus nerves in abdomen just below the diaphragm), selective vagotomy (cutting the vagus nerve that supplies only stomach), and highly selective vagotomy (cutting the vagus nerve that preferentially innervate the parietal cell) (Fig. 39.15). Usually, the parietal cell vagotomy is preferred as other two types are associated with complications.

2. Gastrectomy: Partial gastrectomy removes the antral portion of stomach, as this part contains G cells. Antrum is the pump of the stomach that propels food into duodenum. Therefore, antrectomy results in stasis of food. To avoid such complication, usually gastroduodenostomy or gastrojejunostomy (the drainage procedures) is performed with gastrectomy (Fig. 39.16). Gastrojejunostomy is also performed with truncal vagotomy.
CHAPTER SUMMARY

KEY CONCEPTS

1. Though the primary function of stomach is temporary storage, grinding and mixing of food and controlled emptying of chyme into the intestine, gastric acid secretion is useful for acid-peptic digestion of food, providing IF for Vitamin B₁₂ absorption and killing microorganisms in food in stomach.

2. Gastric distension, spicy food, emotion and stress are important stimulant for gastric secretion. Mental relaxation, healthy food, Yoga and adequate sleep are important to have control over secretion of gastric acid.

3. *H. Pylori* is an important causative factor for gastritis and peptic ulcer.

4. Though endoscopy is the surest method for diagnosis of gastritis and peptic ulcer, estimation of gastrin level is useful in the management.

Important to Know (Must Read)

1. In examinations, 'Mechanism and regulation of gastric secretion' comes as a Long Question.

2. Phases of gastric secretion, Composition and functions of gastric secretion, Mechanism of gastric secretion, Regulation of gastric secretion, Gastric function tests, can come as Short Questions.

3. In Viva, examiner may ask……. Structure and functions of stomach, Amount of gastric secretion/day, Names of gastric glands, Innervation of stomach, Composition and function of gastric secretion, Function of each constituent of gastric secretion, Mechanism of gastric secretion, What are the Phases of gastric secretions and how are they regulated, What are the stimuli for different phases of gastric secretion, How different phases of gastric secretion can be studied, What are the gastric pouches and how they differ from each other, What are the effects of parasympathetic and sympathetic stimulation on gastric secretion, What is appetite juice, Classify gastric function tests, Procedure and normal values of important gastric function tests, Causes of gastritis and peptic ulcer, Who got Nobel prize for discovery of *H. pylori*, What is the role of *H. pylori* in peptic ulcer.

4. Functions of stomach, and Composition and functions of gastric juice are usually asked in viva. Mechanism of HCl secretion, and Regulation of different phases of gastric secretion are usually asked in theory exam. A student is expected to answer these questions; otherwise it may be difficult for him to pass.
The exocrine pancreas plays a major role in digestion and absorption of all essential nutrients from the GI tract. The exocrine pancreas constitutes about 80% of the total mass of the pancreas (12% by ducts and blood vessels, and 2% by endocrine tissues). This is a unique organ in the body having both major endocrine and exocrine tissues in it. The endocrine pancreas is involved in energy metabolism, deficiency of which results in diabetes mellitus, exocrine pancreatic deficiency results in severe indigestion, malabsorption and malnutrition.

History and Secretory Apparatus

Histologically, exocrine pancreas resembles salivary glands. The exocrine tissue of pancreas consists of lobules that contain multiple acini (Fig. 40.2).

1. Acini are sac-like dilatations composed of single layer of pyramidal (acinar) cells. Acinar cells contain multiple endoplasmic reticulum, Golgi apparatus and zymogen granules that are located in the apical region of the acinar cells (Fig. 40.3).
2. A few centroacinar cells line the lumen of the acinus.
3. Acini open to intercalated duct which in turn empty into intralobular duct.
4. Intralobular duct drains into extralobular duct that finally open to the main collecting duct, the duct of Wirsung.
5. Sometimes an accessory pancreatic duct, the duct of Santorini, drains separately from the head of the pancreas into the duodenum.
6. Collecting ducts combine to form pancreatic duct that drains into the common bile duct and form hepatopancreatic duct with an ampulla (Ampulla of Vater), which opens to the second part of duodenum through the sphincter of Oddi.
7. The acini secrete enzymes of the pancreatic juice.
Chapter 40: Pancreatic Secretion

8. The aqueous component of pancreatic juice is produced by epithelial cells that line the pancreatic ducts.

Scientist contributed

**Ruggero Ferdinando Antonio Giuseppe Vincenzo Oddi** (1864–1913) was an Italian physiologist, studied medicine at Perugia, Bologna and Florence, and in 1894 was appointed as Head of the Physiology Institute at the University of Genoa. While still a student, Oddi described a small group of circular and longitudinal muscle fibers that wrapped around the end of the bile and pancreatic ducts, and he demonstrated the physiology of these muscles. This structure was later named as the eponymous "sphincter of Oddi." Though this sphincter was initially identified by English physician Francis Glisson, it was Oddi who was first to characterize its physiological properties. Inflammation of the junction of the duodenum and common bile duct at the sphincter of Oddi is referred to as "Odditis".

**Nerve supply**

Pancreas is supplied by both parasympathetic (vagal fibers) and sympathetic fibers.

---

**Vagal Fibers**

These fibers innervate both the acinar cells (exocrine tissue) and islet cells (endocrine tissue). Stimulation of parasympathetic fibers increases exocrine pancreatic secretion.

**Sympathetic Fibers**

The postganglionic sympathetic fibers from celiac and superior mesenteric plexuses innervate pancreatic blood vessel and tissue. Stimulation of sympathetic fibers inhibits pancreatic secretion.

---

**PANCREATIC SECRETION**

**Composition and Functions**

**Composition**

The pancreatic secretion has aqueous component (98%) and enzyme component (2%).

**Aqueous Component**

This contains mainly water and ions. The cations are Na\(^+\), K\(^+\), Ca\(^{2+}\), Mg\(^{2+}\), and Zn\(^{2+}\), and the anions are HCO\(_3\)\(^-\), Cl\(^-\), PO\(_4\)\(^{3-}\), and SO\(_4\)\(^{2-}\).
Enzyme Component

Enzymes for Lipid Digestion
Enzymes for lipid digestion are pancreatic lipase (triacylglycerol hydrolase, cholesterol ester hydrolase, and phospholipase A₂), colipase and phospholipases.
1. The pancreatic lipase digests neutral lipids into fatty acids and monoglycerides.
2. The colipase facilitates the action of lipase.
3. The phospholipase acts on phospholipids.
4. Cholesterol hydrolase splits cholesterol esters into cholesterol and fatty acids.

Enzymes for Protein Digestion
Enzymes for protein digestion are trypsin, chymotrypsin, carboxypeptidase, procollagenase, proelastase, and nucleases.
1. These proteolytic enzymes are secreted in the inactive forms like trypsinogen, chymotrypsinogen, procarboxypeptidase, procollagenases, proelastase, and pronucleases (Table 40.1).
2. The enzymes are activated in the intestine.
3. The first step in the process of activation is the activation of trypsinogen to trypsin, which is mediated by the intestinal enzyme enteropeptidase (enterokinase).
4. Once trypsin is formed, it converts other proenzymes to their active forms (Flowchart 40.1).
5. Trypsin is strongly proteolytic. Therefore, once it is activated in the pancreas, it digests the pancreatic tissue (Clinical Box 40.1). However, normally it remains inactivated in pancreas.

Enzymes for Carbohydrate Digestion
Pancreatic amylase splits starch at α-1,4-glycosidic linkage. This is an α-amylase that acts on starch to produce maltose, α-limit dextrin, etc. It differs from salivary amylase by its action on both boiled and unboiled starch (salivary amylase acts only on boiled starch).

Functions of Pancreatic Secretion
1. Pancreatic secretion contains enzymes that help in digestion of fat, protein and carbohydrate as listed in Table 40.1. Pancreatic enzymes are the primary requirement for digestion and absorption. Therefore, pancreatic deficiency leads to severe malabsorption syndrome.
2. Pancreatic secretion contains bicarbonate and water that neutralizes acidic chyme entering intestine from stomach. It also neutralizes the effects of bile acids. Thus, it prevents formation of duodenal ulcer (Clinical Box 40.2).

Factors that normally prevent autodigestion of pancreas are:
1. Enzymes are present in inactive form.
2. Trypsin inhibitor in pancreatic tissue does not allow active trypsin to be formed (trypsin remains inhibited).
3. The wall of acini is thick, and therefore does not allow pancreatic enzymes to escape into the pancreatic tissue.

Clinical Box 40.1
Autodigestion of pancreas in acute pancreatitis: Normally, trypsin is not formed in the pancreas due to the presence of trypsin inhibitor in the pancreatic juice which prevents the activation of trypsinogen to trypsin. In acute pancreatitis, the trypsin inhibitor is deficient. Therefore, activation of trypsin results in autodigestion of pancreatic tissue.

Flowchart 40.1: Steps of activation of pancreatic proteolytic enzymes.

Clinical Box 40.2
Upper part of duodenum is the commonest site for duodenal ulcer: Acidic chyme from stomach is neutralized by alkaline pancreatic juice. However, as acidic chyme in the 1st part of duodenum (part above the ampulla of Vater, the site of opening of major pancreatic duct) remains mostly unaffected by alkaline pancreatic secretion, it is the commonest site of peptic ulcer.
Chapter 40: Pancreatic Secretion

Mechanism of Secretion

Secretion of Aqueous Component

Aqueous component of pancreatic secretion is mainly produced by the columnar epithelial cells that line the pancreatic ducts.

1. Pancreatic juice is nearly isotonic with plasma at any rate of formation and flow. The ionic composition includes mainly cations (Na\(^+\) and K\(^+\)) and the anions (HCO\(_3\)\(^-\) and Cl\(^-\)). The Na\(^+\) and K\(^+\) concentration of pancreatic juice is similar to that of plasma. But, HCO\(_3\)\(^-\) and Cl\(^-\) concentration varies according to the rate of secretion.
   - At lower rate of secretion, concentration of HCO\(_3\)\(^-\) and Cl\(^-\) is about 70% of plasma.
   - At higher rate of secretion, their concentration is more than 100% of plasma (Fig. 40.4).

2. The aqueous component secreted by the duct cell is hypertonic to plasma as it contains more HCO\(_3\)\(^-\).

3. But, when the secretion passes through the ducts, water moves into the duct lumen to make the pancreatic juice isotonic, during which HCO\(_3\)\(^-\) is partly exchanged with Cl\(^-\) by HCO\(_3\)\(^-\)-Cl\(^-\) exchanger present on the luminal membrane (Fig. 40.5).

4. In the resting state (interdigestive phase), the secretion of aqueous component occurs mainly from intercalated and intralobular ducts, but in the stimulated state (after eating) the secretion occurs additionally from extralobular ducts, which has higher HCO\(_3\)\(^-\) concentration.

Defect in the chloride channel causes thick exocrine secretion in the duct (Clinical Box 40.3)

Secretion of Enzyme Components

Pancreatic enzymes are synthesized in the acinar cells and stored in the zymogen granules. The granules are located toward the apical region of the cells. In response to appropriate stimulation, the granules are released by exocytosis into the lumen of acinus.

Clinical Box 40.3

Defect in CFTR produces viscid secretion: The Cl\(^-\) enters the acinar cells and duct epithelial cells via voltage gated Cl\(^-\) channels. The primary defect in cystic fibrosis is the mutation of the gene that encodes for Cl\(^-\) channel. Cystic fibrosis gene is located on chromosome 7, mutation of which alters the function of its product, cystic fibrosis transmembrane conductance regulator (CFTR). CFTR is localized in the apical membrane of epithelial cells in the pancreatic ducts. Alteration of CFTR results in decreased number of Cl\(^-\) channel. Therefore, Cl\(^-\) transport into duct lumen is impaired. This also impairs the transport of Na\(^+\) and water. As a result, the secretion becomes thick causing duct obstruction which in turn causes destruction of acinar cells and duct system. This leads to severe pancreatic deficiency causing severe impairment of absorption of important nutrients. This is also accompanied by progressive pulmonary disease causing lung infection, especially in children.

Factor That Influence Secretion

Pancreatic secretion is influenced by neural and hormonal factors.
Section 5: Gastrointestinal System

1. The hormonal factors are mainly cholecystokinin (CCK) and secretin. Cholecystokinin stimulates enzymatic pancreatic secretion, whereas secretin stimulates pancreatic secretion rich in water and bicarbonate.

2. The neural factors are sympathetic and parasympathetic. Parasympathetic stimulation increases secretion whereas sympathetic stimulation decreases secretion. However, the control mechanism varies according to the phases of secretion (described below).

### Hormonal Factors

1. CCK: CCK has two receptors. (CCK A and CCK B receptors, gastrin acts through CCK B receptors)
2. Secretin
3. Gastrin: Gastrin receptors, CCK B receptors
4. GRP
5. GIP
6. VIP

(CCK: Cholecystokinin).

### Neural Factors

1. Parasympathetic: stimulates secretion
2. Sympathetic: inhibits secretion

### Regulation of Secretion

### Phases of Pancreatic Secretion

There are three phases of pancreatic secretion: cephalic, gastric, and intestinal. Mechanisms of pancreatic secretion are different in different phases of secretion (Table 40.2).

#### Cephalic Phase

The cephalic phase is induced by smell, sight, thought and taste of food, and by chewing and swallowing of food.

1. Cephalic phase is mediated by vagus nerve. The efferent impulses originating from brain directly stimulate pancreatic secretion. The fibers mediating this response are cholinergic vagal fibers.
2. Also, gastrin released from the stomach in response to vagal stimulation increases pancreatic secretion.
3. The pancreatic secretion in cephalic phase is rich in enzymes. Cephalic phase contributes to 15–30% of pancreatic secretion.
**Gastric Phase**

When food enters the stomach, gastric phase is initiated.

1. Distension of stomach elicits vagovagal reflex that stimulates pancreatic secretion.
2. Presence of amino acids and peptides in the gastric content stimulate gastrin release from stomach that in turn stimulate pancreatic secretion (Fig. 40.7).
3. Gastric phase has greater effects on enzyme secretion.
4. About 40% of pancreatic secretion occurs in this phase.

**Intestinal Phase**

When chyme enters the duodenum, intestinal phase starts.

1. Acidic chyme increases release of secretin from S cells present in the mucosa of upper part of small intestine. Secretin stimulates pancreatic juice rich in aqueous (water and bicarbonate) component.
2. The presence of products of protein digestion like amino acids and peptides, and the products of fat digestion like fatty acids and monoglycerides in chyme evoke pancreatic secretion rich in enzymes, which is mediated by CCK secreted from I cells in intestinal mucosa (Fig. 40.7).
3. CCK potentiates the effect of secretin on ducts and secretin potentiates the effect of CCK on acinar cells.
4. The vagovagal reflex also mediates pancreatic secretion during gastric and intestinal phases. Intestinal phase contributes to 40–60% of pancreatic secretion.

**APPLIED PHYSIOLOGY**

**Acute Pancreatitis**

**Pathophysiology**

This is a serious condition of acute abdomen that occurs due to inflammation of the pancreas.

1. The disease is characterized by severe pain in the epigastric or periumbilical region that often radiates to back.
2. The physiological alteration in the disease is the activation of trypsin inside the pancreatic tissue that causes autodigestion of the gland.
3. Trypsin also activates phospholipase-A₂ which forms lyssolecithin from fatty acid of lecithin.
4. Lyssolecithin damages pancreatic tissue and produces necrosis of surrounding fat.
5. In severe case, hemorrhage occurs into abdominal cavity (hemorrhagic pancreatitis).
Etiology
The common causes of acute pancreatitis are gall stone causing obstruction of sphincter of Oddi, chronic alcoholism, hypertriglyceridemia, blunt abdominal trauma and drugs like azathioprine, sulfonamides, tetracycline, valproic acid, etc.

Diagnosis
Acute pancreatitis is diagnosed by its typical presentation of abdominal pain associated with increased plasma level of serum amylase.

Treatment
In 90% of patients, symptoms disappear with conservative treatment with i.v. fluid, nil orally, analgesics, antibiotics and nasogastric suction. In severe cases, especially in hemorrhagic form, abdomen is opened, and blood is collected from abdominal cavity of the patient and filtered, abdomen is thoroughly washed, bleeding points are closed, and the filtered blood is transfused (autotransfusion).

Chronic Pancreatitis
Slow and chronic inflammation of pancreas occurs without any definite etiology.
1. It may be due to improper recovery from pancreatitis or persistence of low grade acute pancreatitis.
2. Patient develops steatorrhea due to pancreatic lipase deficiency and malnutrition due to indigestion and malabsorption of various nutrients.
3. Patient may develop diabetes mellitus due to associated endocrine deficiency.

Cystic Fibrosis
This is an autosomal recessive monogenic disorder, in which the major defect is in the Cl– channel.
1. The disease occurs due to mutation in the CFTR gene (cystic fibrosis transmembrane-conductance regulator gene), located on chromosome 7.
2. The disease usually starts in childhood.
3. Lung is the most common organ affected and decreased nasociliary clearance is the common pathology.
4. Respiratory features are chronic sinusitis, nasal obstruction, rhinorrhea and cough with expectoration of viscous-purulent sputum.
5. Common gastrointestinal features are intestinal obstruction and exocrine pancreatic deficiency.

PANCREATIC FUNCTION TESTS
Exocrine pancreatic function tests are based on assessment of pancreatic secretion in response to hormonal stimulation, or a meal or measurement of production of digestion in the stool that assesses digestion and absorption of nutrients. Apart from color, odor, pH (8–8.3), volume (maximum 3 L), specific gravity (1.007–1.042) and bicarbonate concentration of pancreatic secretion, the important parameters analyzed are serum and fecal enzymes such as trypsin, amylase, lipase, etc.

Classification
Pancreatic function tests are described in detail in biochemistry books. However, in this section, we describe the physiological principles of these tests. These tests are usually employed to diagnose pancreatic deficiencies as in pancreatitis, cystic fibrosis, etc. These are of two types: invasive and non-invasive tests.

Invasive Tests
Invasive tests are of two types.
1. First type uses stimulation of pancreatic secretion by meals such as Lundh meal or duodenal infusion of amino acids.
2. Second type makes use of hormonal injection intravenously such as secretin, CCK, etc.

Secretin Stimulation Test
Secretin is injected IV at a dose of 1 unit/kg and then the duodenal samples are collected for 80 minutes. It increases rate of formation and flow, and aqueous component of pancreatic juice.

CCK Stimulation Test
CCK increases enzymatic component of pancreatic secretion.

Meal Stimulation Test
The test meal is called Lundh meal (Lundh and Borgstrom, 1962). It consists of milk protein, corn oil, and dextrose. Following ingestion of the meal, duodenal content is aspirated for analysis.

Non-Invasive Tests
These are simpler and cheaper. Therefore, noninvasive tests are preferred to invasive tests. However, they are not as sensitive and specific as the invasive tests.

Visualization of pancreas and scanning by ultrasonography, CT scan, MRI, cholangiopancreatography, etc., are usually performed before opting for biochemical pancreatic function tests. These tests are of three types.
1. First type includes estimations in stool for food particles that are not absorbed (fecal estimation of fat) and fecal enzymes (trypsin, chymotrypsin and elastase).
2. Second type includes estimations in blood, urine and breath for products of digested food due to action of pancreatic enzymes that are absorbed into systemic circulation.
3. **Third type** includes estimations in plasma or blood for hormones (Schilling test) and enzymes, amino acids, etc.

**Fecal Estimation of Fat**

Normally, about 5 g of fat is excreted per day in the feces. In pancreatic deficiency, excretion **more than 20 g of fat** is common. In severe deficiency, fat excretion may be 50 g or more.

**Fecal Estimation of Nitrogen**

About **7 g of nitrogen** is excreted in stool per day in a healthy individual. In pancreatic deficiency, due to decreased proteolytic enzyme activity, nitrogen excretion increases in stool.

**D Xylose Absorption Test**

A pentose sugar called xylose is administered (25 g, usually) and its recovery in urine is measured over next 5 hours and in blood in next 2 hours. This is a test that distinguishes between malabsorption due to pancreatic (normal absorption) and jejunal (low absorption) insufficiencies. It also helps evaluate response to therapy.

**Schilling Test**

It is done to assess the absorption of **vitamin B₁₂**, which requires intrinsic factor. Vitamin B₁₂ deficiency is seen in chronic pancreatitis because trypsin helps in binding B₁₂ to intrinsic factor after which the complex is reabsorbed.

**Serum Amylase Estimation**

Normal level of serum amylase is **60–120 units** per liter. In acute pancreatitis, serum amylase concentration becomes very high. This differentiates pancreatitis from other conditions of acute abdomen.

**Cholangiopancreatography**

This is a special radiodiagnostic investigation in which the details of the contour of hepatopancreatic duct system are visualized by introducing an endoscope. The procedure is called endoscopic retrograde cholangiopancreatography (ERCP). This is the most accurate test for assessing pancreatic structure and function.

---

**CHAPTER SUMMARY**

**Key Concepts**

1. Pancreas secretes enzymes for digestion of all types of nutrients. Therefore, pancreatic deficiency leads to severe indigestion and malabsorption.
2. Pancreatic juice is alkaline. It helps in protecting the mucosa of intestine from acidic chyme that may damage the intestinal epithelium.
3. CCK stimulates pancreatic juice rich in enzymes, and secretin increases secretion of aqueous component.
4. Trypsin inhibitors prevent activation of trypsin inside pancreas. It is activated in duodenum by enterokinase. Activation of trypsin inside pancreas causes acute pancreatitis and autodigestion of pancreas, as trypsin is strong proteolytic agent.

**Important to Know (Must Read)**

1. In examinations, “Composition and function of pancreatic secretion, and mechanism and regulation of pancreatic secretion” may come as a **Long Question**.
2. Phases of pancreatic secretion, Composition and functions of pancreatic secretion, Mechanism of pancreatic secretion, Regulation of pancreatic secretion, Pancreatic function tests, can come as **Short Questions**.
3. In **Viva**, examiner may ask… Structure and functions of pancreatic acini, Amount of pancreatic secretion/day, Composition pancreatic juice and function of each constituent pancreatic secretion, Name pancreatic enzymes and tell their functions, Mechanism of gastric secretion, What are the Phases of pancreatic secretions and how are they regulated, What are the stimuli for different phases of pancreatic secretion, What are the effects of parasympathetic and sympathetic stimulation on pancreatic secretion, Classify pancreatic function tests, Procedure and normal values of important pancreatic function tests, Causes of acute and chronic pancreatitis, What is cystic fibrosis and which ion channel is defective in this disease.
4. Composition pancreatic juice and functions of each constituent, and Pancreatic function tests, are usually asked in viva. A student is expected to answer these questions.
Learning Objectives
On completion of study of this chapter, the student MUST be able to:
1. List the functions of liver.
2. Understand the importance of knowing hepatic physiology in learning medicine.
4. Outline the bilirubin metabolism.
5. Understand the physiological basis of classification of jaundice.
6. Appreciate the differences in laboratory findings of different types of jaundice.
The student MAY also be able to:
1. Describe details of bilirubin metabolism.
2. Explain the pathophysiology of jaundice.

Physiology of Liver
Liver is an essential organ of the body as it is the center of all metabolisms and crucial for many other vital functions. Therefore, liver dysfunctions result in major abnormalities of the body. In adults, liver weighs about 1.5 kg. Liver is protected by a thin but strong capsule, called Glisson's capsule.

Scientist contributed
Francis Glisson (1599–1677) was a British physician, anatomist, physiologist, and writer on medical subjects. He did important work on the anatomy of the liver, and wrote on rickets. A physiology experiment he performed that helped debunk the balloonist theory of muscle contraction, as he demonstrated that when a muscle contracts under water, the water level does not rise, and thus no air or fluid could be entering the muscle. Glisson is a well-known medical eponym, the Glisson's capsule of Liver, named after him.

Functional Anatomy
The main function of the liver is the bile synthesis and secretion. The bile is secreted into hepatic ducts. The hepatic ducts join to form common hepatic duct. Bile is continuously formed and delivered to the gallbladder, the process known as bile secretion (described in detail in next chapter). In the gallbladder, the bile is stored and concentrated and delivered via the common bile duct into second part of duodenum in response to chyme entering the duodenum.

Blood Supply
Liver receives blood supply from two sources.

Portal Vein
Portal vein is formed by the union of two veins, viz. superior mesenteric vein and splenic vein. Thus portal vein supplies blood from most parts of the stomach and intestine as well as from the spleen and pancreas. Therefore, portal blood is rich in end products of digestion, GI hormones and pancreatic hormones. However, this blood is comparatively poor in oxygen.

Hepatic Artery
Hepatic artery contains pure arterial blood and is rich in oxygen.

Portal Circulation
The portal vein and hepatic artery break up into large number of branches.
1. Blood of these two sets of vessels get mixed up in the sinusoids of the liver. The hepatic cells receive oxygen and nutrients from the sinusoids.
2. The various substances produced by the liver, products of metabolism, the waste products and the CO₂ are discharged into the sinusoids.
3. The sinusoids drain into the central vein of the lobule.
4. Central veins from different lobules unite to form larger veins, which in turn join ultimately and drain into hepatic vein.
5. The hepatic vein opens into the inferior vena cava.

**Bile Secretion by Liver Cells**
The liver cells synthesize bile, which is first secreted to small canaliculi. The smaller canaliculi join and ultimately form two hepatic ducts (right and left).

**Histology of Liver**
Liver is formed by large number of lobules (Fig. 41.1). Each lobule is delineated by a connective tissue sheath.
1. The individual lobule is polygonal in shape with a central vein at the center.
2. From the central vein, plates of liver cells radiate like spokes of a bicycle wheel to the periphery of the lobule (Fig. 41.2).
3. The plates are one cell thick and are separated by liver sinusoids. Liver cells have the capacity to regenerate (Application Box 41.1).

**Sinusoids and Bile Canaliculi**
In a typical lobule, between the plates of hepatic cells, the sinusoids are present that carry blood.

---

**Fig. 41.1:** Histology of liver showing hepatic lobules. 1: Central vein; 2: Radiating cord of hepatocytes; 3: Branch of portal vein; 4: Branch of hepatic artery; 6: Interlobular duct. Note, 3, 4, 5 form the portal triad.

**Fig. 41.2:** Detailed structure of liver lobule.

---

1. Each sinusoid receives blood from a branch of portal vein and hepatic artery of the portal tract, and drains into the central vein.
2. Wall of the sinusoids are mostly made up of endothelial cells, but at places macrophage cells, called Kupffer cells, are occasionally present.
3. The bile canaliculi run in between the two layers of cells (layer of cells that make the thickness of each plate) (Fig. 41.3). The liver cells (hepatocytes) synthesize the bile acids and transfer them into bile canaliculi.
4. The space that lies between sinusoid and hepatocytes is the space of Disse (perisinusoidal space). The space of Disse serves as a route through which hepatocytes remove certain substances from blood and discharge certain products into the blood.

**Portal triad**
Portal triads are typically found at the angles of liver lobules. Each portal triad consists of a branch of portal vein, a branch of hepatic artery and a bile ductule (Figs. 41.2 and 41.3).
1. The angular space that contains portal triad and its surrounding connective tissue is called portal canal.
2. Portal sinusoids originating from portal veins remain in close proximity with bile canaliculi that drain into interlobular bile duct (Fig. 41.4).
3. A small space between hepatocyte and portal canal is called space of Mall, the site of origin of lymph in liver.

**Application Box 41.1**

**Hepatic regeneration:** Despite its slow rate of cell renewal, liver has the capacity of regeneration. The loss of hepatic tissue by surgical removal, injury or effect of toxin triggers a mechanism by which hepatocytes begin to divide and grow till the normal size is attained. This property of liver tissue is used in liver transplantation, in which a small portion of transplanted liver tissue proliferates to become the normal size liver.
Section 5: Gastrointestinal System

Functions of Liver

Liver is the center for most of the metabolisms. It synthesizes many essential proteins, stores nutrients that are released into circulation at the time of starvation, and detoxifies harmful substances. It plays an essential role in maintaining blood glucose level. Therefore, liver is among the vital organs of the body.

1. **Secretory functions**: Liver forms and secretes bile into the biliary tract.

2. **Metabolic functions**: Liver is involved in metabolism of major nutrients such as carbohydrate, fat, proteins, and fat soluble and water soluble vitamins. Liver plays a central role in the metabolisms of urea, iron, and alcohol.

3. **Synthetic functions**: Liver is the major organ for the synthesis of proteins that include clotting factors, acute phase proteins that mediate inflammation, hormone binding proteins, lipids, carbohydrates, vitamins and bile salts.

4. **Storage functions**: Liver stores glucose, protein, fat, and vitamins. These nutrients are released from liver and utilized during their scarcity, and are stored in liver when they are in excess.

5. **Detoxifying action**: Liver detoxifies many chemicals. Toxins released from infecting organisms are neutralized in liver.

6. **Degradation of drugs and chemicals**: Liver is the site of inactivation of many drugs. Liver degrades enzymes, hormones, cytokines, and various other chemicals.

7. **Excretory function**: Liver excretes bile pigments, cholesterol, and some metals.

8. **Immunity**: Kupffer cells of liver are part of mononuclear phagocyte system (reticuloendothelial system) that forms the nonspecific defenses of the body. These cells phagocytose and kill microorganisms.

9. **Endocrine functions**: Liver converts vitamin D₃ to 25-hydroxyvitamin D₃. Liver is a major site for conversion of T₄ to T₃. Somatomedin (insulin-like growth factor) that mediates important functions of growth factor is secreted from liver. Many hormones like insulin, glucagon, growth hormone, GI hormones, etc., are degraded in liver.

**LIVER FUNCTION TESTS**

In view of multiplicity and complexity of the liver functions, it is obvious that no single test can establish the disturbance in liver function. Thus a battery of liver function tests is employed for accurate diagnosis, to access the severity of damage, to judge prognosis and to evaluate therapy. These tests are listed below in relation to major liver functions. A summary of various liver function tests and their significance is depicted in Table 41.1.

1. **Tests for manufacture and excretion of bile**
   1. Bilirubin estimation
### Table 41.1: Liver function tests and their significances.

**PATHOPHYSIOLOGY OF JAUNDICE**

Jaundice is the yellowish discoloration of sclera, skin and mucous membrane due to the deposition of bilirubin. This happens when concentration of bilirubin increases in blood. Bilirubin is the product of hemoglobin breakdown. Therefore, to understand pathophysiology of jaundice, it is necessary to learn the process of hemolysis and hemoglobin breakdown.

**Red Cell Breakdown**

Red cells have an average lifespan of 120 days. The aged red cells are trapped by the macrophages of mononuclear phagocytic system (MPS) that are present in spleen, liver, lymph nodes, and bone marrow. Macrophages, especially in the spleen, after destroying red cells and hemoglobin, release their components into blood. For details of red cell destruction and bilirubin metabolism, refer to Chapter 13.

**Hemoglobin Catabolism**

Macrophages split hemoglobin into heme and globin.
1. **Globin** is the protein component, which is degraded into amino acids that enter the amino acid pool of the body and are reutilized whenever required.
2. **Heme** is catabolized by the microsomal oxygenase system to release iron, which joins the iron pool of the body.
3. Some of the heme molecules are simultaneously oxidized to biliverdin.
4. Then, biliverdin is reduced to bilirubin by the enzyme biliverdin reductase. Bilirubin for its lipophilic nature crosses cell membrane easily. However, for its water-insolubility, it is transported in body fluids only after conjugation in the liver or in combination with albumin.

**Bilirubin Metabolism**

Bilirubin released from macrophages enters the blood stream, where it forms a complex with albumin. Bilirubin bound to albumin (**albumin-bilirubin complex**) is not excreted in urine, as albumin molecule is large enough not to get filtered in renal glomeruli. Bilirubin-albumin complex is split in the liver, bilirubin enters liver cells and albumin stays back in the blood.

In liver cells, bilirubin undergoes three-step metabolism: uptake, conjugation, and excretion.

1. **Uptake:** Bilirubin after splitting from albumin-bilirubin complex is transported into the hepatocyte, where it forms a complex with a cytoplasmic protein, called ligandin. Formation of bilirubin-ligandin complex prevents bilirubin to return back to the blood as the complex is too big to pass through the liver cell membrane.
2. **Conjugation:** Hepatocytes conjugate bilirubin with glucuronic acid, which takes place in the endoplasmic reticulum and involves UDP-glucuronic acid and glucuronyl transferase. This forms **bilirubin glucuronide** (Fig. 41.5).
3. **Excretion:** Bilirubin glucuronide is excreted from hepatocytes into the biliary canaliculi. This is an active process, and is the rate-limiting step in the hepatic bilirubin metabolism.

**Fate of Conjugated Bilirubin**

Bilirubin glucuronide is excreted in bile to be discharged into the small intestine. In large intestine, bilirubin is acted upon by the bacterial flora, where glucuronic acid is split and bilirubin undergoes a series of reduction reactions to form **stercobilinogen**.

Stercobilinogen, a colorless compound has two fates:

1. In the intestine, 80% of stercobilinogen is oxidized to **stercobilin**, which is excreted in stool. Stercobilin is a brownish compound that imparts brown color to the stool.
2. The remaining 20% stercobilinogen is absorbed into the portal circulation and re-excreted by liver into the bile, and re-enters the intestine. A part of the absorbed stercobilinogen enters the general circulation and is filtered and excreted by the kidneys. In urine, the stercobilinogen is called urobilinogen.
3. Conjugated bilirubin is not reabsorbable, whereas it metabolic products, urobilinogen is reabsorbed and enters enterohepatic circulation. The major differences between conjugated and unconjugated bilirubin are summarized in Table 41.2.
Normal Plasma Bilirubin Level: The normal concentration of bilirubin in plasma is 0.2–0.8 mg/dL. Jaundice is detected clinically only when the bilirubin level exceeds 2 mg/dL.

Types of Jaundice

Clinically, jaundice is detected when bilirubin level is more than 2 mg/dL. Bilirubin level between 0.8 and 2 mg% is called latent or subclinical jaundice. Jaundice first appears in sclera (Fig. 41.6), because bilirubin has an extremely high affinity for scleral protein called elastin.

Physiologically, the causes of jaundice are divided broadly into two categories: increased production of bilirubin and decreased excretion of bilirubin.

Increased Production of Bilirubin

Production of bilirubin is increased in hemolysis. Therefore, the jaundice is called hemolytic jaundice. This is seen in hemolytic anemias (for details, refer “Pathophysiology of Anemia, Chapter 15”).

Decreased Excretion of Bilirubin

The excretion of bilirubin is impaired when liver cannot conjugate bilirubin efficiently, which is called hepatic jaundice, or when conjugated bilirubin cannot be excreted in bile due to biliary obstruction, which is called obstructive jaundice.

1. Hepatic jaundice commonly occurs in viral hepatitis and obstructive jaundice is commonly seen in gallstones (stone in the common bile duct) or stricture of bile duct. However, hepatic and obstructive jaundice overlap in their pathophysiologic processes.
2. In hepatic jaundice, narrowing of biliary canaliculi occurs very often resulting in \textit{intrahepatic obstruction (stasis)}. This adds an obstructive element to the hepatic jaundice.

3. In obstructive jaundice, \textit{biliary stasis} behind the site of obstruction causes damage to the hepatocytes. This adds hepatocellular element to the obstructive jaundice.

### Laboratory Diagnosis of Jaundice

#### Hemolytic Jaundice

In hemolytic jaundice, \textit{excessive production of bilirubin} allows liver to conjugate more than the normal quantity of bilirubin.

1. Therefore, more quantity of \textit{bilirubin glucuronide} is delivered to the intestine.
2. Consequently, the amount of \textit{stercobilinogen} formed in the intestine is increased.
3. This leads to \textit{increased excretion of fecal stercobilinogen and urinary urobilinogen} (Table 41.3).
4. Bilirubin in plasma forms a complex with albumin, which cannot be excreted in the urine. Therefore, hemolytic jaundice is \textit{acholuric jaundice} (absence of bilirubin in urine). Liver function tests are usually normal.

#### Hepatic Jaundice

In hepatic jaundice, all three steps of bilirubin metabolism (\textit{uptake, conjugation, and excretion}) are affected. But as mentioned earlier, the \textit{rate-limiting step is excretion}, and therefore that may be the most affected. Therefore, not only the conjugation of bilirubin is impaired, but also some amount of conjugated bilirubin is not excreted in bile.

1. The conjugated bilirubin that accumulates in liver cells diffuses across the cell membrane into the bloodstream. Thus, in hepatic jaundice the \textit{blood contains excess of bilirubin-albumin complex} as diseased liver may not be able to conjugate all the load of bilirubin. Also, conjugated bilirubin diffuses back into the bloodstream.

2. Consequently, \textit{conjugated bilirubin (bilirubin glucuronide) is excreted in the urine}. This makes urine \textit{yellow} due to the presence of urinary bilirubin.

3. Bilirubin excreted in bile is reduced. Hence \textit{fecal stercobilinogen and urinary urobilinogen are reduced}.

4. Plasma albumin may be low as diseased liver cannot synthesize the normal amount of albumin. Plasma globulins are high in liver disease because of a \textit{rise in the gamma-globulin fraction}. Thus, albumin-globulin ratio is altered.

5. \textit{Neonatal jaundice} could be due to defective conjugation of bilirubin (Clinical Box 41.1).

#### Obstructive Jaundice

Obstructive jaundice occurs due to obstruction to bile secretion into intestine.

1. In obstructive jaundice, no bile reaches the intestine. Hence, neither bilirubin nor bile salts is present in the intestine. Therefore, \textit{no fecal stercobilinogen is formed}, and stool becomes clay colored.

2. Also, \textit{urinary urobilinogen is absent}.

3. As bile salt is reduced in intestine, there is an increased fecal excretion of fat \textit{(steatorrhea)}.

4. The conjugated bilirubin accumulates proximal to the obstruction, and is regurgitated by the liver cells into the bloodstream. Therefore, the level of \textit{conjugated bilirubin in the blood is high}, which is excreted in urine and causes \textit{deep yellow urine}.

5. Like conjugated bilirubin, bile salts are also regurgitated into the blood stream, and excreted in urine. Initially liver function tests are normal. But, later, prolonged biliary stasis damages the liver and impairs liver functions.

\textit{van den Bergh test}: Van den Bergh test detects whether \textit{bilirubin is conjugated or not}. The test is based on the principle that excess of water soluble bilirubin-glucuronide gives a reddish-violet color when brought in contact with \textit{diazo reagent}.

1. If the color appears immediately, the test is said to be \textit{direct positive}.
2. If the color appears late, or only after addition of alcohol, the test is said to be \textit{indirect positive}.
3. In hemolytic jaundice, the Van den Bergh test is \textit{indirect positive}.
4. In obstructive jaundice, the Van den Bergh test is \textit{direct positive}.
5. In hepatic jaundice, the test may be \textit{biphasic}, i.e. an atypical color develops almost immediately.

**Clinical Box 41.1**

\textbf{Physiological jaundice}: This is seen in some newborns and therefore this is also known as \textit{neonatal jaundice}. It is common in premature babies and neonates having low birth weight. The jaundice usually appears on the second or third day of life and disappears within a week. It occurs due to subnormal activity of glucuronyl transferase that impairs conjugation of bilirubin in hepatocyte. It is unlikely to be due to hemolysis.
## CHAPTER SUMMARY

### Key Concepts

1. Liver is the site of all metabolisms.
2. Bilirubin released from hemolysis is conjugated in liver and conjugated bilirubin is secreted in bile into intestine.
3. Excess production of bilirubin by hemolysis leads to hemolytic (Prehepatic) jaundice, diseases of liver (defect in conjugation) causes hepatic jaundice, accumulation of bilirubin due to obstruction to flow of bile causes obstructive (posthepatic) jaundice.

### Important to Know (Must Read)

1. In examinations, **Long Questions** usually do not come from this chapter. However, Liver function tests may come as a question.
2. Functions of liver, Bilirubin metabolism, Pathophysiology of jaundice, Differences in laboratory diagnosis of types of jaundice, Liver function tests, can come as **Short Questions**.
3. In **Viva**, Structure of a hepatic lobule, Portal triad, Relationship between sinusoidal capillary and bile canaliculi, Functions of liver, Steps of bilirubin metabolism, How is bilirubin metabolized in liver and excreted from the body, Differences between conjugated and unconjugated bilirubin, Pathophysiology of hemolytic, hepatic, and obstructive jaundice, Common causes of hemolytic, hepatic, and obstructive jaundice, Differences in laboratory diagnosis of three types of jaundice, Classification of liver function tests (LFT), Common values and interpretation of LFT, What is physiological jaundice.
4. “Functions of liver” and “name important LFT” are very common questions in viva. A student, who fails to answer these questions satisfactorily, may get fail mark.
Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Give the composition and functions of bile.
2. List the differences between hepatic and gallbladder bile.
3. Name bile salts and acids and give their functions.
4. Understand the importance of enterohepatic circulation.
5. Outline the mechanism and regulation of bile secretion.
6. Learn the physiological abnormality in gallstone formation.

The student **MAY** also be able to:
1. Describe the regulation of bile secretion.
2. Explain the mechanism of enterohepatic circulation.

Hepatobiliary System

Bile is secreted from liver. Human liver secretes about **0.5 to 1 liter of bile per day**. Secretion of bile is important for digestion and absorption of fat.

Functional Anatomy

Bile is formed in the liver and is excreted through the bile ductules. The bile ductules along with the branches of portal vein and hepatic artery form the **portal triad**. The portal triad opens into the hepatic sinusoids. The sinusoids are surrounded by hepatocytes. The hepatocytes are in intimate contact with the sinusoidal blood. The **bile canaliculi** start at the space between two hepatocytes (refer to Figs. 41.3 and 41.4, Chapter 41), which opens into bile ductules. Bile ductules then form the bile duct which leads to **hepatic duct**. The right and left hepatic ducts join to form **common hepatic duct** (Fig. 42.1). The **cystic duct** from gallbladder combines with hepatic duct to form **common bile duct**. Common bile duct combines with pancreatic duct and opens to second part of duodenum through sphincter of Oddi.

Composition of Bile

Bile is a greenish yellow fluid formed in the liver and stored in gallbladder. It is composed of water (98%), and solids that mainly include bile salts and pigments and different ions (Table 42.1).
Chapter 42: Biliary Secretion

Biliary Secretion

The color of bile is greenish yellow due to the presence of glucuronides of bile pigments. The bile pigments are bilirubin and biliverdin.

Hepatic and Gallbladder Bile

There are differences between hepatic bile (bile formed in the liver) and gallbladder bile (bile stored in gallbladder) as bile is concentrated and acidified in gallbladder (Table 42.2).

1. Water absorption is the major mechanism for concentration of bile that occurs secondary to Na⁺ absorption (secondary active transport).
2. Na⁺-K⁺ ATPase in the basolateral membrane of epithelial cell lining transports Na⁺ actively out of the cell and creates gradient for Na⁺ transport into the cell.
3. Water is reabsorbed passively by osmotic gradient created by Na⁺ movement.
4. H⁺ is exchanged with Na⁺ that causes acidification of bile.

Bile Acids and Salts

Bile Acids

There are two types of bile acids: primary and secondary.
1. The primary bile acids are cholic acid and chenodeoxycholic acid. The primary bile acids are formed in the hepatocytes from cholesterol.
2. Secondary bile acids are deoxycholic acid and lithocholic acid. The secondary bile acids are produced in the intestine where intestinal bacteria convert primary bile acids into secondary bile acids.

Bile Salts

Bile salts are Na⁺ and K⁺ salts of bile acids. Bile acids are conjugated with taurine or glycine to form taurocholic acid or glycocholic acid. These acids then combine with sodium and potassium salts to form Na⁺-taurocholate, Na⁺-glycocholate, K⁺-taurocholate, and K⁺-glycocholate, respectively.

Functions of Bile Salts

Bile salts are primarily responsible for absorption of fat and fat soluble nutrients. Therefore, bile deficiency causes steatorrhea. Bile salts perform following important functions.

1. Absorption of fat: Bile salts are essential for absorption of fat from intestine. This depends on formation of micelles by bile salts in the intestine. For their amphipathic (both hydrophilic and hydrophobic domains) property, along with lecithin and cholesterol, bile salts form cylindrical disks, called as micelles (for details, refer the chapter “Principles of Digestion and Absorption : Chapter 51”. Lipids are transported in micelles from the lumen to the membrane of intestinal mucusosal epithelial cells where micelle dissociates and lipids are absorbed.

2. Emulsification of fat: Bile salts are surface tension reducing agents. Along with phospholipids and monoglycerides, they cause emulsification of fat, which is essential for digestion and absorption of fat.

3. Source of bile acid: Bile salts are converted to bile acids in the intestine, which are then absorbed into portal blood. Thus, bile salts are important sources of bile acids that add to the bile acid pool of the body.

4. Bile secretion: Bile salts are important cholericins. They are constituent of bile and also they stimulate bile secretion.

7. Prevention of gallstone formation: Bile salts along with lecithin solubilize cholesterol. Thus, they prevent formation of stones in the gallbladder.

8. Physiological purgatives: Bile salts act as physiological purgatives. Constipation occurs in conditions of deficiency of delivery of bile into intestine as occurs in obstructive jaundice.

9. Stool color: Bile salts add natural brownish color to the stool.

Enterohepatic Circulation

Bile acids and salts are absorbed from the intestine and re-excreted in the bile, and this cycle is repeated so many times, which is called enterohepatic circulation of bile acids and salts.
Bile salts are produced in liver (200 to 500 mg/day) and conjugated. Conjugated bile salts (CBS) through biliary tract enter intestine.

From intestine, they are absorbed into the portal blood to reach liver.

Also, in the intestine CBS is deconjugated and unconjugated bile salt is absorbed into portal circulation.

The free bile acids in terminal ileum and colon by the action of bacteria are converted into secondary bile acids (SBAs), i.e., deoxycholic acid and lithocholic acid.

SBAs are also reabsorbed into portal circulation.

Thus, from gut, about 95% of secreted bile salts and bile acids are transferred back to liver via portal circulation, and only 200 to 500 mg/day of bile acids are excreted from stool.

From liver, again they are excreted through biliary tract into the intestine. This forms the loop-pathway for enterohepatic circulation (Fig. 42.2).

Enterohepatic circulation ensures preservation and reutilization of various substances. For example, bile salts are recirculated 4–12 times a day. The substances that undergo enterohepatic circulation include bile salts, bile acids, bile pigments, vitamin D, vitamin B₁₂, thyroxine, drugs, etc.

Importance of Enterohepatic Circulation

The primary function of enterohepatic circulation of bile acids and salts is to maintain the total bile acid pool of the body.

Total amount of bile acids (conjugated and unconjugated, and primary and secondary) in the body ranges from 2 to 4 g.

Bile acid is cycled several times a day during meals, so that a small pool of bile acid can efficiently provide enough bile salts to facilitate adequate lipid absorption from small intestine.

Though absorption of bile acids and salts from intestine occurs efficiently, some amount is lost with every cycle of passage through intestine. This accounts for loss of about 500 mg of bile acid daily, which is replenished by synthesis of new bile acids from cholesterol.

Thus, fecal excretion of bile acid accounts for an efficient medium for loss of body cholesterol.

Determinants of Enterohepatic Circulation

The major determinants of enterohepatic circulation of bile acids and salts are integrity of intestinal epithelium to reabsorb them and efficiency of hepatocytes to pick them up from portal blood.

Integrity of Intestinal Epithelium

Bile salts are absorbed mainly in the terminal ileum by an efficient carrier mediated process so that only a 5% of intestinal bile salts enter the colon. Also in the intestine, bacteria deconjugate the bile salts to bile acids, and bile acids are absorbed passively and easily as they are more lipophilic than bile salts.
1. Thus, *intestinal absorption of bile acids and salts into portal blood is an important determinant* of enterohepatic circulation of these substances.
2. Further, bacteria convert primary bile acids to secondary bile acids that are also absorbed into portal circulation. Therefore, lipid malabsorption occurs in chronic inflammatory conditions of intestine (Clinical Box 42.1).

**Effectiveness of Hepatic Uptake**

In the portal blood, bile salts are transported bound to HDL or albumin. Once they reach liver, hepatocytes efficiently pick-up bile salts from hepatic blood, which accounts for removal of more than 80% of portal bile salts.

1. This *hepatic uptake of bile salts is an important determinant* of secretion of bile salts in the bile.
2. Thus hepatic uptake is the determinant of efficiency of enterohepatic circulation of bile salts.

**Clinical Box 42.1**

Enteritis and hepatitis cause lipid malabsorption: Bile salts are absorbed mainly in the distal ileum and bile salts promote lipid absorption. Therefore, inflammation of lower part of small intestine (enteritis) that inhibits absorption of bile salts in intestine results in loss of large quantity of lipid in the stool (due to malabsorption of fat). Similarly, inflammation of liver (hepatitis) impairs the uptake of bile acid and salts from portal blood that in turn decreases their secretion in the bile. This also can cause intestinal malabsorption of fat.

---

**BILE SECRETION**

**Mechanism of Secretion**

The secretion of bile consists of *canalicular flow* and *ductular secretion*. In the canaliculi, bile acids and Na⁺-K⁺-ATPase contribute to bile flow. In the ducts, epithelial cells secrete HCO₃⁻ and Cl⁻ actively into the lumen.

**Mechanism of Bile Acid Secretion**

Bile is formed in hepatocytes. Bile acids are taken up from the sinusoidal blood by transport proteins that are present on the basolateral membrane of the hepatocytes.

1. In cytoplasm of hepatocytes, bile acids bind with *bile acid binding proteins*. This *prevents bile acids to accumulate in higher concentration* in cytoplasm. It should be noted that high concentration of free bile acids destroys the organelles of hepatocytes.
2. Bile acids are *conjugated with glycine or taurine* and then *secreted into the lumen of hepatic canaliculi by facilitated diffusion*.
3. Bile acids move into the bile down their electrochemical gradient. The concentration gradient is maintained by formation of *micelles in the bile* present in the canaliculi.

**Mechanism of Water and Electrolyte Secretion**

Water and electrolyte concentration of bile in the bile canaliculi is same with that of plasma.

---

1. The bile duct epithelial cells secrete bicarbonate rich fluid into the lumen.
2. The ions are transported in a similar way to that of pancreatic extralobular ducts.

**Modification of Bile in Gallbladder**

Bile is continuously synthesized and secreted from liver and is stored in the gallbladder. Gallbladder is a small sac like structure with the capacity of 30–60 mL. Gallbladder performs **three functions**:

1. **Storage of bile**
2. **Acidification of bile**: The hydrogen ion is secreted from gallbladder epithelial cell into the bile to make the bile acidic.
3. **Concentration of bile**: H⁺ is secreted into the lumen of gallbladder in exchange for Na⁺ (Na⁺-H⁺ exchanger). For Na⁺ transport into the cell, the gradient is created by Na⁺-K⁺ pump located in the basolateral membrane of the epithelial cells. Water is reabsorbed from the gallbladder bile so that bile is concentrated (Fig. 42.3).

**Regulation of Bile Secretion**

Bile secretion is influenced by choleretics and cholagogues.

---

**Clinical Box 42.1**

Enteritis and hepatitis cause lipid malabsorption: Bile salts are absorbed mainly in the distal ileum and bile salts promote lipid absorption. Therefore, inflammation of lower part of small intestine (enteritis) that inhibits absorption of bile salts in intestine results in loss of large quantity of lipid in the stool (due to malabsorption of fat). Similarly, inflammation of liver (hepatitis) impairs the uptake of bile acid and salts from portal blood that in turn decreases their secretion in the bile. This also can cause intestinal malabsorption of fat.
Choleretics
The substances that enhance the secretion of bile are called choleretics. The important choleretics are:
1. Bile salts
2. Secretin
3. Vagal stimulation.
   Secretin increases aqueous component of bile.

Cholagogues
The substances that cause contraction of gallbladder to increase the output of bile from the structure are called cholagogues. The important cholagogues are:
1. Cholecystokinin
2. Fatty acids.
   Cholecystokinin causes contraction of smooth muscles of gallbladder and empties its contents.

Functions of Bile
Functions of bile are mainly due to presence of bile salts in it.
1. Bile helps in absorption of lipids from intestine by forming micelles.
2. Bile salts in bile are important choleretics (increase bile secretion).
5. Bile pigments (bilirubin and biliverdin) are responsible for greenish-yellow coloration of gallbladder that helps to identify the organ especially in small animals.
6. Bile salts are physiological purgative.

APPLIED PHYSIOLOGY

Gallstones
Presence of stone in the biliary tract (gallbladder, and bile ducts) is called gallstone or cholelithiasis. Gallstone is commonly associated with five Fs: females, forty to fifty age, fair looking individuals, fertile ladies, and fat people.

Types
There are two types of stones: cholesterol stones and calcium bilirubinate stones. In USA and Europe, 85% of stones are cholesterol stones (pigment stones). Bile salts along with lecithin solubilize cholesterol. Thus, they prevent formation of stones in the gallbladder. When cholesterol concentration is high or bile concentration is less, cholesterol stone develops.
   Factors that favor stone formation are:
1. Bile stasis. Decreased bile flow or decreased gallbladder emptying facilitates stone formation.
2. Supersaturation of bile with cholesterol.
3. Nucleation factor that favors formation of stones from the supersaturated bile. Glycoproteins in gallbladder mucous form the nucleus surrounding which gallstones are formed.
   Usually cholesterol stones are big and may be one or two stones are present in gallbladder. The calcium bilirubinate stones are multiple, and more than 50 stones may be present in gallbladder of the patient (Fig. 42.4).

Features
Usually, gallstones are silent stones. But, when stones come out of the gallbladder and pass through the biliary ducts, severe colicky or spasmodic acute abdominal pain occurs.
1. Chronic gallstones may present with acute cholecystitis, bile stasis inducing inflammation of gallbladder.
2. The stone may induce inflammation and edema of gallbladder, resulting in chronic cholecystitis (Fig. 42.4).
3. Gallstones may also present with obstructive jaundice.

Diagnosis
Diagnosis is usually made by ultrasound or cholecystography. Plain X-ray may sometime detect stones.

Treatment
There is no effective medical treatment, though many drugs have been advocated to dissolve stone. Gallstones are treated surgically by removal of gallbladder (cholecystectomy).

Effects of Cholecystectomy
Gallbladder is not absolutely essential for digestive functions. The patients those who have undergone cholecystectomy, maintain normal health and usually their nutrition is not affected. Only problem they face is the steatorrhea, if they eat excess of fat food. Cholecystectomized patients tolerate fat foods to some extent. It decreases body fat and may be beneficial for obese people.
CHAPTER SUMMARY

Key Concepts
1. Bile is required for absorption of fat from intestine.
2. Enterohepatic circulation of bile salts and bile acids prevents loss of important metabolizes from the body and ensures their reutilization.
3. Cholecystectomy is not detrimental to health, and may be useful in the treatment of obesity.

Important to Know (Must Read)
1. In examinations, usually Long Questions are not asked from this chapter. However, ‘Mechanism and regulation of bile secretion’ may sometime come as a question.
2. Bile salts, Bile acids, Functions of bile salts, Enterohepatic circulation, Mechanism of bile secretion, Regulation of bile secretion, Choleretics and cholagogues, may come as Short Questions.
3. In Viva, examiner may ask…… Name bile salts and tell their functions, Name bile acids and tell their functions, Composition of bile and functions of bile, What is enterohepatic circulation and what is its importance, What are the common substances that undergo enterohepatic circulation, Mechanism of bile secretion, Regulation of bile secretion, Name choleretics and cholagogues, Cause, types and features of gallstones.
4. “Enterohepatic circulation” is usually asked as a short note, or in viva.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Appreciate the importance of intestinal secretion in digestion and absorption of nutrients.
2. Understand the mucosal modifications in intestinal epithelium to increase the surface area for absorption.
3. Give the composition and functions of intestinal secretion.
4. Understand the importance of intestinal flora in GI physiology.
5. Learn the physiological basis of malabsorption syndrome.
The student MAY be also able to:
1. Describe the details of mechanism and regulation of intestinal secretion.

Functional Anatomy

Small intestine consists of duodenum, jejunum and ileum. It is the longest segment of GI tract, which is about 285 cm (duodenum 25 cm + jejunum-ileum 260 cm) in adults. Though duodenum is well demarcated from jejunum, there is no distinct separation between jejunum and ileum. For its length and capacity, small intestine is the most important segment of GI system for digestion and absorption of all nutrients.

1. Secretion of small intestine is called succus entericus.
2. It contains most enzymes for carbohydrate, protein and fat digestion.
3. Small intestine secretes about 2–3 liters of isotonic fluid per day.

Intestinal Glands

As discussed in chapter 36, the intestinal wall has all the layers of the gut (Refer to Fig. 36.3): serosa, outer longitudinal and inner circular muscle layers, submucosa, muscularis mucosa, and mucosa (Figs. 43.1A and B). The mucosa is highly developed to contain villi and intestinal glands.

Intestinal secretion is produced by the glands in the small intestine. The intestinal glands are called crypts of Lieberkühn:

1. These are tubular glands present at the base of the villi. Throughout the length of small intestine, the mucous membrane is covered by villi. There are about 20–40 villi per square millimeter of mucosa (Fig. 43.2).
2. Each villus is a fingerlike projection covered by a layer of columnar epithelium and contains a network of capillaries and lacteals (lymphatics).
3. The villi have numerous microvilli on their surface that are called brush border. Brush border considerably increases the surface area for absorption.
4. Some quantity of secretion is also added by Brunner’s glands that are coiled acinotubular glands present in the duodenum in addition to crypts of Lieberkühn.
5. The intestinal mucosa is supported externally by thin layer of smooth muscle fibres, muscularis mucosae. The mucous membrane is thrown into folds or plicae which are more in the jejunum and less in the ileum, thus increasing the absorptive surface enormously.

Scientist contributed

Johann Nathanael Lieberkühn (1711–1756) was a German physician and physiologist. Initially he studied theology, then physics (mechanics) and then medicine. He served as a MEDICAL professor and medical doctor. Besides his physiological work, Lieberkühn was most known for his preparation of medical specimens—these were still presented up to the nineteenth century, especially in Moscow, as masterpieces. The Crypts of Lieberkühn (intestinal glands) are named after him, which he first described these in detail. He had developed microscopes for studying blood vessels were called ‘Wundergläser’, ‘wonder-glasses’ by his contemporaries.
Chapter 43: Intestinal Secretion

**Intestinal Mucosa**

The mucosa of small intestine contains lymphatic nodules (Peyer’s patches). There are also enterochromaffin cells, Paneth cells and undifferentiated cells in the intestinal mucosa (Fig. 43.3):

1. The mucous membrane of the intestine contains many valve-like folds called **valvulae conniventes**, which add to the surface area for absorption.
2. In intestine, the surface area for absorption is **increased by about 600 fold** by villi, brush border and valvulae conniventes.
3. **Paneth cells** are endocrine cells present in the crypts of Lieberkühn in their deeper part. They secrete **defensins**, the naturally occurring antibiotics that protect developing enterocytes against infections. Paneth cells also secrete **guanylin**.
4. The **undifferentiated cells** are the progenitor cells in the mucosa present in the crypts of Lieberkühn that...
form new epithelial cells, which migrate to the surface. The epithelial cells are continuously renewed by progenitor cells.

5. After the life span of about 2–5 days, enterocytes are sloughed along with mucosal cells. Shedding of these epithelial cells accounts for daily excretion of about 30 g of protein as the cells are protein-rich.

6. Goblet cells secrete mucus that form a gel solution on the surface of mucosa.

**Types of Cells in Villi**

The absorptive surface of intestinal mucosa is increased by the intestinal villi. Villi are finger like or leaf like projections which contain 3 types of cells:

i. **Simple columnar cells:** They perform absorptive function due to the presence of brush border consisting of large number of villi.

ii. **Goblet cells:** These are mucous secreting cells and are interspersed between the columnar cells.

iii. **Endocrine cells:** These are scattered in the villi as well as are widely distributed throughout the gastrointestinal tract. These cells are:
   a. Kulchitsky cells: After the name of its discoverer
   b. Enterochromaffin cells: Due to their resemblance to chromaffin cells of the adrenal medulla
   c. Argentaffin cells: As the intracytoplasmic granules stain positively with silver salts by reduction reaction (agyrophil cells, on the other hand, require the addition of exogenous reducing substances for staining)
   d. Enterochromaffin cells: As these specialized cells are considered to be part of APUD cell system (having common properties as amine content, Amine Precursor Uptake and Decarboxylation). APUD cells are considered to be endodermal in origin, while previously they were thought to be neural crest derivative. Other endocrine cells belonging to the APUD cell system are C-cells of the thyroid, chromaffin cells of the adrenal medulla, certain cells of the carotid body, bronchi, hypothalamus, pituitary and sympathetic ganglia.

Endocrine cells are heavily populated in the proximal small bowel as this is the most active site for absorption and secretory activities. They are sparse in the colon which is less active site for such functions.

**INTESTINAL SECRETION**

**Composition**

Daily secretion from small intestine varies from 1–2 liters:

1. Intestinal secretion is isotonic, watery and alkaline.
2. The pH is about 8. It consists of water (98.5%) and solids (1.5%).
3. The solids contain anions (HCO$_3^-$, Cl$^-$, PO$_4^{3-}$, and SO$_4^{2-}$), cations (Na$^+$, K$^+$, Ca$^{2+}$ and Mg$^{2+}$), enzymes (Table 43.1), and mucous.

4. Enterokinase is present in the brush border of enterocytes and is extruded with denudation of mucosal epithelium.

**Mechanism and Regulation of Secretion**

**Mechanism**

The exact mechanism of intestinal secretion is not clear:

1. The cations are secreted by active transport and anions are transported along with cations to maintain electroneutrality.
2. Water follows the ions to maintain osmotic balance.
3. Mucus is secreted by surface epithelial cells, Brunner’s gland and goblet cells are present in the mucosa of the intestine.
4. Mucin is the major component of mucus that forms a gel to cover the mucosal epithelium.
5. Mucous protects the intestinal epithelium and helps in smooth passage of chyme through the intestinal lumen. Mucous also traps bacteria and holds immunoglobulin.
6. Secretion of Brunner’s gland, a thick alkaline mucus protects duodenal mucosa from acidic chyme.

**Regulation of Secretion**

Intestinal secretion is mainly controlled by GI hormones and vagus nerve:

1. VIP stimulates secretion. Therefore, diarrhea is a major feature of VIPomas.
2. The vagal stimulation increases intestinal secretion.
3. Many toxins stimulate intestinal secretion (Clinical Box 43.1).

**Clinical Box 43.1**

**Cholera is a secretory diarrhea:** Cholera toxin increases cyclic AMP concentration in the enterocytes that stimulate active secretion of HCO$_3^-$ and Cl$^-$ into the lumen and produces watery diarrhea.

**Experiment to Study Intestinal Secretion**

In animal models, experiments are performed to study the rate and composition of intestinal secretion. In these animals, a loop of intestine is resected and both ends of the loop are connected to anterior abdominal wall in such a way that they open to outside. Thereafter, various stimuli are applied on the loop and their effects are studied. Such an intestinal loop is called Thiry-Vella loop.
Functions of Intestinal Secretion

1. Intestinal secretion helps in proper mixing of chyme. This provides suitable environment for digestion and absorption of food materials in the intestine.
2. Intestinal secretion contains enzymes for digestion of various nutrients.
3. Mucus of intestinal secretion protects intestinal epithelium from damage. It also traps and kills bacteria.
4. Mucus in the intestinal secretion contains immunoglobulins that play an important role in local defenses.
5. The alkaline secretion of Brunner’s gland protects upper intestinal mucosa from damage by acidic chyme.
6. Intestinal secretion helps in forward propulsion of chyme in the intestine.

Absorption of Water

Normally, about 8.5 liters of fluid is added to GI tract daily. However, only about 100 ml of water is excreted in the stool. Thus, GI tract absorbs more than 99.5% of water load presented to it per day. 75% of water absorption takes place in the distal part of small intestine (For details, see next chapter).

Intestinal Bacteria

Normally, a group of bacteria are present in the intestine. They constitute normal intestinal flora. These microorganisms are present mainly in the ileum than in upper part of the intestine. This is because the acidic content of duodenum and upper jejunum do not favor growth of bacteria:

1. The organisms in the flora mainly include E. coli, Enterobacter aerogenes and Bacteroids fragilis.
2. There are also few other bacteria like, cocci and bacilli of various types.
3. Normally, bacteria are lost in the stool and replaced in the intestine by their natural growth. However, excess loss of bacterial flora in diseases like acute diarrhea results in improper digestion and absorption (Clinical Box 43.2).

Functions of Intestinal Flora

Intestinal bacteria are essential for many gut functions:

1. Normal bacterial flora is essential for digestion and absorption of essential nutrients including vitamins, minerals, and water.
2. They synthesize vitamin K and B complexes.
3. They produce chemicals that help in formation of short chain fatty acids, which help in growth of the intestinal mucosa.
4. Some bacteria species like Salmonella inhibit inflammatory processes. They do so by inhibiting ubiquitination of I Ba, the step that helps the transcription of factor NF B to initiate inflammation. Bacteria also secrete anti-inflammatory cytokines like IL-10. Recently, commensal bacteria are genetically programmed to produce IL-10.
5. Some bacteria utilize substances like ascorbic acid and cyanocobalamin. Therefore, these vitamins are usually given in higher dosages.
6. Bile salts are converted to bile acids by intestinal bacteria, which are then absorbed into portal blood from intestine and colon. Thus, intestinal flora maintains bile acid pool of the body.
7. They impart brown color to the stool by forming pigments from bile pigments. Therefore, acholic (pale) stool is seen in biliary obstruction.
8. They produce gases that cause normal flatus. Normal flatus is required for normal distension and motility of intestine. Exaggeration or decrease flatus indicates abnormality in intestinal flora.
9. They also contribute to the odor of the feces. This occurs due to production of amines like indole and skatole by intestinal bacteria.
10. They contribute to plasma lipid level by interfering in absorption of LDL and cholesterol. Therefore, poorly absorbable antibiotic like neomycin that modifies bacterial flora decreases plasma cholesterol.

Though these bacteria are nonpathogenic and beneficial, their entry into systemic circulation can cause systemic sepsis as occurs in ionizing radiation that breaks the intestinal defense barrier. This results in radiation poisoning.

Clinical Box 43.2

Lactobacilli is used in treatment of diarrhea: Apart from antibiotics, lactobacilli are included as part of the treatment of severe acute diarrhea that causes loss of intestinal flora. Bacterial flora is not well developed in infants and is slowly established during early childhood. Therefore, lactobacilli treatment is a must in any acute gastroenteritis in children. Many antibiotics interfere in growth of intestinal bacteria. Hence, lactobacilli supplement is given along with higher antibiotics.

Applied Physiology

Malabsorption Syndrome

The commonest abnormality due to inappropriate intestinal secretion is malabsorption syndrome. However, malabsorption also occurs due to gastric, hepatic and pancreatic deficiencies.

1. In malabsorption due to intestinal causes, the digestive and absorptive functions of small intestine are impaired. The small intestine is very long (about 285 cm in adults). Therefore, unless the disease process significantly affects the adequate length of intestine, malabsorption does not develop. Similarly, only in surgical procedure that removes or bypasses more than 50% of the intestine, significant malabsorption occurs.
2. The common intestinal conditions that produce malabsorption are sprue (tropical sprue), celiac disease (gluten enteropathy), Crohn’s disease, Whipple’s disease and radiation enteritis (for details of malabsorption, refer the Chapter “Principles of Digestion and Absorption”).
3. In these conditions, hypoproteinemia develops early due to deficient absorption of amino acids.
Absorption of carbohydrate and fat is also impaired. Fat soluble vitamins (A, D, E, and K) are also not properly absorbed due to defective fat absorption. Excretion of large amount of fat (steatorrhea) results in bulky, pale and foul-smelling stool.

**Blind Loop Syndrome**

Though normal bacterial flora is essential for health, overgrowth of bacteria is harmful:

1. Such overgrowths occur when there is stasis of intestinal contents.
2. This condition is commonly observed in patients with **surgically created blind loops** of small intestine, which is popularly known as blind loop syndrome.
3. It causes **macrocytic anemia, malabsorption of vitamin B₁₂**, and steatorrhea.
4. Steatorrhea occurs due to excessive hydrolysis of conjugated bile salts by the bacteria.

---

**CHAPTER SUMMARY**

**Key Concepts**

1. Intestinal secretion is very useful for digestion and absorption of nutrients from intestine, as it contain enzymes for digestion of all types of nutrients. Therefore, nature has given a vast surface area for absorption by providing microvilli and brush borders.
2. Intestinal bacteria facilitate the process of digestion and absorption and help in synthesis of few vitamins.
3. 75% of water is absorbed in distal part of small intestine. Diarrhea occurs, if the secretion of water is increased or absorption of water is decreased.

**Important to Know (Must Read)**

1. In examinations, usually **Long Questions** are not asked from this chapter.
2. Intestinal glands, Intestinal mucosa, Intestinal endocrine cells, Mechanism and regulation of intestinal secretion, Composition and functions of intestinal secretion, Bacterial flora of intestine, may come as **Short Questions**.
CHAPTER 44

Secretion of Large Intestine

Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Appreciate the importance of physiology of the colon.
2. Understand the importance of colonic bacteria.
3. Learn the physiology of water absorption and secretion through GI tract.

The student MAY also be able to:
1. Describe the details of secretion from colon.

The secretion of large intestine is not considered so important physiologically as it does not help in digestion. The major function of large intestine is the absorption of water and electrolytes. It absorbs about 90% of its load (mainly water is absorbed) in the form of chyme presented to it from the ileum. Of about 2 liters of isotonic chyme that enters large intestine, only about 200 ml is excreted as feces.

Physiology of Colon

Functional Anatomy

Large intestine consists of cecum, colon and rectum (Fig. 44.1). Colon forms the major part of the large gut:
1. Length of colon (ascending, transverse, descending and sigmoid colon) in adult is about 110 cm.
2. The diameter of large intestine is bigger than small intestine, which favours slow passage of chyme through it and also absorption of maximum quantity of water during its passage.
3. There are no villi, though the mucosal epithelium is folded to give villi like appearance to some extent.
4. There are many crypts of Lieberkühn in the mucous membrane that secrete a solution isotonic to that of plasma.
5. There are numerous goblet cells in the mucosal epithelium that secretes mucous.
6. Lamina propria contains intestinal glands and submucosa contains lymphatic nodules (Fig. 44.2).
7. No digestive enzymes are secreted in the colon.

Colonic Secretion

Composition of Secretion

Secretion of large intestine contains mainly mucous secreted by goblet cells. It contains $\text{HCO}_3^-$ and $\text{K}^+$ in large amount and some amount of sodium and water. The pH is about 8.

Mechanism of Secretion

There are crypts in the mucous membrane that secrete a solution isotonic to that of plasma.
1. There are plenty of goblet cells that secrete mucous. Mucous secreted from goblet cells has following functions:
   - Protects intestinal mucosa
   - Help in stool formation
   - Lubricate the intestinal mass
   - Neutralize the acid which is formed by bacteria in the large intestine.
2. Water and bicarbonate are secreted in significant amount.
3. $\text{Na}^+$ is reabsorbed and $\text{K}^+$ is secreted in large amount.
4. The bacterial flora of large intestine is similar to that of small intestine.
5. About 90% water is reabsorbed from the intestinal contents:
   - Therefore, when content of large intestine passes very slowly or there is stagnation, constipation occurs due to absorption of more water that causes solidification of stool.
   - Conversely, when the contents pass faster due to increased motility, diarrhea occurs. Secretion of water and electrolyte in large quantity can also cause diarrhea.

Transfer of electrolytes and water: Large intestine can absorb \( \text{Na}^+ \), \( \text{K}^+ \), \( \text{Cl}^- \), glucose and certain vitamins. However, secretion of \( \text{K}^+ \) and \( \text{HCO}_3^- \) into the colon is more. Colon cannot absorb protein, fat or Ca\(^{2+}\). \( \text{Na}^+ \) is actively absorbed from the colon and water follows along the osmotic gradient generated by absorption of \( \text{Na}^+ \) and \( \text{Cl}^- \).

**Colonic Bacteria**

Colonic bacteria resemble the intestinal flora inhabiting ileum. They produce about 8 liter of gas per day that contributes to flatus and colonic motility. They have trophic effects on colonic mucosal growth. Ammonia is produced by colonic bacteria, which is detoxified in the liver. Hence, in severe liver disease, hepatic encephalopathy (suppression of brain activities) occurs.

**Organisms**

At birth, the colon is sterile but the colonic bacterial flora becomes established early in life. The micro-organisms habituating the colon are bacilli such as mainly *Escherichia coli* and *Enterobacter aerogenes*. Gas gangrene bacilli may be present.

**Functions of Colonic Bacteria**

The physiological role of colonic bacterial flora are:

1. **Synthesis of the vitamins**: Vitamins e.g. vitamin K, number of B complex vitamins and folic acid are produced by these colonic organisms.
2. **Production of gas**: \( \text{CO}_2 \), hydrogen sulphide, hydrogen and methane which contribute to the flatus, are produced by bacterial flora (Application Box 44.1)
3. **Smell of stool**: The smell of stool is largely due to sulphides.
4. **Acidic reaction of stool**: Organic acids formed from carbohydrates by bacteria causes slightly acidic reaction of the stool (pH 5 to 7):
   a. **Production of amines**: A number of amines are formed in the colon by bacterial enzymes that decarboxylate amino acids. These amines are *histamine* and *tyramine* which may be harmful if produced in excess quantity. *Indole* and *skatole* are responsible for the odour of the faeces.
5. **Colour of stool**: Pigments biliverdin and stercobilinogen formed from the bile pigments by the intestinal bacteria are responsible for the brown colour of the stool.
6. **Decrease blood lipids**: Intestinal bacteria play some role in *cholesterol metabolism* and decrease plasma cholesterol and LDL levels.

**Application Box 44.1**

**Excess gas production causes borborygmi**: The volume of gas normally found in the human gut is approximately 200 mL, and the daily production is 500–1,500 mL. In some individuals, more gas is produced in the intestine that causes cramps, borborygmi (rumbling noise) and abdominal discomfort.
Absorption of Water

Normally, about 1.5 liters of water is ingested per day and 7 liters is added from GI secretions per day. However, only about 100 ml of water is excreted in the stool daily. Thus, **GI tract absorbs more than 99.5% of water load** presented to it per day:

1. Water is not absorbed from mouth, esophagus, and stomach.
2. As most of the nutrients are absorbed mainly in the duodenum and jejunum, the osmolality of intestinal content which is about 600 mOsm/kg H₂O, decreases to about 200 mOsm/kg H₂O in the ileum and colon.
3. Therefore, **water is absorbed mainly from terminal ileum and colon** (Fig. 44.3) by osmotic gradient as osmolality of blood is about 290 mOsm/kg H₂O.

**PHYSIOLOGY OF RECTUM**

Rectum stores fecal materials. Role of rectum in defecation reflex is discussed in “Motility of Large Intestine”. Though, normally absorption of water from rectum is not significant, the **absorptive capacity is more** (Clinical Box 44.1)

**Clinical Box 44.1**

Rectal administration of drugs: The absorptive capacity of mucosa of colon and rectum is large. Therefore, sometimes drugs are administered through rectum. Rectal administration is more preferred in children. Drugs that are administered rectally include purgatives, sedatives, anesthetics, and tranquilizers. However, care should be taken to control the volume of enema introduced into rectum in children as excess water absorption can cause water intoxication.

**Fig. 44.3:** Water absorption in small and large intestines. Note, out of 8.5 liters of load of fluid to the intestine per day, about 75% of absorption takes place in small intestine (6.8 L) and about 25% occurs in large intestine (1.6 L). Thus, total 99.5% of water presented to gut, is absorbed to blood by intestine. Thus, intestine plays an important role in water homeostasis of the body.
CHAPTER SUMMARY

**Key Concepts**

1. Large intestine does not produce any enzyme for digestion of nutrients. However, significant quantity of water is reabsorbed from colon.
2. Colonic bacteria are involved in gas production that facilitates the process of bowel movement by distending the bowel and also they help in synthesis of few vitamins.

**Important to Know (Must Read)**

1. In examinations, no Long Question is asked from this chapter.
2. Colonic bacterial flora, Colonic secretion, Role of colon in water and electrolyte absorption, Absorption of water by intestine, may come as Short Questions.
3. In Viva, examiner may ask... Layers of wall of large intestine, Structure of large intestinal glands, Structure of large intestinal mucosa, Mechanism and regulation of colonic secretion, Types of bacteria in bacterial flora of intestine, Functions of bacterial flora in large intestine, How is water secreted and absorbed in different parts of the colon.
CHAPTER 45

Introduction to GI Motility

**LEARNING OBJECTIVES**

On completion of study of this chapter, the student **MUST** be able to:
1. Correlate the electrophysiology of smooth muscle with GI movements.
2. Draw a labeled diagram of slow wave of GI smooth muscle.
3. List the types of GI motilities and give their functions.
4. Understand the role of VARIOUS sphincters in GI tract.
5. Appreciate the applied aspects of physiology of GI motility.

The student **MAY** also be able to:
1. Describe the electrophysiological properties of GI smooth muscle.

**PHYSIOLOGY OF GI SMOOTH MUSCLES**

Movements of GI tract assist in propelling foodstuffs in the forward direction, breaking down foodstuffs into smaller particles and mixing of food with GI secretions for proper digestion and absorption. This is possible due to the presence of **smooth muscles** in the wall of the GI tract and presence of a developed system of **enteric motor neurons**.

1. GI smooth muscles are **unitary type** of smooth muscles.
2. The unique feature of GI smooth muscles is that they **contract spontaneously without external neural and humoral influences**.
3. They also **contract when stretched** without external innervation.
4. There is no structured neuromuscular junction.
5. GI smooth muscles are long (about 500 mm) and slender (5–20 mm in width).
6. They are arranged in bundles.

**Electrophysiology of GI Smooth Muscle**

**Types of Couplings**

There are three types of couplings: electromechanical, pharmacomechanical, and mechanomechanical.

**Electromechanical Coupling**

Like skeletal muscle, smooth muscle have electromechanical coupling. That means, depolarization of the membrane causes opening of voltage-gated Ca\(^{++}\) channels and increases cytosolic calcium, which leads to muscle contraction.

**Pharmacomechanical Coupling**

In addition, smooth muscles have an additional mechanism of pharmacomechanical coupling, in which binding of a ligand to its receptor on the muscle membrane leads to opening of Ca\(^{++}\) channels and increase in cytosolic calcium without change in membrane potential.

**Mechanomechanical Coupling**

Stretch of smooth muscle causes muscle contraction, which is known as mechanomechanical coupling. Stretch on muscle opens stretch-sensitive calcium channel on the muscle cell membrane. Calcium influx causes muscle contraction.

**Syncytial Tissues and Pacemaker Tissues**

GI smooth muscles have numerous gap junctions that easily transmit electrical impulse from cell to cell. This accounts for the syncytial nature of smooth muscle in GI...
tract. There are also pacemaker tissues in GI tract that generate and spread electrical impulses.

**Basic Electrical Rhythm and Slow Waves**

Resting membrane potential (RMP) of smooth muscle of GI tract exhibit wide range of fluctuation.

1. The electrical slow waves are wide spontaneous rhythmic fluctuations in the membrane potential ranging between –65 and –40 mV (Fig. 45.1).
2. The slow waves, which oscillate significantly are called basal electrical rhythm (BER) that occurs due to wide variation in the RMP of GI smooth muscles.
3. The BER is present in all parts of GIT except in the esophagus.

**Slow Waves**

Slow waves in many regions of GI tract represent only as BER, whereas at other places like gastric antrum and intestine, they trigger action potential.

1. Slow waves are generated by the interstitial cells of Cajal located between the longitudinal and circular muscle layers.
2. Interstitial cells have long processes that form gap junctions with longitudinal and circular muscle cells. This enables easy and rapid conduction of slow waves from the interstitial cells into the smooth muscles.
3. The slow waves spread throughout the smooth muscles of each segment of GI tract.

**Phases of Slow Waves**

A typical slow wave has four phases (Fig. 45.2).

**Phase 1:** This is the rising phase (depolarization), which occurs due to opening of voltage gated Ca\(^{2+}\) channel.

**Phase 2:** This is the plateau phase that occurs due to balance between inward Ca\(^{2+}\) current and outward K\(^+\) current.

**Phase 3:** This is the falling phase (repolarization) occurring due to activation of voltage gated K\(^+\) channel.

**Phase 4:** Return to membrane potential.

**Frequency:** The frequency of slow waves is 3/min in stomach, 6 to 10/min in colon, 15/min in jejunum and ileum, and 18/min in duodenum (Fig. 45.3).

- The amplitude and the frequency of slow waves are influenced by the activity of extrinsic and intrinsic nerves, and by hormones.
- Usually, sympathetic stimulation decreases the amplitude and parasympathetic stimulation increases the amplitude of slow waves.

**Action Potentials**

When the peak of a slow wave exceeds the threshold, action potential is triggered from the peak (Fig. 45.4). These action potentials facilitate the force of contraction of smooth muscle.

1. Action potentials have longer duration (10–20 ms). Usually, they do not overshoot.
2. The rising phase of the action potential is caused by influx of Ca\(^{2+}\) and Na\(^+\).
Chapter 45: Introduction to GI Motility

3. The repolarization phase is due to $K^+$ efflux.
4. The magnitude and frequency of action potential are enhanced by vagal stimulation and inhibited by sympathetic stimulation.

Relationship between electrical and mechanical responses:
Slow waves that are not accompanied by action potentials do not elicit contraction, whereas, slow waves that are accompanied by action potentials evoke contraction. The greater the frequency of action potential (that occur at the peak of slow waves), the more intense is the contraction (Fig. 45.5).

**Electrical Coupling between Cells**
The smooth muscle cells of the GIT are well coupled (better coordinated). Electrical charge spreads rapidly from cell to cell. However, the electrical coupling between circular cells is better than the longitudinal cells because the circular cells have more gap junctions.

**Enteric Motor Neurons**
Enteric motor neurons innervate the smooth muscles of GI tract and are the final pathway for output of information from autonomic nervous system (ANS) and enteric nervous system (ENS) to the muscle cells (Fig. 45.6).
1. They neither form regular neuromuscular junctions nor do they release neurotransmitters at their axon terminal. Rather, most of motor axons release neurotransmitters from varicosities that occur all along their axon, during propagation of an action potential, and the neurotransmitter diffuses to reach the muscle or interstitial cells (refer to Fig. 36.6, Chapter 36).
2. The major excitatory neurotransmitters are acetylcholine and substance P, and inhibitory neurotransmitters are catecholamines, ATP, VIP, and NO.
3. Cell bodies of excitatory motor neurons are present in the myenteric plexus and the axons project aborally to innervate muscle fibers.
4. There are also secretomotor neurons that stimulate secretion of water, electrolytes and mucous from GI tract. The cell bodies of secretomotor neurons are present in the submucosal plexus.
5. Stimulation of secretomotor neurons release histamine during allergic reactions and produce neurogenic secretory diarrhea during stress.

**BASIC PATTERNS OF GI MOTILITY**
GI motility is required for propulsion, trituration (crushing and grinding), and mixing of food. Propulsion of food is achieved by peristaltic movement; trituration and mixing are accomplished by retropulsive and segmental movements.
Section 5: Gastrointestinal System

Peristalsis

**Definition**

This is a reflex response of GI tract to stretch, which results in organized propulsion of luminal content of the gut in forward direction. This response is present in all parts of GIT starting from esophagus to rectum. When the gut wall is stretched by the contents of its lumen, peristalsis is initiated.

**Mechanism**

Stretch initiates a circular ring like contraction behind the stimulus (i.e. the part before the area of distension) and relaxation in front of it.

1. The part behind the stimulus is called **propulsive segment** as it propels the bolus of food or chyme and the part ahead of the stimulus is called **receiving segment** as it receives the bolus (Fig. 45.7).

2. In the propulsive segment, the circular muscles contract and longitudinal muscles relax, and in receiving segment the circular muscles relax and longitudinal muscles contract.

3. The contraction wave then moves in forward direction, i.e. from oral to anal direction. It helps in propelling the contents aborally.

**Role of Cholinergic Neurons**

The local **cholinergic neurons** play an important role in the transmission of peristaltic waves.

1. Cholinergic neurons that are **present in a retrograde direction** (with cell bodies toward anus and terminals toward oral cavity) activate the neurons that release **substance P and acetylcholine**. These neurons **stimulate circular muscle contraction**, and help in formation and progression of contractile ring behind the stimulus.

2. Cholinergic neurons that are **present in antegrade direction** (cell bodies toward oral cavity and terminals toward anus) activate the neurons that secrete **VIP and nitric oxide**. These neurons assist in ensuing **relaxation of circular muscle** in the portion of the gut ahead of the stimulus.

**Factors Influencing Peristalsis**

The normal rate of transmission of peristaltic wave varies in different parts of GI tract, ranging between 2–15 cm/s. This is influenced by intrinsic and extrinsic nerve supply.

1. **Sympathetic stimulation** inhibits peristalsis and **parasympathetic stimulation** enhances it. Though the transmission of peristalsis is affected by autonomic influence, its **genesis is independent of it**.

2. It is affected by the **hormones** secreted locally. **Serotonin**, secreted by local stretch of gut enhances peristalsis.

**Migrating Motor Complex**

During the interdigestive period, the electromechanical activity of GI smooth muscles is altered. A cycle of motor activity migrates from stomach to distal ileum. This is called migrating motor complex (MMC) or **long (mass) peristalsis**.

**Phases**

MMC has three phases:

**Phase-I:** The quiescent phase

**Phase-II:** The period of irregular electrical and mechanical activity.

**Phase-III:** The period of burst of electrical activities.

Usually it originates in the stomach and transmitted aborally at a rate of 5 cm/min. It occurs at an interval of 90 min, after which the cycle is repeated.

**Significance**

MMC occurs in the **interdigestive phase**.

1. The phase III of MMC results in long peristalsis, which starts from stomach and terminates in distal part of the ileum. Therefore, it sweeps the gastric and intestinal contents into the large intestine. Consequently, MMC is alternatively called **sweeper of GI tract**.

2. This clears the stomach and intestine of their luminal contents, so that they are ready to receive and digest the next meal whenever ingested.

3. Characteristically, MMC immediately stops when food is ingested.
Retroperistalsis

Normally, peristalsis moves in forward direction. However, if there is an obstruction in the lumen, reverse peristalsis occurs. This is called retroperistalsis.

1. Vomiting occurs due to retroperistalsis.
2. Retroperistalsis is also initiated by emotional factors or due to stimulation of medullary vomiting centers.

Segmentation

This commonly occurs in small intestine.

1. It is characterized by closely spaced contraction of the circular muscle layer.
2. These contractions divide the small intestine into many segments. Therefore, the movement is called segmentation.
3. It is primarily meant to mix chyme with pancreatic and intestinal secretions and also bring the fresh chyme into contact with the mucosal surface.
4. Therefore, segmentation is also called mixing movement (for details, refer to “Intestinal Motility”).

ROLE OF SPHINCTERS

Sphincters are rings of smooth muscles that remain in a state of continuous contraction. There are anatomical and physiological sphincters. Upper esophageal sphincter is an example of physiological sphincter, which prevents esophageal content to regurgitate back into oral cavity. Anatomical sphincters are located at gastroesophageal, gastroduodenal and ileocecal junctions, and at the opening of bile duct in the duodenum and opening of rectum into anus. Thus, sphincters:

1. Separate two specialized compartments,
2. Regulate movement of content from upper compartment to lower compartment,
3. Prevent backward movement of content from lower to upper compartment.

Usually, when wall of the gut contracts sphincters relax and when gut wall relaxes sphincters relax. Hence, sphincters regulate coordinated propulsion of contents aborally. They also mediate reflex activities like gastrocolic, gastroileal reflexes, etc.

CHAPTER SUMMARY

Key Concepts

1. Electrical slow waves that oscillate significantly in GI smooth muscles are called basal electrical rhythm (BER). BER is due to the wide variation in RMP in GI smooth muscle.
2. Number of spikes on slow waves determines the magnitude of contraction.
3. Peristalsis is the propulsive movement and segmentation is the mixing movement.

Important to Know (Must Read)

1. In examinations, no Long Question is asked from this chapter. However, “Describe the electrical properties of GI smooth muscles”, may come as a long question.
2. Basal electrical rhythm of GI smooth muscle, Slow waves of GI smooth muscle, Enteric motor neurons, Migrating motor complex, may come as Short Questions.
3. In Viva, examiner may ask…. What are the specialities of electrical activity of GI smooth muscles, What is basal electrical rhythm of GI smooth muscle, Slow waves of GI smooth muscle, Organization of enteric motor neurons, Function and mechanism of peristalsis, segmentation, retroperistalsis, and migrating motor complex.
LEARNING OBJECTIVES

On completion of study of this chapter, the student MUST be able to:
1. List the functions of mastication.
2. Understand the mechanism of deglutition.
3. Appreciate why one should not speak while eating.

The student MAY also be able to:
1. Describe the mechanism of deglutition reflex.

CHEWING (MASTICATION)

Chewing or mastication is mostly a voluntary activity. The process of mastication is initiated usually reflexly following the arrival of food in the mouth.

Mastication has following functions:
1. Mastication cuts and grinds larger food particles into smaller particles.
2. It increases salivary secretion (Application Box 46.1).
3. It mixes food with saliva.
4. It lubricates content of the oral cavity, so that swallowing becomes easier.
5. It breaks down starch and allows saliva to mix with the broken starch particles. Therefore, chewing improves the taste of starch containing foods.
6. It improves dental strength and hygiene. To keep the teeth strong and in good health, dentists always encourage chewing of food adequately before swallowing. Chewing occurs due to forceful contraction of four groups of muscles of mastication.

- Masseter elevates mandible and helps in clenching of teeth.
- Temporalis helps in retracting mandible.
- Pterygoids (external and internal) protrude mandible and depress chin. This helps in opening the mouth. Alternative contractions of right and left pterygoids help in grinding movements.
- Buccinator prevents accumulation of food between cheek and mouth.

Application Box 46.1

Food should be chewed adequately before swallowing: Mastication breaks the larger food particles into smaller particles. Mastication is the major stimulus for salivary secretion. More saliva is required for a smooth swallowing. Digestion of salivary amylase takes place in the stomach. More quantity of saliva facilitates more breaking down of food particles so that the work load on stomach for grinding food becomes less, and grinding and mixing of becomes easier. This helps in easy digestion of food. Therefore, it has been said that one should chew 32 times before swallowing. As it is always not possible to chew 32 times, chewing should be done at least 10 times.

SWALLOWING (DEGLUTITION)

Swallowing or deglutition is the process by which the food material from oral cavity is transported into esophagus. Though it is initiated voluntarily, most part of it is involuntary or reflexive. Therefore, this is also called deglutition reflex.

1. During the reflex act of deglutition, respiration is inhibited, which prevents entry of food into the trachea.
2. The receptors for deglutition reflex are present near the opening of the pharynx.
3. The afferent impulses are transmitted to deglutition centers in medulla and pons.
4. The efferent impulses are directed to the muscles of pharynx and upper esophagus via cranial nerves.
Chapter 46: Chewing and Deglutition

399

Stages of Deglutition
Swallowing is divided into three stages (phases): oral phase, pharyngeal phase, and esophageal phase. Oral phase is voluntary and pharyngeal and esophageal phases are involuntary.

Oral Phase
This is also called buccal phase. This is the voluntary phase of swallowing. It is initiated when the tongue separates a bolus of food from the mass of foodstuff present in the mouth. At the beginning, the tip of the tongue presses against the hard palate and then the body of tongue presses on it. This action of the tongue moves the food backward in the oral cavity. Thus, the food bolus is forced into the pharynx. Once the food touches the receptors at the pharyngeal opening, swallowing reflex is initiated.

Pharyngeal Phase
The major objective of pharyngeal phase is to push food bolus into the esophagus without its entry into respiratory passage.

Reflex Pathway
Receptors: Receptors are present around the pharyngeal opening.

Afferent: Impulses from pharyngeal receptors are transmitted to centers through trigeminal, glossopharyngeal, and vagus nerves.

Centers: Centers for deglutition are nucleus tractus solitarius and nucleus ambiguous located in the medulla.

Efferents: Efferent organs are muscles of pharynx and tongue that are innervated by trigeminal, glossopharyngeal, vagus and hypoglossal nerves.

Events
The events in pharyngeal phase occur in sequence within few milliseconds (Figs. 46.1A to C).

1. The soft palate is pulled in upward direction. The palatopharyngeal folds move in inward direction. These movements prevent entry of food into the nasopharynx. This also provides a small passage for food to enter the pharynx.

2. Laryngeal opening is closed by vocal cords pulled together. The larynx moves forward and upward against the epiglottis. These events prevent entry of food into trachea (Clinical Box 46.1).

3. The superior constrictor muscles of pharynx constrict, which forces food to enter deep into the pharynx and then from there into the esophagus. Simultaneously, relaxation of upper esophageal sphincter (UES) occurs that allows the food to easily enter the esophagus.

4. During this phase, respiration is reflexly inhibited due to inhibition of respiratory centers. This is called deglutition apnea.

Esophageal Phase
Once food enters into esophagus, which is facilitated by relaxation of UES, the peristaltic wave (primary peristalsis) is initiated just below the UES.

1. Reflexly, UES contracts that prevent regurgitation of food back into the pharynx.

2. The peristaltic wave travels at about 3–5 cm/s. It takes about 10 seconds for food bolus to pass through the entire esophagus.

3. If the primary peristalsis is ineffective, a second peristaltic (secondary peristalsis) wave is initiated to push the food bolus. Motility of esophagus is discussed in detail in next chapter “Esophageal Motility”.

Clinical Box 46.1
Do not speak while eating: During, deglutition, respiration is temporarily arrested and food does not enter the respiratory passage. Laryngeal opening is closed by vocal cords pulled together. Larynx moves forward and upward against the epiglottis. Speaking or coughing during swallowing keeps the laryngeal outlet opened and therefore there is risk of food particle entering into the respiratory passage. Food or water entering into respiratory passage causes laryngeal and bronchial spasm. Sometimes it may cause sudden respiratory arrest and death. Therefore, one should eat in silence and concentrate on the universal energy that he receives through the food.

Disorders of Deglutition
1. Decreased or Absence of deglutition reflex: If deglutition reflex is impaired or abolished, regurgitation of
### Chapter Summary

#### Key Concepts

1. Though swallowing is a voluntary process, most of it is a reflex phenomenon.
2. Laryngeal opening closes during deglutition, preventing entry of food into the respiratory passage. Speaking or coughing during eating allows food to enter the trachea and may cause choking in severe cases.
3. Mastication increases salivary secretion and facilitates swallowing and digestion in the stomach. Therefore, food should be chewed enough before swallowing.

#### Important to Know (Must Read)

1. In examinations, no Long Question is asked from this chapter.
2. Deglutition reflex may come as Short Questions.
3. In Viva, examiner may ask... Functions of mastication, phases of deglutition, afferent and efferent pathways and mechanism of deglutition in each phase, Problems of deglutition.

---

- Air swallowed is usually transferred to lower part of GI tract, but partly air is regurgitated into the oral cavity (belching). Most of it passes down to the colon and is then expelled as flatus through the anus.

2. **Aerophagia**
   - Aerophagia is an unavoidable swallowing of air along with swallowing of food bolus and liquids.
   - It is seen in nervous individuals who have decreased tone of the upper oesophageal sphincter.

3. **Dysphagia**: Dysphagia is difficulty in swallowing due to any cause. Usually it occurs in acute and severe pharyngitis. But it can occur due to motor problems in pharynx, upper esophagus or foreign body, acute inflammation in oral cavity.
Esophageal Motility

CHAPTER 47

Learning Objectives

On completion of study of this chapter, the student MUST be able to:

1. Understand the functions of lower and upper esophageal sphincters.
2. Learn the mechanism of esophageal peristalsis.
3. Understand the physiological abnormalities in reflux esophagitis and achalasia cardia.

Esophagus serves as a conduit to transfer food from pharynx into the stomach. Once food enters the esophagus, reflex contraction of esophagus is initiated that transports food into the stomach.

Functional Anatomy

Parts of Esophagus

Esophagus is divided into three parts: upper esophageal sphincter, body of esophagus and lower esophageal sphincter.

1. In the upper part of esophagus, the muscles are striated (like skeletal muscles) muscles, in the lower part the muscles are smooth muscles and in the middle part, there is mixture of smooth and skeletal muscles (Fig. 47.1).

2. However, all esophageal muscles are mainly innervated by vagal fibers. Even the striated esophageal muscles receive vagal motor fibers.

Special Features

1. Esophagus differs from other parts of GI system for not having electrical slow waves to trigger contraction. Therefore, excitability of its muscle is low.
2. Muscles in the body of the esophagus are relaxed always, except during deglutition.
3. All muscle fibers including striated fibers are innervated by vagus nerve.
4. Activation of deglutition reflex initiates peristaltic contraction by neural mechanism (primary peristalsis) or presence of food bolus locally stimulates peristalsis (secondary peristalsis).

Esophageal Sphincters

Upper Esophageal Sphincter

Upper esophageal sphincter is mainly a physiological sphincter.
1. It reflexly relaxes to allow the food from pharynx to enter the esophagus.
2. However, once food has entered the esophagus, it constricts to prevent regurgitation of food back into the pharynx.

**Lower Esophageal Sphincter**

Lower esophageal sphincter remains tonically contracted. It relaxes only when food from the esophagus enters the stomach. Therefore, it always prevents reflux of food back into the esophagus from the stomach.

1. The significant fraction of basal tone of lower esophageal sphincter is contributed by vagal cholinergic fibers.
2. However, vagal fibers inhibit circular muscles of the sphincter in response to primary peristalsis that relays the sphincter and allows food to enter the stomach. This inhibitory action is mediated by stimulation of other neurons through activation of cholinergic vagal neurons that secrete VIP and nitric oxide (NO).

**ESOPHAGEAL PERISTALSIS**

Two types of peristalsis occur in esophagus: primary and secondary.

**Primary Peristalsis**

Primary peristalsis is initiated by deglutition reflex. In the third phase of deglutition, when food bolus enters esophagus, a ring of contraction appears just cephalad to the bolus, which pushes the bolus towards stomach. This is the primary peristalsis and it appears due to the act of swallowing whether or not food is present in the mouth. Even swallowing of saliva activates it.

**Secondary Peristalsis**

When primary peristalsis fails to push the bolus from the body of the esophagus, secondary peristalsis starts. Secondary peristalsis is initiated by activation of mechanoreceptors due to presence of food bolus in the esophagus. Experimentally, it can be induced by inflating a balloon in the body of the esophagus.

**Applied Physiology**

**Reflux Esophagitis and Barrett’s Esophagus**

Lower esophageal sphincter (LES) remains always tonically contracted except during swallowing when food in the esophagus stimulates esophageal peristalsis. The tonic contraction of LES prevents regurgitation of gastric content back into the esophagus.

1. When LES becomes incompetent, reflux of acid gastric content into esophagus produces esophagitis, known as reflux esophagitis.
2. Popularly, it is known as “heartburn” as the patient describes the pain in the retrosternal area. In the long run, it can cause stricture or ulceration of esophagus.

3. It is treated by proton pump blocker or H₂ receptor blocker.
4. Fundoplication may also be tried in this condition, in which a portion of the fundus of the stomach is wrapped around the lower esophagus so that LES remains inside a narrow tunnel of the stomach.

**Barrett’s Esophagus**

In few cases of chronic reflux esophagitis, the normal squamous epithelium of esophagus is replaced by columnar epithelium. This is called columnar metaplasia. This is a premalignant condition.

**Achalasia Cardia**

‘Achalasia’ means failure to relax. Normally, when food enters esophagus, esophageal peristalsis pushes food into the stomach. During this process, LES relaxes so that food easily passes into the stomach. However, in some individuals, resting tone of LES is high. Therefore, the sphincter fails to relax completely during deglutition. This causes inadequate emptying of esophagus and food collects in the esophagus and the organ is massively dilated. The condition is called achalasia cardia.

**Causes**

It occurs due to deficiency of myenteric plexus at LES in the esophagus. Also, the secretion of VIP and NO, the neurotransmitters that cause relaxation of GI muscles, is defective in this condition. Thus, resting tone of LES becomes high.

**Diagnosis**

Diagnosis is made by demonstrating rat tail in barium meal X-ray (body of esophagus is dilated and lower part is narrowed giving appearance of a rat) (Fig. 47.2) or by demonstrating retained food and fluid in esophagoscopy (Fig. 47.3)

**Treatment**

Treatment for achalasia is mechanical pneumatic dilatation of the sphincter.

1. In severe cases, surgical weakening of the sphincter by myotomy (incision of the esophageal muscle) is performed.
2. Also, administration of drugs that decrease tone of the sphincter has been successfully tried. For example, injection of botulinum toxin into LES that inhibits acetylcholine release produces relaxation of the sphincter.

**Aerophagia**

While eating and drinking, some volume of air is automatically swallowed. This is called aerophagia. A small volume of the swallowed air is removed by belching (regurgitation of air) and a volume of it enters into the intestine.
1. Intestinal and colonic bacteria add hydrogen, hydrogen sulfide, CO$_2$ and methane to this air that are expelled from rectum as flatus.
2. The daily production of gas by GI tract is about one liter.
3. The volume of gas present in GIT at any given time is about 200 mL as a large volume of produced and swallowed air is removed regularly as flatus.
4. The smell of the flatus is mainly due to the presence of sulfides.
5. Some individuals have more aerophagia or more production of gas. Disturbance in intestinal flora also leads to more gas production. These individuals develop abdominal discomfort and borborygmi (rumbling noises in the intestine and colon).

**CHAPTER SUMMARY**

**Key Concepts**
1. Esophagus is a unique structure having both striated and smooth muscle, and both the muscle are innervated by vagus nerve.
2. Esophagus does not exhibit electrical slow waves.
3. Esophageal peristalsis is initiated by swallowing, which may be air, or saliva, and need not be food.
4. Relaxation of LES mediated by VIP and NO released from vagal neurons.

**Important to Know (Must Read)**
1. In examinations, no Long Question is asked from this chapter.
2. Esophageal peristalsis may come as Short Questions.
3. In Viva, examiner may ask…… Special features of esophageal muscles, Esophageal sphincters, Types and mechanism of esophageal peristalsis, Causes and treatment of achalasia cardia and reflux esophagitis.
Functionally, stomach is divided into two parts: the **proximal stomach** (consisting mainly the body of the stomach), which acts as a reservoir, and the **distal stomach** (consisting mainly the antrum of the stomach), which acts as a pump.

1. The **proximal stomach**, for its property of **receptive relaxation**, receives and stores food, and for its **tonic contractions** pushes food toward the antrum.
2. The **distal stomach** for its property of **phasic contractions**, mixes, grinds, and breaks down food into smaller particles and regulates emptying of food into small intestine through gastroduodenal junctions.

Thus, **major objectives** of gastric motility are:
1. To allow the stomach to act as a **reservoir for storage of large amount of food** of a single meal.
2. To cut foodstuff into smaller particles and mix the food with gastric juice, the process in which **food is converted into chyme**.
3. To allow gastric contents to **enter the duodenum at a slow but controlled rate**, so that duodenum and jejunum being narrower tubes, handle the chyme appropriately.

**Scientist contributed**

William Beaumont (1785–1853) was a surgeon in the US Army who became known as the “Father of Gastric Physiology” following his extensive research on human digestion, gastric juice and gastric functions. He was the first scientist to systematically study the digestive processes in human beings. He was first physiologist to study gastric motility in a patient with a gastric fistula.

**FUNCTIONAL ANATOMY**

**Parts of Stomach**

As described above, for understanding gastric motility, stomach is divided into **two parts**: the proximal stomach and distal stomach (Fig. 48.1).

**Proximal Stomach**

The proximal part of stomach accommodates large volume of food (as large as 2 to 4 liters) without much increase in intragastric pressure.
Chapter 48: Gastric Motility

1. This becomes possible due to the phenomenon of receptive relaxation.
2. The contractile ability of fundus and body of stomach is normally poor. Therefore, food in fundus and body remains relatively unmixed for a longer duration.
3. Thus, the proximal stomach serves mainly as reservoir of food.

Distal Stomach
It consists mainly of the antrum.

1. The antrum, physiologically acts as a mechanical pump, which propels food towards the pylorus and helps in grinding and mixing of food.
2. Antral contractions break foodstuff into smaller particles and mix food thoroughly with gastric juice that help in partial digestion of food.
3. *Pyloric sphincter remains partially closed* and does not allow easy entry of gastric contents into the duodenum.
4. However, vigorous contractions of gastric antrum help gastric content enter the duodenum at a slow but controlled rate.
5. After grinding and mixing of food with gastric juice, the gastric content is now called chyme.

Structure of Stomach Wall
Stomach wall contains all general components of the wall of the GI tract.

1. However, the *circular muscle layer of the muscularis externa is more prominent* than the longitudinal layer.
2. In general, muscularis externa in fundus and body is thin and in antrum and pylorus is considerably thick. The *thickness of muscularis externa increases from body toward pylorus* (Figs. 48.2A and B). The highly developed muscle coat helps antrum work as effective pump.

Gastroduodenal Junction
The junction between the stomach and duodenum is called gastroduodenal junction. The pylorus separates antrum and duodenum. There is a sphincter in the pylorus consisting of a ring like thickening of circular muscle fibers, known as *pyloric sphincter*.

**Important functions** of gastroduodenal junction are:
1. To allow gastric contents to enter the duodenum at a slow and controlled rate (the rate at which duodenum is capable of possessing the chyme).
2. To prevent regurgitation of duodenal contents back into the stomach.

Gastroduodenal Mucosa
The duodenal mucosa is relatively resistant to bile acids but sensitive to gastric acid, whereas gastric mucosa is apparently resistant to gastric acid but sensitive to bile acids.

1. Therefore, in case of *incompetent pyloric sphincter*, regurgitation of duodenal content (containing bile acids) into the stomach usually results in *gastric ulcer*.
2. On the other hand, *rapid emptying of gastric contents* (containing acidic chyme) into the duodenum promptly causes *duodenal ulcer*.
3. Normally, as soon as acidic chyme from stomach enters the duodenum, the acidic pH stimulates release of secretin from S cells of duodenum and upper jejunum. Secretin stimulates pancreatic secretion rich in water and bicarbonate. Therefore, immediately the *acidic chyme is neutralized* by the aqueous component of pancreatic juice. This is the physiological mechanism that prevents formation of duodenal ulcer.
4. However, when gastric emptying is faster or secretion of pancreatic juice is less, the possibility of duodenal ulcer is more. Moreover, the content in the part of the duodenum above the sphincter Oddi does not get well mixed with pancreatic secretion.

Neural Control of Pyloric Part
The pylorus is richly innervated by parasympathetic (vagal) and sympathetic fibers.

1. Normally, *sympathetic stimulation causes constriction of pyloric sphincter*.
2. However, activation of *parasympathetic fibers have both stimulating and inhibiting effects*.
3. The stimulatory effects are mediated by cholinergic vagal fibers and the inhibitory effects are mediated by the *vagal fibers* that release VIP or nitric oxide (NO).
4. Constriction of pyloric sphincter also occurs in response to hormones like CCK, gastrin, GIP, and secretin. Therefore, these hormones slow gastric emptying.

Innervation of Stomach
Stomach is densely innervated by both the division of ANS and the neurons of the enteric nervous system.
1. Parasympathetic innervation (vagal fibers) stimulates whereas sympathetic innervation (fibers originate from celiac plexus) inhibits gastric motility and secretion.

2. Axons arising from intramural plexuses innervate smooth muscles and secretory cells.

3. Sensory fibers from stomach travel to CNS via vagal and sympathetic fibers. Some of the sensory fibers act as afferent link between the sensory receptors of the gastric mucosa and the intramural plexuses.

4. Few of these afferent fibers provide information about an intragastric pressure, gastric distention, chemical composition and pH of gastric content, and pain sensation originating in the stomach.

5. All these stimuli influence gastric motility.

**Electrophysiology of Gastric Motility**

The peristaltic waves in the stomach occur usually at the frequency of gastric slow waves. These peristaltic waves are generated by a pacemaker zone located in the middle of the body of the stomach. The frequency of peristaltic wave is about 3 per minute in human being and the waves are conducted from body toward pylorus.

1. The gastric slow wave has four phases that resemble the action potentials of cardiac muscle (Fig. 45.2; Chapter 45). However, it does not overshoot and last for a longer period (10 times that of cardiac action potential).

2. The smooth muscles of stomach contract when the depolarization of the slow wave exceeds the threshold for contraction.

3. The force of contraction depends on the degree, frequency and duration of depolarization.

4. Greater the depolarization and longer the muscle cells remain depolarized (above threshold), greater is the force of contraction.

5. In antrum of the stomach, action potential spikes occur in the plateau phase. The contractions that result from these action potentials are stronger than the contractions that occur in the absence of these action potentials.

6. Acetylcholine and gastrin improve gastric contractility by enhancing the amplitude and duration of the plateau phase of gastric slow waves. Norepinephrine inhibits by the opposite mechanism.

**TYPES OF GASTRIC MOTILITY**

The types of gastric movements are hunger contractions (movements of empty stomach), receptive relaxation, peristalsis, migrating motor complex and reverse peristalsis. The peristalsis of stomach results in a regulated gastric emptying.

**Hunger Contractions**

When, stomach is empty, motility of the stomach increases. If stomach is allowed to remain empty for a longer duration, contractions become vigorous. These contractions are called hunger contractions.

1. Usually, hunger contractions are distressing and painful.

2. The antral contractions are intense in such a situation and are associated with the relaxation of pyloric sphincter.

**Gastric Relaxations**

**Receptive Relaxation**

This is the relaxation of the fundus and body of the stomach in response to chewing and swallowing of food. Thus, stomach prepares itself to receive food (Fig. 48.3). The

---

Figs. 48.2A and B: Layers of the stomach wall. (A) Fundus and body of the stomach; (B) Antrum of the stomach. Note, muscularis externa is more developed in the antrum of the stomach (B) compared to the body of the stomach (A).

relaxation continues till food continues to enter the stomach, so that a large meal is easily accommodated in it.

1. Because of receptive relaxation, the intragastric pressure does not rise in spite of accumulation of a large volume of food.
2. The receptive relaxation is mediated by vagus nerve (Fig. 48.4). Normally, gastric motility induced by vagal stimulation is mediated by cholinergic fibers. However, receptive relaxation mediated by vagus is due to release of neurotransmitters like VIP and NO (non-cholinergic fibers) at its nerve ending.

Adaptive and Feedback Relaxations

There are other two types of gastric relaxations: adaptive and feedback.
1. The adaptive relaxation is the relaxation of stomach triggered by distension of stomach. Receptive relaxation starts even before food reaches stomach whereas adaptive relaxation occurs in response to stretching of stomach wall. This is mediated by vagovagal reflex (Fig. 48.4) and is meant to accommodate a greater volume of food.
2. The feedback relaxation of stomach is a reflexive relaxation that occurs due to presence of food in proximal segment of small intestine. Acidic chyme and fatty acid in intestine inhibit gastric motility by both hormonal and neural mechanisms that cause feedback relaxation of stomach (Fig. 48.4).

Peristalsis

After about half an hour following gastric filling, gastric peristalsis starts.
1. The peristaltic movements are initiated by gastric slow waves.
2. The pacemaker for gastric peristalsis is located in the middle of the stomach close toward greater curvature.

Migrating Motor Complex

During the interdigestive phase, antrum of the stomach remains silent for about 75–90 minutes, after which a burst of electrical and motor activities occurs.
1. This causes intense antral contraction with relaxation of pylorus. Therefore, the remaining gastric content is emptied into the duodenum.
2. The wave of contraction progresses from stomach toward terminal ileum. Thus, it helps in cleaning the stomach and intestine and keeps the GI tract ready for the next meal.
3. Usually, it is repeated every 90 minutes during interdigestive phase.

Reverse Peristalsis

Sometimes in abnormal situations, peristalsis occurs in reverse direction, which starts in the lower parts of the body and proceeds toward esophagus.
1. The lower and upper esophageal sphincters relax so that gastric content is forced out of esophagus and oral cavity.
2. This results in vomiting (described below).
GASTRIC EMPTYING

This is the process by which the content of the stomach is emptied into the duodenum. Usually, it occurs at a slow but controlled rate so that duodenum and jejunum comfortably accommodate and process the chyme at a desired rate.

Mechanism of Gastric Emptying

When food enters stomach, stomach relaxes due to receptive and adaptive relaxations. Later, after about half an hour, slowly gastric motility begins. Gastric emptying occurs by three mechanisms: peristaltic contraction, antral contraction, and retropulsion (Figs. 48.5A to D).

Peristaltic Contractions

The peristaltic contractions usually begin in the middle of the stomach and proceeds in a ring like fashion toward pylorus (Fig. 48.5A). These contractions mainly push food into the antral part of the stomach.

1. The velocity and magnitude of contraction increase as the contractile waves approach pylorus.
2. As contractions are weak in the fundus and body of the stomach, the proximal portion of stomach mainly serves the reservoir function. Therefore, usually proper mixing of food with gastric secretion does not occur in these parts of the stomach.
3. Major amount of mixing takes place in the antrum, as antrum contracts vigorously.

Antral Contractions

Antral contractions help thorough mixing of food with the gastric juice.

1. The forceful contraction of antrum forces gastric contents toward the pylorus. But, as the pyloric sphincter remains closed, peristaltic wave fails to push food into the duodenum, rather food returns back into the body of the stomach (Fig. 48.5B).
2. After few such contractions, pylorus opens partially with a narrow opening at the center.
3. Therefore, stomach empties in small squirts with each peristaltic wave.

Retropulsion

The terminal part of antrum exhibits rapid and forceful contractions that forces the chyme to be propelled back toward the proximal part of the antrum and body of the stomach (Fig. 48.5C). This movement is called retropulsion.

1. Retropulsion is very effective in mixing and grinding the larger food particles into smaller ones.
2. Then, pyloric sphincter partially opens and gastric pump slowly pushes food into duodenum (Fig. 48.5D).

Physiological Significance

As the muscle layers in the fundus and body are thin, contractions in these parts of the stomach are weak. Therefore, gastric content in body of stomach settles into different layers based on their density.

1. Fat content of the food forms an oily layer on the top of the other gastric contents. This is why fat is emptied slower than the carbohydrate and protein (Application Box 48.1).
2. Liquid portion of the food flow around the mass and enter the antrum, and from there into the duodenum. Therefore, liquid is emptied faster than the solid.

Application Box 48.1

A cup of fat is taken in cocktail party: As fat decreases gastric emptying, usually a cup of fat is ingested before drinking alcohol in cocktail party. Fat ensures slow gastric emptying and slow absorption of alcohol from intestine, and therefore the person drives his car back after the party, even after a heavy drink.

Regulation of Gastric Emptying

Gastric emptying is regulated by both neural and hormonal mechanisms. The upper part of the small intestine (duodenum and jejunum) contains receptors that detect change in pH, osmotic pressure, and products of fat and protein digestion. The chyme that enters duodenum is highly acidic and hypertonic and contains products of protein and fat digestion. All these stimuli influence gastric emptying.

1. Acid in the duodenum: With decrease in the pH of the duodenal content the rate of gastric emptying decreases.
This response is mediated by both neural and hormonal mechanisms. The acidic chyme in the duodenum releases secretin that decreases gastric emptying by inhibiting contraction of the antrum and by stimulating the contraction of pyloric sphincter.

2. **Products of fat digestion:** Products of fat digestion like fatty acids and also some fat molecules in the duodenal content inhibit gastric emptying. This response is mediated by CCK and GIP. CCK is secreted from duodenum and jejunum in response to fatty acids and it inhibits gastric emptying. GIP, which is released in response to fatty acids also inhibits gastric emptying.

3. **Osmolality of duodenal content:** The chyme entering into duodenum has higher osmolality. There are osmoreceptors in the mucosa of duodenum and jejunum that detect change in osmolality of the duodenal content. Hypertonic solutions in the duodenum release hormones that inhibit the rate of gastric emptying.

4. **Products of protein digestion:** Presence of peptides and amino acids in the duodenum release gastrin from the G cells located in the duodenum. Gastrin increases antral contraction but at the same time also causes constriction of pyloric sphincter. Therefore, the net effect is decreased rate of gastric emptying.

- The products of protein digestion also release CCK and GIP from duodenum and jejunum that inhibit gastric emptying.

5. **Volume of the meal:** Whenever a large amount of food is taken in a meal, the time taken for gastric emptying prolongs. However, if the volume is mainly due to liquid then emptying is faster.

6. **Stretching of duodenum:** Entry of chyme into the duodenum stretches the wall of duodenum. This initiates enterogastric reflex that inhibits gastric emptying. Enterogastric reflex is also activated by acid in the duodenum.

7. **Neural factors:** Vagal stimulation promotes gastric emptying. Therefore, **vagotomy produces gastric stasis.** Consequently, whenever vagotomy is performed for the treatment of peptic ulcer, usually a **drainage procedure** like pyloroplasty or gastrojejunostomy is also performed to ensure proper passage of food from the stomach into the duodenum (Clinical Box 48.1). **Sympathetic stimulation inhibits** gastric emptying.

8. **Hormonal factors:** Most of the hormones liberated from duodenum and jejunum like CCK, GIP, secretin, etc., inhibit gastric emptying.

**Clinical Box 48.1**

**Drainage procedure is done with vagotomy:** As vagotomy decreases gastric motility and produces gastric stasis, whenever vagotomy is performed as done for the treatment of peptic ulcer, usually a drainage procedure like gastrojejunostomy is also performed to ensure proper passage of food from the stomach into the duodenum.

### APPLIED PHYSIOLOGY

#### Dysfunctions of Gastric Emptying

**Delayed Gastric Emptying**

1. Gastric emptying is delayed in **autonomic neuropathy** as occurs in diabetes mellitus.
2. Paralysis of propulsive movements occurs following **vagotomy,** which is called **gastroparesis.** Therefore, a drainage procedure like pyloroplasty is performed to overcome post-vagotomy gastric stasis.
3. **Hypertrophic pyloric stenosis** can cause gastric stasis.

**Rapid Gastric Emptying**

Normally, vagus stimulation promotes gastric emptying.

1. Therefore, states of increased vagal activity increase emptying.
2. Conversely, **sympathetic stimulation inhibits emptying.** Therefore, loss of appetite is a feature of acute stress, a state of sympathetic overactivity.
3. Hormones like **thyroxine** stimulate gastric emptying and intestinal motility. Hence, increased appetite and hyperdefecation are features of hyperthyroidism.
4. Increased liquid content of food increases gastric emptying.

**Vomiting**

**Definition**

Vomiting is the expulsion of gastroduodenal content from GIT to the external environment via mouth.

**Associated Features**

Vomiting is usually preceded by the feeling of **nausea,** **tachycardia,** **sweating,** **pallor,** **dizziness,** and dilatation of pupils. It is associated with retching that forces contents of the stomach into the esophagus.

**Stimuli and Vomiting Centers**

Vomiting is a reflex phenomenon, the center for which is located in the medulla (Fig. 48.6).

1. The receptors present in many parts of the body provide inputs to the **vomiting center,** in the brainstem. Vomiting center present in the reticular formation of medulla consists of various scattered group of neurons that control different aspects of vomiting.
2. **Vestibular nuclei** mediate vomiting in response to motion sickness.
3. **Pharyngeal stimulation induces vomiting by activating nucleus tractus solitarius.**
4. **Area postrema** mediate vomiting activated by drugs (opiates, chemotherapeutic agents, etc.) and hormones (as in pregnancy).
5. Vomiting activated by emotion influenced by limbic and diencephalic inputs.

---

**Chapter 48: Gastric Motility**
The important stimuli that activate these afferent fibers are:
1. Distension of stomach
2. Tickling the back of throat
3. Painful injury of the genitourinary tract
4. Conditions associated with dizziness and nausea
5. Many chemicals or drugs can elicit vomiting.

**Emetics and Antiemetics**

Drugs that induce vomiting are called emetics. The common emetics are apomorphine, ipecac, etc.
1. These chemicals stimulate the receptors that are present in the CTZ (chemoreceptor trigger zone), located in area postrema, a V-shaped band of tissue on the lateral wall of the fourth ventricle.
2. Many antiemetics prevent vomiting by inhibiting CTZ.
3. There are 5-HT$_3$ and D$_2$ receptors in area postrema. Serotonin stimulates vomiting through 5-HT$_3$ receptors. Ondansetron, a 5-HT$_3$ receptor antagonist is an antiemetic.
4. Chlorpromazine, a D$_2$ receptor antagonist and haloperidol are also effective antiemetics.
5. Corticosteroids, cannabinoids, and benzodiazepines are useful antiemetics for chemotherapy-induced vomiting.

**Mechanism of Vomiting**

Vomiting reflex is executed in a sequence of events.

The steps of vomiting are:
1. Genesis of reverse peristalsis that starts from the middle of the jejunum. This sweeps the content of intestine and duodenum into the stomach.
2. Relaxation of the pyloric sphincter that allows the intestinal content to enter the stomach.
3. Forced inspiration occurs against the closed glottis. Lowering of the diaphragm increases intra-abdominal pressure.
4. This is followed by vigorous contraction of abdominal muscles. Thus, intra-abdominal pressure sharply increases, which forces the gastric contents to enter the esophagus.
5. Relaxation of the lower esophageal sphincter allows gastric content to enter the esophagus.
6. Normally, the upper esophageal sphincter remains closed and prevents regurgitation of food into the pharynx. With stronger retching and sharp rise in intra-abdominal pressure, upper esophageal sphincter relaxes, which allows chyme to enter the pharynx and then from there into the mouth. Entry of vomitus into the trachea is prevented by central movement of vocal cords, closure of glottis and inhibition of respiration.

**Dumping Syndrome**

This is a distressing syndrome consisting mainly of weakness, dizziness and sweating that develop in about **two hours after meal** in persons who have undergone gastrectomy or gastrojejunostomy (that bypasses stomach). This occurs due to **two causes**:
1. Hypoglycemia: Rapid entry of food into intestine causes quick absorption of glucose from intestine and produces prompt hyperglycemia, which in turn increases insulin secretion. Insulin produces hypoglycemia that produces weakness, dizziness, and sweating.
2. Hypovolemia: The speedy entry of hypertonic meal from esophagus directly into intestine produces **high osmotic load on intestine that transfers water from blood into the gut**. This produces hypovolemia, dehydration and hypotension that lead to weakness, dizziness and sweating.
CHAPTER SUMMARY

**KEY CONCEPTS**

1. The proximal stomach is mainly for receiving and storing food, and the distal stomach is meant for mixing and emptying food.
2. Antral contractions help in proper mixing and grinding food that finally becomes chyme.
3. LES sphincter partially opens in response to every antral pump activity so as to allow small quantity of chyme to be delivered to duodenum at a time.
4. Degree of distension and type of food mainly contribute to gastric emptying. Vagal fibers stimulate and sympathetic fibers inhibit gastric emptying.
5. Vomiting is mainly a central phenomenon initiated by stimulation of vomiting center in medulla, though local factors contribute to it.

**Important to Know (Must Read)**

1. In examinations, “Mechanism and factors affecting gastric emptying” may come as a Long Question.
2. Gastric relaxations, Reverse peristalsis of stomach, Electrophysiology of gastric smooth muscles, Gastric emptying, Vomiting, may come as Short Questions.
3. In Viva, examiner may ask... What are the parts of the stomach and what are their functions, Who is the Father of Gastric Physiology, What are the special electrophysiological properties of gastric smooth muscles, Types of gastric relaxations, What is the importance of receptive and adaptive relaxation, What is the mechanism of gastric emptying, What are the factor affecting gastric emptying, What is Retropulsion, What is the specialty of gastric peristalsis, Who is the pacemaker of gastric contractions, What is hunger contraction, What are the causes of rapid and delayed gastric emptying, Reverse peristalsis of stomach, Mechanism of vomiting, What is dumping syndrome and how is it treated.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:

1. Understand the importance of intestinal movements in mixing, propelling, and absorption of food materials in GI tract.
2. Name intestinal motilities, and give their mechanisms and functions.
3. Name the intestinal reflexes and give their functions.
4. Appreciate the physiological basis of motility disorders.

The student MAY also be able to:

1. Describe the detailed mechanism of intestinal movements.

The main objective of the motility of the small intestine is to **thoroughly mix the chyme** with the pancreatic, bile and intestinal juices so that proper digestion and absorption of the essential nutrients can take place. Intestinal motility also **propels chyme** into the colon.

**FUNCTIONAL ASPECTS**

The length of small intestine is about **three-fourths of the length** of the whole of the GI tract. It measures 285 cm.

1. It takes 2–4 hours for the chyme to traverse the small intestine.
2. Small intestine consists of duodenum, jejunum, and ileum. Duodenum is the first part of the intestine and constitutes 5% of it. Jejunum constitutes 40% and ileum constitutes more than 55% of the small intestine. However, there is no definite demarcation between jejunum and ileum.
3. The wall of small intestine have all the layers of the gut (refer to Figs. 36.3 and 36.4, Chapter 36). However, the **muscularis externa** consisting of outer longitudinal and inner circular muscles is well developed in small intestine (Fig. 49.1). This helps in effective intestinal motility.
4. Though the **lymphatic nodules** are less in jejunum, they are more in number in ileum, and they extend into the submucosa (Fig. 49.2).
Electrophysiology of Intestinal Smooth Muscles

The frequency of slow wave is maximum in small intestine that occurs regularly. The frequency is highest in duodenum (about 15 per minute) and decreases slowly toward ileum where it is about 8–10 per minute.

1. Slow waves are not always accompanied by bursts of action potential spikes. When slow wave is associated with spike, the contraction is stronger and in its absence (no spike), contraction is weaker or absent (refer to Fig. 45.5; Chapter 45).

2. A characteristic feature of slow waves of intestine is that they are localized to a short segment of the intestine. Therefore, contraction is also localized to the segments. This results in segmentation type of movement in the intestine.

3. The basic electrical rhythm is purely intrinsic.

4. The frequency of action potential spike, which determines the strength of muscle contraction, depends on excitability of the smooth muscles. The excitability in turn depends on autonomic innervation, activity of the enteric neurons and the circulating hormones.

5. Parasympathetic stimulation enhances and sympathetic stimulation inhibits intestinal contractility.

TYPES OF INTESTINAL MOVEMENTS

Intestinal movements carry out three primary functions:

1. **Mixing the chyme** with digestive secretions.
2. Bringing the chyme in contact with the absorptive surface of the microvilli to increase absorption.
3. Propelling the chyme toward colon.

These functions are achieved by various small intestinal motilities. The motilities are segmentation, peristalsis, migrating myoelectric complex, contraction of the muscularis mucosa, villus contractions, and movements due to intestinal reflexes.

**Segmentation**

This is the most common variety of movement of the small intestine.

1. It is characterized by closely spaced contraction of the circular muscle layer. These contractions divide the small intestine into many segments (Fig. 49.3A).

2. The rate of segmental contraction is same as the frequency of slow waves. It is about 18/min in duodenum, 15/min in jejunum, and 12/min in ileum.

3. Segmentation contractions effectively mix chyme with pancreatic and intestinal secretions.

4. Two nearby propulsive segments force the chyme toward each other into the receiving segment (Fig. 49.3B), which efficiently helps in mixing.

5. They also bring the fresh chyme into the contact with the mucosal surface.

6. Therefore, segmentation movements are also called mixing movements. They help in digestion and absorption of nutrients.

**Peristalsis**

Peristalsis is the progressive contraction of successive portions of circular smooth muscles of the small intestine.

1. The wave of contraction moves in orthograde direction, i.e. toward colon. In fact, peristaltic wave spreads in both directions. However, wave toward oral cavity (oral spread) dies out after a short distance, and wave...
toward colon (aboral spread) continues progressively. This is called law of the intestine.
2. Peristaltic waves involve only a short length of intestine. When chyme enters the intestine, the bolus of the chyme stretches its wall. The part of the intestine behind the chyme contracts and the part of the intestine in front of the chyme relaxes and the ring of contraction proceeds in forward direction (Figs. 49.4A and B).
3. The primary function of peristaltic movements is to propel chyme in forward direction. Sometimes, the frequency of peristalsis increases to an extent that intestinal contents are emptied very fast (with a speed of 20 cm/s) into the colon. This is called rush peristalsis. This is typically seen in acute diarrhea.
4. There are also antiperistaltic contractions of intestine. Antiperistalsis results in vomiting.

Short Range Peristalsis
Short range peristalsis also occurs in the intestine, but less frequently.
1. Short range peristalsis along with segmentation contraction decreases the net rate of propulsion of chyme in forward direction.
2. This allows the chyme to stay more time in intestine to facilitate digestion and absorption.

Clinical Significance
1. Administration of codeine decreases the motility of the intestine, therefore decreases the frequency of defecation.
2. The decreased motility also prolongs the transit time for the intestinal contents so that more water and nutrients are reabsorbed. Therefore, this also decreases the volume of stool.

Other Motilities

Migrating Myoelectric Motor Complex
In the interdigestive phase, the pattern of motility of small intestine changes.
1. There are bursts of intense electrical and contractile activity, once in about every 90 minutes. This is called migrating motor complex or migrating myoelectric complex (MMC).
2. MMC starts in the stomach and is propagated throughout the intestine to the terminal part of the ileum. Once, a MMC reaches the distal end of the ileum, a next MMC begins in the stomach. Likewise, MMC is repeated every 75–90 minutes.
3. MMC results in vigorous and strong propulsive contraction; therefore, this sweeps the intestine and empties the remaining contents into the colon.
4. MMC cleans the entire lumen of the stomach and intestine, to keep the house ready for the next meal. This is why the MMC is known as housekeeper of small intestine.
5. MMC also inhibits the migration of colonic bacteria into the intestine.

Contraction of Muscularis Mucosa
The muscularis mucosa of small intestine contracts irregularly. These contractions alter the patterns of the mucosal folds.
1. Contractions occur at a frequency of about 3 per minute.
2. Such contractions help in mixing the luminal contents and also in bringing the fresh chyme in contact with mucosal surface.

Villus Contraction
The villi of small intestine also contract irregularly. This is called villus contraction.
1. This is typically seen in upper part of the small intestine.
2. These contractions are especially meant for emptying the central lacteals of the villi.
3. They also increase intestinal lymph flow.

Intestinal Reflexes
There are two reflexes observed in the intestine: intestino-intestinal reflex and gastroileal reflex.
**Intestinointestinal Reflex**

When a part of the intestine is over-distended, the rest of the intestine relaxes. This is called intestinointestinal reflex. It is mediated by local enteric neurons and vagovagal pathways.

**Gastroileal Reflex**

When food enters the stomach (stretching of stomach), the motility of the terminal part of the ileum is enhanced. This increases entry of contents of ileum into the colon through ileocecal sphincter. This reflex is believed to be mediated by vagus nerve.

**Law of the Intestine**

When a bolus of chyme enters the intestine, the part of the intestine behind the bolus contracts and the portion of the intestine ahead of it relaxes. This helps in propagation of ring of contraction in aboral direction. This response is known as law of the intestine. This is meant to propel the intestinal content in the forward direction as occurs in peristalsis.

**Function of the Ileocecal Sphincter**

This is also known as ileocecal valve. It separates terminal part of the ileum from the cecum.

1. Normally, the ileocecal sphincter is tonically contracted, and therefore the sphincter remains closed most of the time and prevents small intestinal emptying.
2. When a peristaltic wave reaches the terminal part of the ileum, the sphincter relaxes so that the ileal content enters the cecum.
3. Distention of ileum also causes opening of ileocecal sphincter. On the other hand, distention of cecum causes closure of the ileocecal sphincter.
4. Ileocecal sphincter is also controlled by extrinsic nerve fibers. For example relaxation of the sphincter occurs by vagal stimulation as seen in gastroileal reflex.

**APPLIED PHYSIOLOGY**

**Adynamic Ileus**

When the intestine is injured, excessively handled or mishandled, the smooth muscles of the intestine are inhibited. This decreases the intestinal motility, sometimes even resulting in paralysis of the gut. This is called adynamic ileus or paralytic ileus.

1. This usually occurs following abdominal surgery. Following such procedures, GI tract remains paralyzed for about 6 hours to few days. Peristalsis first starts in the small intestine (6–8 hours later) followed by in the stomach (8–12 hours) and finally in the colon (2–3 days).
2. Adynamic ileus is also observed in peritonitis.
3. This occurs due to increased discharge of non-adrenergic fibers in the splanchnic nerves.

**Intestinal Colic**

Severe abdominal cramps are experienced in localized obstruction of small intestine.

1. The segment proximal to the obstruction dilates and gets filled with fluid and gas. This increases the pressure inside the lumen that causes compression of blood vessels in the intestinal wall. Resulting local ischemia of the intestinal wall produces severe cramping pain.
2. Abdominal cramps are also experienced in other diseases that result in distention of the intestine.

**CHAPTER SUMMARY**

**Key Concepts**

1. The primary function of small intestine is to adequately mix the chyme with intestinal and pancreatic juice. This is archived by Segmentation. Therefore, segmentation is called mixing movement.
2. The other important function of intestine is to push the chyme into the colon. This is achieved by peristalsis. Therefore, peristalsis is called propulsive movement.
3. The peristaltic movements move in aboral (away from oral cavity) direction. This is called the law of the gut.

**Important to Know (Must Read)**

1. In examinations, “Describe the mechanism and significance of intestinal motilities” may come as a Long Question.
2. Segmentation, Peristalsis, MMC, Villous contraction, Intestinal reflexes, Gastroileal reflex, Law of the gut, may come as Short Questions.
3. In Viva, examiner may ask… What are the special electrophysiological properties of intestinal, Name the types of intestinal movements, What is segmentation and peristalsis and what are their functions, What is MMC, What is Villous contraction, Name the intestinal reflexes and what are their functions, What is law of the gut, What is inflammatory bowel disease.
Large intestine consists of cecum, colon, rectum, and anal canal. Colon constitutes about 90% of large intestine and consists of ascending, transverse, descending, and sigmoid colons. Anatomically, cecum is considered as part of the ascending colon (refer to Fig. 44.1; Chapter 44).

1. Small intestine receives chyme of meals sequentially with no mixing of individual meals, whereas large intestine contains mixture of chymes of many meals of one to three days.
2. On average the total transit time of chyme of a meal through large intestine as recorded from passage of radiopaque markers is about 30 to 48 hours.

   The transit time of chyme through different parts of gut is as follows:
   1. In small intestine: 4 hours
   2. In ascending colon: 6 hours
   3. In transverse colon: 8 hours
   4. In descending and pelvic colons: 12 hours
   5. From pelvic colon to rectum, the transit is very slow, which may take 2 to 3 days.

   However, transit time depends on the fiber content of diet. Transit time is less in high fiber diet, sometimes may even be reduced to 6 hours through the entire gut.

### Motility of Colon

The major functions of colon are storage of chyme that arrives from small intestine, and absorption of salt and water from the chyme. Therefore, though colon receives about 2 liters of chyme per day from small intestine, its output is only about 200 mL.

1. The objectives of colonic contractions are to mix the chyme and circulate it across the mucosal surface of the colon so that maximum contact occurs between the chyme and the mucosal epithelium.
2. This, plus the slow movement of the chyme across the colon, which is about 5–10 cm/hour allows maximum absorption of salt and water.

### Physiological Anatomy

Structure of the wall of large gut resembles the general structure of the GI tract. However, the special features are:

1. Longitudinal muscle layer of muscularis externa is concentrated into three bands, called as tenia coli. These bands are shorter than rest of the colon. Therefore, the wall of the colon forms haustra (outpouchings).
2. There are no villi on the mucosa. There are many goblet cells.
3. The colonic glands are small inward projections of the mucosa. They secrete mucus.
4. The circular muscles usually do not exhibit action potentials.
5. outer longitudinal muscle layer is specialized into tenia coli (Fig. 50.1).
Innervation of Large Intestine

1. **Parasympathetic innervation** to cecum, ascending, transverse and most part of descending colon comes via vagus nerve, whereas innervation to the sigmoid colon, rectum, and anal canal comes via pelvic nerves that arise from the sacral spinal cord.

2. **Sympathetic fibers** to large gut come via superior and inferior mesenteric plexuses, and superior and inferior hypogastric plexuses.

3. Parasympathetic stimulation increases and sympathetic stimulation decreases colonic movements.

**Electrophysiology of Colonic Muscle**

Colon consists of both circular and longitudinal muscle.

**Circular Muscle**

There are two types of pace making (rhythm generating) cells in the colon. They are made up of interstitial cells.

1. The one set of cells that are present near the inner border of circular muscles produce regular slow waves of high amplitude like that of gastric slow waves.

2. The second set of interstitial cell is present near outer border of the circular muscle that produces waves with low amplitude and high frequency oscillations called myenteric potential oscillations (MPO).

3. Circular muscles **do not fire action potentials**.

**Longitudinal Muscle**

These muscles also exhibit myenteric potential oscillations MPO. However, longitudinal muscles sometimes fire **action potentials** at the peak of MPO that elicit contractions of the large intestine.

**Colonic Movements**

Colonic movements include haustral contractions, propulsive movements, mass peristalsis, and colonic reflexes.

**Haustral Contractions**

These are contractions similar to that of segmentation. Haustra become more prominent in these contractions. Therefore, they are called haustral contractions. They help in mixing and circulation of chyme within the large intestine.

**Propulsive Movements**

These are peristaltic movements that propel colonic contents toward the rectum. The mechanism of colonic peristalsis is same as intestinal peristalsis.

**Mass Peristalsis**

Mass colonic peristalsis is a stronger peristaltic contraction that forcefully pushes the contents from colon into the rectum. Activation of mass peristalsis in colon finally leads to the initiation of defecation reflex. It also cleans the large intestine. It occurs 3 to 4 times a day, and is initiated usually after a meal. Mass peristalsis is not affected after colostomy (Clinical Box 50.1).

**Colonic Reflexes**

Colonic reflexes include colonocolonic reflex and gastrocolic reflex.

**Colonocolonic Reflex**

Colonocolonic reflex is the relaxation of the entire colon in response to distention of one part of the colon. This is partly mediated by sympathetic fibers.

**Gastrocolic Reflex**

Gastrocolic reflex is initiated when food accumulates in the stomach.

1. Distention of the stomach causes motility of proximal and distal colon.

2. This pushes colonic content into the rectum, which stimulates the desire for defecation. Therefore, usually after taking a large meal, the urge for defecation is enhanced.

3. This reflex is more developed in children.

4. Gastrocolic reflex is proposed to be mediated by gastrin secreted from stomach in response to gastric distension, and not by neural factors.
Section 5: Gastrointestinal System

Clinical Box 50.1

Colostomy: When a large part of colon is removed (colectomy), the terminal part of ileum or proximal part of colon is brought to the anterior abdominal wall through an opening. This is called ileostomy or colostomy. The chyme that comes out from the gut is collected in a colostomy bag fastened around the colostomy opening. Usually, colectomy or hemicolectomy is performed for cancer of colon. This procedure per se does not affect the health of the individual if water and electrolyte balance are maintained.

MOTILITY OF RECTUM AND ANAL CANAL

Normally, rectum remains empty. Mass colonic peristalsis pushes contents in the colon into the rectum.

1. Anal canal always remains closed by the tonic contractions of internal and external anal sphincters. The internal anal sphincter is made up of thickening of circular smooth muscle of the anal canal.

2. The external anal sphincter consists of striated muscle (Fig. 50.2). Thus, external sphincter is innervated by somatic motor fibers via pudendal nerves, which brings it under voluntary control.

Before initiation of the defecation reflex, colonic peristalsis pushes colonic contents into the rectum. This causes filling and distension of the rectum that initiates relaxation of internal anal sphincter and constriction of external anal sphincter.

- **With initiation of defecation reflex,** the external sphincter opens and the person defecates.
- **However,** the reflex relaxation of the internal sphincter in response to rectal distention is a temporary phenomenon.
- **If defecation is delayed,** the internal sphincter regains its normal tone and the reflex is inhibited.

Defecation

This is a reflex phenomenon with a voluntary control. Thus, it has both reflexive (automatic) and voluntary components. The center for defecation is present in the sacral portion of the spinal cord, which is influenced by higher centers. The efferent pathway involves cholinergic parasympathetic fibers in the pelvic nerves.

**Stimulus**

Defecation reflex is initiated when mass peristaltic movement of the descending and sigmoid colons pushes the colonic content into the rectum (filling of the rectum).

1. As the external anal sphincter is innervated by somatic nerves, the voluntary effort is also important in initiating defecation.
2. However, normally defecation is inhibited by the acute anorectal angle, which is about 90°, and contraction of external sphincter and puborectalis muscle.

**Pathway**

1. **Receptors** for defecation reflex are stretch receptors located in the wall of rectal rectum.
2. **Afferent information** from the wall of rectum is conveyed to sacral segment (S3) of spinal cord via pelvic nerve.
3. **Effferent input** from spinal cord to rectum and internal anal sphincter comes via pelvic nerve and to external anal sphincter via somatic nerve (Fig. 50.3).
4. **Higher center,** especially cortex influences spinal cord center via corticospinal pathway.
5. Relaxation of internal anal sphincter is due to inhibitory signals that originate in myenteric plexus in response to peristaltic wave approaching anus. This allows the fecal matter to press onto the anal canal.
Mechanism

The individual sits on toilet and strains. This increases intra-abdominal pressure, which forcefully expels the rectal contents through the anal canal. This is assisted by relaxation of external anal sphincter, decreased anorectal angle and relaxation of puborectalis muscle.
1. Evacuation of bladder is preceded by a deep breathing that pushes the diaphragm downward.
2. Contraction of respiratory muscles increases intrathoracic and intra-abdominal pressures.
3. Contraction of abdominal wall muscle further increases abdominal pressure.
4. When all these mechanisms elevate the intra-abdominal pressure to about 200 cm of H2O, the feces is forced out through the external anal sphincter.

Applied Aspect

Defecation reflex is a spinal reflex. Therefore, following spinal transection, defecation is never complete. However, evacuation of bowel and bladder can be achieved by activating mass reflex in paraplegic patients.

Feces

Stool is a semisolid mass of about 200–250 mL excreted form large gut per day. It contains inorganic material, undigested fibers, bacteria, and water. Water constitutes 75% and solids 25% of the total volume. The undigested fibers include cellulose and other fibers. Bacteria and inorganic materials constitute 30% and 15% of the total solids respectively. The composition of feces is relatively not affected by diet as a large fraction of it comes from non-diary origin. Even in fasting, a good amount of feces is passed. The color of the stool is due to the presence of bile pigments. The smell of feces is due to presence of indole and skatole, the amines that are produced by colonic bacterial flora.

Applied Physiology

Hirschsprung’s Disease

Cause

This is also known as congenital megacolon or aganglionosis. In this condition, the entire neuronal plexuses in the wall of the colon are congenitally absent.
1. The enteric neurons are usually markedly absent in the anus and distal part of the rectum.
2. Failure of migration of neural crest from cranial to caudal region results in absence of ganglion in both myenteric and submucosal plexuses in distal part of colon and rectum.
3. This prevents relaxation of rectal outlet and internal anal sphincter in response to rectal filling. Thus, obstruction occurs to the outflow of feces and feces accumulate behind the obstruction.
4. Consequently, distention of the colon ensues.

Features

Clinically, it manifests as abdominal distention, anorexia and lassitude. In severe cases, symptoms appear in newborns as early as third day after birth.

Treatment

Usually, it is treated by surgical dilation.

Diarrhea

Diarrhea occurs in many conditions.
1. Physiologically it may be due to either increased secretion as occurs in cholera or increased GI motility.
2. In any case, acute diarrhea results in dehydration and hypovolemia.
3. Oral rehydration therapy is the immediate treatment to prevent volume and electrolyte loss. Oral rehydration solution (ORS) contains salt, electrolytes, and glucose. ORS contains both Na+ and glucose so that Na+ is absorbed via SGLT 1 (Na+-glucose cotransporter). Glucose facilitates Na+ transport.

Constipation

Constipation occurs due to many causes. However, the physiological basis is the decreased intestinal motility that causes stasis of chyme in the large intestine, which facilitates water absorption and dehydration of intestinal contents. The chyme hardens and feces become more solid. Usually it is treated by distending rectum by inert material.

Irritable Bowel Syndrome

This condition has been known by several synonyms such as mucous colitis, spastic colon, irritable colon, and colonic neurosis. In the West 20–30% of gastrointestinal disorders are constituted by IBS. In India this is very common and many cases used to be misdiagnosed as chronic amebiasis in the past.
1. IBS is a functional disorder of the intestine characterized by alteration of the bowel habits and abdominal pain in the absence of any detectable organic pathology.
2. There is no morphologic, histologic, microbiologic, or biochemical abnormalities in IBS. Changes in gut motility are observed in several studies though they poorly correlate with the symptoms.
3. In the constipated variety the frequency of high altitude peristaltic contraction is less whereas nonpropulsive segmentation contractions are more.
4. Moreover food induced hypermotility of the colon occurring normally about one hour after the meal is reduced in many patients. This may account for their postprandial symptoms.
5. Emotional stress is seen to aggravate the motility disorder.

Electrical Abnormalities

Normally gut has two types of myoelectrical activity, the basal electric rhythm (BER) and spike activity (SA). The BER
is in the continuous wave form at the rate of 6 cycles per minute. The SA is in the form of electrical bursts superimposed on BER and this is responsible for the mechanical contraction of the gut.

1. BS patients have a slow BER at the rate of 3 cycles per minute.
2. In normal people, feeding induces SA immediately which peaks in 30 minutes and lasts for about 50 minutes. But in the IBS patients the feeding induced SA is dampened in the first 50 minutes, but it becomes stronger later on.

**Clinical Features**

In India the female to male ratio is 1:3, though in the West, female suffer more. The clinical spectrum is wide. The presentations include

i. Painless functional diarrhea
ii. Painless simple constipation
iii. Alternating diarrhea and constipation
iv. Bloating of abdomen
v. Pain due to spasm of colon and small intestine.

The common age group is 20–40 years. Symptoms are vague and these include abnormal bowel habits ranging from constipation to diarrhea (often alternating irregularly), pallet like stools, increased gastrocolic reflex, vague abdominal pain ranging from dull ache to severe colic, flatulence relieved by belching, capricious appetite and insomnia. Around 20% of subjects complain of weight loss. All patients are emotionally tense and they tend to exaggerate the disability.

**Inflammatory Bowel Disease (Crohn’s Disease and Ulcerative Colitis)**

The term “inflammatory bowel disease (IBD)” is commonly used to include 2 idiopathic bowel diseases having many similarities but the conditions usually have distinctive morphological appearances.

These 2 conditions are: Crohn’s disease (regional enteritis) and ulcerative colitis.

1. **Crohn’s disease or regional enteritis** is an idiopathic chronic ulcerative IBD, characterized by transmural, non-caseating granulomatous inflammation, affecting most commonly the segment of terminal ileum and/or colon, though any part of the gastrointestinal tract may be involved.

2. **Ulcerative colitis** is an idiopathic form of acute and chronic ulcero-inflammatory colitis affecting chiefly the mucosa and submucosa of the rectum and descending colon, though sometimes it may involve the entire length of the large bowel.

Both these disorders primarily affect the bowel but may have systemic involvement in the form of polyarthritits, uveitis, ankylosing spondylitis, skin lesions, and hepatic involvement. Both diseases can occur at any age but are more frequent in 2nd and 3rd decades of life. Females are affected more than males.
CHAPTER 51

Principles of Digestion and Absorption

LEARNING OBJECTIVES

On completion of study of this chapter, the student MUST be able to:
1. Understand the principle of digestion and absorption of carbohydrate, protein, fat, and other nutrients from GIT.
2. Appreciate the physiological basis of common malabsorption syndromes.
3. Learn the importance of digestion and absorption of various nutrients.

The student MAY also be able to:
1. Describe the mechanism of digestion and absorption of each category of nutrient.
2. Explain the physiological basis of problems in malabsorption syndrome.

PHYSIOLOGICAL ASPECTS

Digestion is the process by which foodstuff are broken down into smaller particles that can be absorbed from the GIT. Absorption is the process by which the products of digestion, vitamins, minerals, and water are transported from the lumen of the GI tract into the blood and the lymph draining the GI tract.

Digestion is a complex process involving breaking down of foodstuffs by many enzymes into their absorbable form. Though the major part of digestion takes place in the small intestine, digestion starts as soon as food enters the mouth. The mucosal epithelial cells of the small intestine are called enterocytes. Enterocytes have brush border, which is rich in digestive enzymes. The nutrients first pass from lumen of GI tract to the interstitial fluid and then from there into the blood or lymph.

Scientist contributed

Herman Boerhaave (1668–1738) was a Dutch botanist, physician and physiologist of European fame. He is regarded as the founder of clinical teaching and is sometimes referred to as “the father of ancient physiology”; along with his pupil Albrecht von Haller. He is best known for demonstrating the relation of symptoms to lesions and, in addition, he was the first to isolate the chemical urea from urine. He had emphasized the role chemical factors in functional activity, especially in digestive process.

Digestion and Absorption of Carbohydrates

Digestion of Carbohydrate

The dietary carbohydrates are mainly polysaccharides, disaccharides, and monosaccharides. Starch is the polysaccharide that is usually digested in human GI tract.

1. Digestion of carbohydrate begins in the mouth by the action of salivary amylase which catalyses the hydrolysis of α-1, 4 linkage (but not α-1, 6 linkage) to form α-dextrins.
2. The pancreatic amylase also does the same function. The products of amylase digestion are maltose, maltotriose and α-dextrins.
3. The further digestion of starch is carried out by oligosaccharidases that are present in the brush border of the intestine. These membrane enzymes are α-dextrinase that causes hydrolysis of α-1,6 linkage, maltase that causes hydrolysis of maltotriose and maltose, lactase that causes hydrolysis of lactose into glucose and galactose, glucoamylase that splits malto-oligosaccharides into single glucose molecules and sucrase that causes hydrolysis of sucrose into fructose and glucose.
4. The end product of these membrane digestions are glucose, galactose, and fructose (monosaccharides).
Absorption of Carbohydrates

The carbohydrate absorption is maximum in duodenum and jejunum, which progressively decreases toward the terminal part of ileum. The easily absorbable forms of carbohydrate are monosaccharides that are glucose, galactose, and fructose.

1. They are first transported from the lumen into the epithelial cells. The apical membrane of epithelial cells contains SGLT (sodium dependent glucose transporter).

2. The transport is greatly influenced by the concentration of Na\(^+\) in the intestinal lumen. The higher the concentration of Na\(^+\), the greater the degree of glucose absorption. This is because both glucose and Na\(^+\) share the same transport protein, the SGLT. The SGLT that transports glucose and Na\(^+\) is SGLT 1.

3. The concentration of Na\(^+\) is less in the enterocytes, which is created by Na\(^+\)-K\(^+\) pump present on the basolateral membrane of the cells that pumps Na\(^+\) into the lateral intercellular space from the enterocytes in exchange for K\(^+\). Therefore, Na\(^+\) moves into the cells along the concentration gradient (Fig. 51.1). Glucose enters along with Na\(^+\) using the same co-transporter (SGLT 1).

4. From the cell, glucose is transported by GLUT 2 (glucose transporter) into the interstitium (ECF). From the ECF glucose enters the blood.

5. As the glucose transport depends on Na\(^+\)-K\(^+\) pump present on the basolateral membrane that creates gradient for Na\(^+\), this mechanism of glucose transport is a secondary active transport.

6. Galactose uses the same carrier protein (SGLT 1) for absorption.

7. The entry of fructose into the enterocytes is facilitated by GLUT 5, which is present only in the brush border of matured enterocytes.

Applied Aspects

Carbohydrate Malabsorption Syndromes

Carbohydrate malabsorption occurs due to deficiency of oligosaccharidases, the membrane enzymes of enterocytes.

Lactose Intolerance

This occurs due to deficiency of lactase in the brush border of enterocytes. Therefore, lactose is not digested and absorbed from the intestinal lumen. The lactose enters the colon where it is utilized by colonic bacteria that produce gas, and different metabolites. The metabolites increase colonic motility and diarrhea. Excess gas production results in borborygmi (gurgling sounds in the intestine) and abdominal distention.

Sucrase-Isomaltase Deficiency

Deficiency of sucrase and isomaltase in the brush border of enterocytes is an autosomal recessive disease. It is present in 10% of Eskimos (in Greenland) and few North Americans. Ingestion of fructose in this condition results in diarrhea and flatulence.

Glucose-Galactose Malabsorption Syndrome

This is a rare hereditary disorder due to deficiency of SGLT 1 in the brush border of enterocytes. In this condition, ingestion of glucose or galactose or starch produces diarrhea and flatulence. Fructose is well tolerated.

Oral Sugar Tolerance Test

In carbohydrate malabsorption diseases oral sugar tolerance test is performed to diagnose the disease. An oral dose of sugar (in question) is given to the patient following which the concentration of the sugar in patients, blood and stool is monitored. If the patient is intolerant to the sugar, the ingestion of sugar causes diarrhea and flatulence, the concentration of sugar in stool increases, but characteristically the sugar concentration fails to increase in the blood.

Digestion and Absorption of Proteins

The quality and quantity of dietary protein depend on the socioeconomic status and food habit of the individual. Ten to thirty gram of protein is added to the intestinal content from the GI secretions and the ex-foliated intestinal cells. Normally, all ingested protein is digested and absorbed. However, excess protein intake causes excretion of protein in the stool.
Chapter 51: Principles of Digestion and Absorption

**Digestion of Proteins**

Digestion of protein starts in the stomach.

1. **Pepsinogen secreted from chief cells** is converted to pepsin by the action of HCl. Pepsin hydrolyzes proteins into peptides and amino acids.

2. **In the duodenum and small intestine**, the proteins are digested by proteases secreted in the pancreatic secretion. The proteases are trypsin, chymotrypsin, carboxyptidases and elastase.

3. The **enterokinase** secreted from mucosal cells of duodenum and jejunum converts trypsinogen into trypsin, which then acts as an enzyme to convert other proteases.

4. **Peptidases** are also present in the brush border of enterocytes. These enzymes hydrolyze the peptides produced by pancreatic proteases into oligopeptides and amino acids. The **brush border peptidases** are amino peptidases, and dipeptidases.

5. The **products of protein digestion** are small peptides and amino acids.

**Absorption of Proteins**

There are many transport systems (at least seven such systems are known) for absorption of amino acids and peptides. The five protein transport systems require Na⁺ like that of Na⁺-glucose co-transporter. The other two transporters use Cl⁻ (independent of Na⁺). Absorption of amino acid is greater in the duodenum and jejunum and slower in ileum.

**Defects of Protein Digestion**

**Hartnup Disease**

This is a hereditary disorder in which absorption of amino acids in the intestinal and renal epithelial cells is defective. The neutral amino acids appear in the stool and urine.

**Cystinuria**

This is a congenital disease in which the amino acid cystine appears in the urine. The defect is in the protein transporter in the mucosal cells of intestine and epithelial cells of PCT of kidney.

**Prolinuria**

This is a rare disorder in which proline is not reabsorbed from intestine and kidney. This causes prolinuria and hydroxyprolinuria.

**Digestion and Absorption of Lipids**

**Digestion**

Digestion of lipid starts in the mouth.

1. In oral cavity **lingual lipase** is secreted from Ebner’s glands in the tongue.

2. **Gastric lipase** also helps in digestion of fat. However, deficiency of lingual and gastric lipase does not result in malabsorption of fat as pancreatic lipase is actually important for lipid digestion.

3. **Principal fat digestion starts in the duodenum by the pancreatic lipase**, which hydrolyzes 1 and 3 bonds of triglycerides that results in formation of free fatty acid and 2-monoglycerides (2-monoglycerols). Pancreatic lipase acts on lipids that have been emulsified (emulsification by bile acids).

4. Fat digestion is facilitated by pancreatic co-lipase.

5. There is another lipase secreted from pancreas called **bile salt activated lipase**, which also assists in lipid digestion.

6. The dietary cholesterol is hydrolyzed by **cholesteryl ester hydrolase**.

**Absorption**

Lipids are absorbed by passive diffusion and carrier mediated transport. As soon as lipids enter the cell they are esterified, therefore a gradient is maintained for their entry into the cell.

1. For their absorption, fats are emulsified in the intestine by detergent action of bile salts, lecithin, and monoglycerides. With the help of bile salt, lipids form micelles.

2. **Micelles** are cylindrical aggregates of lipids like fatty acids, monoglycerides, and cholesterol with their hydrophobic ends at the center.

3. Micelle solubilizes the lipids and provides a medium for their transport to the intestinal epithelial cells. Thus, micelles help in transport of lipids to the enterocytes, where they disintegrate into the individual lipids and passively diffuse into the cells.

**Short chain fatty acids** are produced in the colon by the colonic bacteria and absorbed there. About 60% of short chain fatty acid is acetate, 25% propionate, and 15% butyrate. Short chain fatty acids are absorbed in exchange for H⁺, therefore help in acid base balance. They also promote the absorption of Na⁺.

**Cholesterol** is easily absorbed from the intestine in the presence of bile, fatty acid and pancreatic juice. The absorbed cholesterol is incorporated into the chylomicrons that enter circulation via lymphatics.

The vitamins **A, D, E, and K** are fat soluble vitamins. Their absorption is facilitated by presence of bile acids and products of lipid digestion in the intestine. Therefore, in the absence of bile acids or malabsorption of fat, deficiency of these vitamins occurs.

**Disorders of Fat Digestion**

**Steatorrhea**

This is a condition in which there is passage of fatty, bulky, and clay colored stool.
1. This occurs due to deficiency of exocrine pancreas. Pancreatic lipase deficiency results in impairment of fat digestion.

2. This is also sometimes seen in patients with excess secretion of gastric acid in which decreased duodenal pH inhibits pancreatic lipase. Acid also precipitates bile salt.

3. Another cause of steatorrhea is impaired reabsorption of bile salts in the distal ileum.

4. Steatorrhea can also occur due to intestinal diseases.

Tropical Sprue

In this condition, the enterocytes are distorted and the density of microvilli is decreased. This causes lipid malabsorption probably due to decreased surface area for absorption of lipids.

Absorption of Water and Electrolytes

Absorption of Water

Normally, about 1–2 liters of water is ingested per day and 7 liters is added from GI secretions. However, only about 100 mL of water is excreted in the stool. Thus, GI tract absorbs more than 99.5% of water load presented to it per day.

1. Water is not absorbed from mouth, esophagus, and stomach.

2. Due to hyperosmolality of duodenal contents, water is secreted from blood into duodenum. As most of the nutrients are absorbed mainly in the duodenum and jejunum, the osmolality of intestinal content which is about 600 mosm/kg H₂O, decreases to about 200 mosm/kg H₂O in the ileum and colon.

3. Water is absorbed from intestinal lumen into blood as osmolality of blood is about 290 mosm/kg H₂O. Thus, water is mainly absorbed in the small intestine and colon.

4. The absorption of water depends on the absorption of electrolytes, especially that of Na⁺ and Cl⁻.

5. In the colon, part of water absorption occurs against an osmotic pressure gradient, the mechanism is known as standing gradient osmosis.

Absorption of Sodium

Sodium is absorbed along the entire length of the intestine. Sodium absorption is mainly a secondary active transport in which, Na⁺–K⁺ ATPase on the basolateral surface pumps sodium out of the enterocytes, which creates low concentration of sodium in the cell. Therefore, sodium enters the enterocytes by facilitated diffusion and via SGLT.

Physiological Importance

The sodium and glucose reabsorption are facilitatory to each other. This physiological process is utilized in oral rehydration therapy (ORT). ORT is commonly prescribed for condition of acute dehydration. ORT includes solution containing sugar (glucose), salt (sodium chloride), and lime juice (Application Box 51.1).

Application Box 51.1

Sodium and glucose facilitate absorption of each other in ORT: The glucose in ORT helps in absorption of sodium and sodium helps in the absorption of glucose. Thus, glucose and sodium content in ORT facilitate each others absorption in the intestine.

Absorption of Other Nutrients

Absorption of Potassium

The average intake of K⁺ per day is 4 g. K⁺ is absorbed mainly passively in the intestine (jejunum and ileum).

1. In small intestine, as water is reabsorbed, the concentration of K⁺ increases in the lumen. This causes diffusion of potassium across the concentration gradient.

2. The mechanism for active transport of K⁺ is absent in the intestine.

3. In the large intestine, potassium is both secreted and reabsorbed. Hypokalemia produces cardiac abnormalities (Clinical Box 51.1)

Clinical Box 51.1

Prolonged diarrhea can cause cardiac arrhythmias: As the K⁺ absorption is dependent on water absorption, significant K⁺ loss occurs in diarrhea. Therefore, prolonged diarrhea, especially in infants and children makes them susceptible to hypokalemia (low plasma K⁺), which may be life threatening. Hypokalemia can cause cardiac complications such as arrhythmias, and muscular dysfunctions.

Absorption of Cl⁻ and HCO₃⁻

HCO₃⁻ is secreted mainly in pancreatic juice into duodenum. Cl⁻ is secreted in gastric, pancreatic and intestinal juices.

1. Cl⁻ and HCO₃⁻ are reabsorbed mainly in the jejunum.

2. In ileum, HCO₃⁻ is secreted and Cl⁻ is absorbed.

3. In colon, Cl⁻ absorption occurs through special Cl⁻ channels in the enterocytes.

Physiological Significance

1. In acute diarrhea like cholera (secretory diarrhea), Cl⁻, Na⁺ and water are secreted into the lumen. The cholera toxin produced by Vibrio cholerae activates adenylate cyclase, therefore increases cAMP concentration in the mucosal cells. The cAMP in turn activates Cl⁻ channels and Cl⁻ is actively secreted into the lumen. This facilitates the secretion of Na⁺ and water resulting in profuse watery diarrhea (Clinical Box 51.2).

2. In cystic fibrosis, an autosomal disorder, the defective gene for Cl⁻ channel causes reduction in these channels in the mucosal cells of intestinal epithelium. Therefore, such patients suffer from less severe secretory diarrheas as compared to normal individual.
Chapter 51: Principles of Digestion and Absorption

Absorption of Vitamins

Absorption of Water Soluble Vitamins

Water soluble vitamins are absorbed mostly by simple diffusion though there are specific transport mechanisms available for them, especially for absorption of B<sub>12</sub>.

Absorption of Vitamin B<sub>12</sub>

Vitamin B<sub>12</sub> present in food is mostly bound to proteins.
1. In the stomach, low pH and pepsin release vitamin B<sub>12</sub> from the protein. The free B<sub>12</sub> then binds with R protein (Cobalophilin secreted in the saliva), which is a glycoprotein, forming R-B<sub>12</sub>-complex (Fig. 51.2).
2. However, vitamin B<sub>12</sub> also binds with intrinsic factor (IF) in the stomach, though it has less affinity for IF than the R proteins.
3. In the intestine, pancreatic proteases degrade the R-B<sub>12</sub>-complex and decrease the affinity of vitamin B<sub>12</sub> for R proteins. This facilitates the binding of vitamin B<sub>12</sub> with IF, forming B<sub>12</sub>-IF complex.
4. B<sub>12</sub>-IF complex resists degradation by pancreatic proteases. Therefore, in pancreatic deficiency, vitamin B<sub>12</sub> absorption is impaired as degradation of R protein is not adequate.
5. Binding of IF with B<sub>12</sub> brings structural change in IF resulting in formation of dimers.
6. Each dimer of IF binds two vitamin B<sub>12</sub> molecules. There are specific receptors on the brush border of the epithelial cells of terminal ileum for IF-B<sub>12</sub> complex that do not recognize free vitamin B<sub>12</sub> or IF alone.
7. The binding of IF-B<sub>12</sub> complex to the receptor is facilitated by cubilin, a high affinity apolipoprotein component of receptor. Then the complex is absorbed by endocytosis.
8. The transport of vitamin B<sub>12</sub> from the epithelial cells into the blood is a remarkably slow process. Therefore, vitamin B<sub>12</sub> concentration in plasma rises after 6–8 hours after a meal.
9. Vitamin B<sub>12</sub> then dissociates from IF and enters the mitochondria of epithelial cells where it binds with transcobalamin II (TC II) forming TC II-B<sub>12</sub> complex. This complex is rapidly cleared from portal blood by the liver by receptor mediated endocytosis.

Absorption of vitamin B<sub>12</sub> is very less (2%) in the absence of IF. However, the IF-independent absorption of B<sub>12</sub> is faster and there is no saturation in this absorption process (Clinical Box 51.3).

Clinical Box 51.3

IF-independent absorption of B<sub>12</sub>: IF-independent absorption of B<sub>12</sub> is faster. Therefore, for treatment of pernicious anemia (megaloblastic anemia due to IF deficiency), a high dose of orally administered vitamin B<sub>12</sub> (1 mg/day) can be given in addition to IV/IM B<sub>12</sub> therapy.

Clinical Significance

Deficiency of IF causes impaired absorption of vitamin B<sub>12</sub> from distal ileum. As vitamin B<sub>12</sub> is essential for maturation of red cells, IF deficiency results in pernicious anemia, a type of megaloblastic anemia.

There are three types of pernicious anemia.
1. Autoimmune pernicious anemia: This is caused by autoimmune atrophy of gastric mucosa that decreases secretion of IF from parietal cells. In most patients, antibodies against parietal cells are detected in the serum.
2. Congenital IF deficiency pernicious anemia: In this condition, IF secretion is deficient despite normal secretion of HCl from parietal cells.
3. Congenital vitamin B<sub>12</sub> deficiency pernicious anemia: This is due to congenital problem in malabsorption of vitamin B<sub>12</sub>, in which gastric function and IF secretions are normal. The disease occurs due to deficiency of ileal receptors that recognize IF-B<sub>12</sub> complex.

Absorption of Fat Soluble Vitamins

The fat soluble vitamins are A, D, E, and K. Most of these vitamins are absorbed in the upper small intestine. Absorption of these vitamins requires intactness of the mechanisms for absorption of fat, which depends on other fat soluble vitamins.
normal pancreatic secretion and bile secretions. Therefore, deficiency of A, D, E, and K are seen in pancreatic deficiency or biliary obstruction that prevents flow of bile into the intestine.

**Absorption of Minerals**

**Absorption of Calcium**

About 50% of dietary calcium is absorbed. Absorption occurs primarily in the upper segments of small intestine.

1. The absorption is mostly by an **active transport**, which is facilitated by **1,25-dihydroxycholecalciferol** that increases expression of calcium binding protein in the mucosal cells.

2. Decreased serum calcium concentration increases 1,25-dihydroxycholecalciferol and increased serum calcium decreases it. This **feedback mechanism** controls calcium absorption according to the need of the body.

3. Calcium absorption is inhibited by phosphates and oxalates, as they form insoluble salts with calcium in the intestine.

**Absorption of Iron**

The normal plasma level of iron is 130 µg/100 mL in males and 110 µg/100 mL in females. Normally, absorption of iron ranges from 3–6% of the iron ingested.

1. Iron is absorbed in the **ferrous (Fe²⁺) form**.

2. The iron ingested in the diet is present in the ferric (Fe³⁺) form. In the stomach, ferric form is converted to ferrous form by the action of **hydrochloric acid**. Gastric secretion dissolves the iron and allows it to form soluble complexes with ascorbic acid, which facilitates iron absorption. Therefore, iron deficiency anemia occurs in chronic gastric disease (Clinical Box 51.4).

3. Iron is mostly absorbed in the **upper part of the small intestine**. There is also the enzyme **ferric reductase** in the brush border of intestine, which converts ferric form of iron to ferrous form. Iron is absorbed in heme-ferrous and nonheme-ferrous form. The heme binds with a transport protein present in the brush border of the enterocytes (Fig. 51.3). This transport protein transfers heme into the enterocytes.

4. In the cytoplasm of enterocytes, **heme oxygenase** removes Fe³⁺ from the porphyrin. Fe³⁺ then is actively transported across the basolateral membrane of the cells to enter the blood where it binds with **transferrin** (the iron bound to transferrin is in the form of Fe⁴⁺).

5. Some of the Fe³⁺ in the enterocytes is **oxidized to the ferric form**, which bind with **apoferitin** to form **ferritin**. This serves as **storage of iron in the form of ferritin**.

6. But it is difficult to release iron from this storage form. They are also lost in the stool with the loss of epithelial cells. Normally, transferrin is only 35% saturated with iron. Therefore, **transport mechanism is usually not exhausted**.

**Clinical Box 51.4**

Gastrectomy or gastric atrophy causes iron deficiency anemia: Gastric secretion dissolves the iron and allows it to form soluble complexes with ascorbic acid, which facilitates iron absorption. Therefore, though iron is not actually absorbed in the stomach, gastrectomy or gastric atrophy causes iron deficiency anemia.

**Hemosiderosis and Hemochromatosis**

Absorption of iron increases when body iron store is less or when there is increased demand for iron like increased erythropoiesis. In conditions of **iron overload**, more ferritin is formed in the enterocytes, which is then excreted in the stool.

1. Ferritin is the principal storage form of iron in the tissue. In the tissue, ferritin molecules aggregate in the lysosomal membranes, which is called **hemosiderin**. Hemosiderin accumulates in the tissue when iron overload is prolonged. The condition is called **hemosiderosis**.

2. Deposition of large of hemosiderin in the tissue causes damage to the tissue. This condition is called **hemochromatosis**, which is characterized by skin pigmentation, diabetes (due to damage to the pancreatic tissue; bronze diabetes), cirrhosis of liver, and gonadal atrophy (testicular atrophy in males).

Iron present in the body is mainly in the form of hemoglobin (70% of the total iron). About 23% is present in the ferritin (in the store form) and only 3% is present in the form of myoglobin.
CHAPTER SUMMARY

**Key Concepts**

1. The major part of absorption of nutrients takes place in the small intestine. Therefore, chronic intestinal disease or intestinal resection leads to malabsorption syndrome.
2. Though the mechanisms are specific for specific nutrient, few of them facilitate each other.

**Important to Know (Must Read)**

1. In examinations, “Describe the mechanism of digestion and absorption of carbohydrate, fat and proteins from intestine” may come as a Long Question.
3. In Viva, examiner may ask… mechanism of digestion and absorption of each nutrient and clinical conditions that occur due to their deficiencies.
4. Usually questions are asked about malabsorption syndrome, in oral.

Introduction to Endocrinology

CHAPTER 52

Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:

1. Appreciate the importance of learning endocrine physiology in understanding medicine.
2. Classify hormones and give examples.
3. Understand the principles of hormone synthesis.
4. Understand regulation of hormone secretion, especially the feedback mechanisms.
5. Learn the physiological importance of binding of hormones to plasma proteins.
6. Know different mechanisms of hormone signaling and intercellular communications, and give examples for each.

The student **MAY** also be able to:

1. Describe the principle of synthesis, secretion and metabolism of hormones.
2. Understand how are the hormones are degraded in the body.
3. Briefly describe the procedure of estimation of hormones.

Endocrine physiology is the branch of physiology that deals with the study of processes involved in regulation and integration of cells and organ systems by specialized chemical substances called hormones. The word ‘hormone’ is derived from ‘hormaein’ - a Greek word, which means ‘to excite’.

1. **Hormone** is defined as specialized organic molecules that are synthesized by endocrine glands or tissues in response to specific stimuli and exert their precise effects on particular target cells.
2. An endocrine gland is a ductless gland that pours its secretion directly into general circulation. Hormones circulate in blood to reach the target tissues on which they act.

**Endocrine physiology** is the branch of physiology that deals with the study of processes involved in regulation and integration of cells and organ systems by specialized chemical substances called hormones. The word ‘hormone’ is derived from ‘hormaein’ – a Greek word, which means ‘to excite’.

1. **Hormone** is defined as specialized organic molecules that are synthesized by endocrine glands or tissues in response to specific stimuli and exert their precise effects on particular target cells.
2. An endocrine gland is a ductless gland that pours its secretion directly into general circulation. Hormones circulate in blood to reach the target tissues on which they act.

**Scientist contributed**

**John Jacob Abel** (1857–1938) was pioneered in the study of endocrine secretions. He received his PhD in physiology from Johns Hopkins University and studied in Germany under Carl Ludwig. His work on the blood-pressure-raising constituent of the adrenal medulla led to the identification and synthesis of catecholamines, and further to the development of many derivatives of catecholamines. Similarly, his studies on the anterior pituitary gland resulted in the isolation of its **oxytocic, pressor and diuretic principles**. He also pioneered with crystalline insulin. With Leonard G Rowntree, he introduced kidney and liver function tests.

3. Target cells are conferred with **receptors that are specific in their affinity** for hormones. Actions of hormones on the target tissues are diverse in nature. Broadly, **functions of hormone** include:

1. Change in cell function
2. Control of growth and development
3. Alteration in body mass and its composition
4. Reproductive functions
5. Digestion, utilization and storage of nutrients
6. Regulation of volume and composition of fluid compartments
7. Behavioral changes
8. Control of senescence.

Hormones to accomplish their functions, **bind to receptors** on the target tissues. **Activation of these receptors** leads to alteration in multiple intracellular mechanisms and signaling pathways that change cell functions.

**ENDOCRINE GLANDS**

**Types**

Endocrine structures can broadly be divided into major endocrine glands (Fig. 52.1) and other endocrine organs:
Section 6: Endocrine Physiology

A. Major endocrine glands
   1. Hypothalamus
   2. Pituitary (anterior and posterior pituitaries)
   3. Thyroid
   4. Adrenals (adrenal cortex and medulla)
   5. Parathyroid
   6. Endocrine pancreas
   7. Gonads (testis and ovary)
   8. Pineal gland.

B. Other endocrine organs
   1. Thymus (secretes thymosin, especially in childhood)
   2. Kidney (secretes erythropoietin, renin, etc.)
   3. Heart (secretes ANP)
   4. Lungs (secrete prostaglandins and activate angiotensin)
   5. GI tract (secretes many GI hormones)
   6. Placenta (secretes many hormones during pregnancy).

Analyzing with Nervous and Immune Systems

The endocrine system is closely associated with the nervous and immune systems of the body and also resembles them in many aspects.

Similarity with Nervous System

Endocrine system like that of nervous system is a major system of communication. In its various physiological aspects, it is analogous to the nervous system:

1. Nervous system requires signaling by a stimulus that evokes a response and a feedback mechanism that controls the response. Similarly, endocrine system needs signaling for hormone secretion and feedback mechanisms for regulation of secretion. The control mechanisms that regulate hormone secretion operate mainly on feedback principle.

2. Moreover, neurons secrete chemicals at their axon terminals, the neurotransmitters, which are basically...
hormones in their chemical structure. In fact, many hormones act locally as neurotransmitters in the nervous system.

Thus, nervous and endocrine systems integrate with each other to bring about desirable effects in response to changes in external or internal environment. Even some of the hormones are called neurohormones.

**Similarity with Immune System**

The immuno-competent cells (immunocytes or immune cells) secrete many chemicals that are grouped as ‘cytokines’:

1. Cytokines resemble hormones in structure and functions. Like hormones, cytokines act on specific receptors on the target tissues to achieve desirable changes.
2. In fact, many hormones are synthesized and secreted by immune cells, though they act locally.
3. Also, cytokines modulate functions of endocrine glands and hormones modulate functions of immunocytes.

**Types of Hormones**

Hormones are broadly classified into three types: peptides, amino acids and steroids.

**Proteins or Peptides**

Peptide hormones include a large group of hormones secreted from a variety of endocrine tissues. These hormones are made up of peptide chains:

1. Depending on the number of amino acids in the chain, they may be **oligopeptides** (less than 10 amino acids) like oxytocin and ADH, and **polypeptides** (10 or more amino acids) like insulin and growth hormone.
2. They originate from a common ancestral gene during evolution.
3. Based on their structure and functions, they are grouped into a **number of families** like insulin, glycoprotein, growth hormone and secretin families (Table 52.1).

**Amino Acids**

These hormones are amines. Many of them are derived from a **common amino acid**, for example dopamine, epinephrine, norepinephrine and thyroxine are derived from tyrosine. They are usually hydrophilic.

**Steroids**

Steroid hormones are **synthesized from cholesterol**, and are lipid soluble and hydrophobic:

1. This group includes hormones of **adrenal cortex** and **many gonadal hormones**.
2. The biological activities of this group are determined by modification of their side chains, hydroxylation and ring aromatization at various sites.

**GENERAL PHYSIOLOGY OF HORMONES**

**Principles of Synthesis and Secretion**

**Peptide Hormone Synthesis**

In general, protein hormones are synthesized in the **rough endoplasmic reticulum** of endocrine cells:

1. They are first synthesized as a signal peptide called **preprohormone**, which is then cleaved to form **prohormone**.
2. Prohormone is then transported into the Golgi apparatus, where it is converted into hormone. Hormone is packaged in the secretory granules for storage (Flowchart 52.1).
3. The hormone is secreted from stored granules on appropriate stimulation. Granules are released by calcium-mediated exocytosis.
4. Hormones are also secreted from neoplastic tissues (Application Box 52.1).

Application Box 52.1

Ectopic Hormone Secretion: Sometimes in pathological conditions, nonendocrine tissues secrete hormones. For example, neoplastic tissues of lungs like small cell pulmonary carcinoma produce several hormones. The condition is called paraneoplastic syndrome. Hormones are usually secreted in such syndromes are ACTH, ADH and parathormone, resulting in Cushing syndrome, water retention and hypercalcemia respectively. Hormones are also secreted from gastrointestinal tumors and the condition is called carcinoid syndrome. Carcinoid tumors are also associated with melanoma, lymphoma and neural tumors.

Pathways of Synthesis

Peptide Hormone Synthesis
Synthesis and secretion of peptide hormones occur in two pathways: the regulated and constitutive pathways.

Regulated Pathway
In regulated pathway, external stimuli trigger release of hormone which is already synthesized and stored in secretory granules, and also promote synthesis of some additional hormones. For example, GnRH from hypothalamus stimulates release of gonadotropins and additional synthesis of gonadotropins from anterior pituitary.

Constitutive Pathway
In constitutive pathway, secretion of hormones occurs more directly from endoplasmic reticulum or vesicles formed from the Golgi apparatus, in which additional hormones are formed simultaneously.

Thus, regulated pathway is capable of secretion of large amount of hormones, whereas constitutive pathway promotes secretory reserve. In any case, stimuli that trigger secretion also increase synthesis of hormones.

Amine Hormone Synthesis
All amine hormones except serotonin are synthesized from the amino acid tyrosine that requires a series of enzymatic reactions. Serotonin is synthesized from 5-HT. Catecholamines are stored in granules and secreted by calcium mediated exocytosis of granules in which they are stored.

Steroid Hormone Synthesis
Steroid hormones are synthesized from cholesterol. Many enzymatic reactions are involved in the process of steroid hormone synthesis:
1. These hormones are not stored in the cell as granules.
2. They are usually present in the cytosol bound to proteins.
3. On stimulation, the hormones become free form intracellular proteins and are transported outside the cell usually by diffusion.

Regulation of Hormone Secretion

Normally, concentration of a hormone in circulation is maintained within a narrow range. Increase or decrease in hormone concentration for a longer period results in major dysfunctions. Alteration in hormone concentration is mainly checked by regulation of hormone secretion. Hormone secretion is principally controlled by four mechanisms:
1. Feedback control,
2. Neural control,
3. Rhythmic or chronotropic control, and
4. Humoral control.

Of these control processes, feedback control is the most common and developed mechanism for regulation of hormone secretion. However, many factors arriving from variety of stimuli play simultaneously to achieve an integrated response of hormone secretion. This is called multiplicity of regulation of hormone secretion.

Feedback Control
When the change in concentration of a hormone in plasma alters its rate of secretion, the mechanism is called feedback control. There are two feedback mechanisms: The positive and the negative feedbacks.

Negative Feedback
When increased concentration of a hormone and its metabolites provide feedback inhibitory signal to the gland that secretes the hormone, the mechanism is called negative feedback mechanism. This is the common mechanism of hormone homeostasis. Depending on the circuit or the pathway involved in the feedback control, the mechanism may be simple feedback or complex feedback.

Simple Feedback Control
This is the first order of feedback control in which the hormone secreted from a gland controls its secretion through
the physiological effects. The endocrine cells that secrete the hormone also sense the biological activity produced by the hormone:

1. When the biological effects are more, the hormone secretion decreases appropriately to maintain normal function of the hormone (Flowchart 52.2). For example, β cells of pancreas secrete insulin that acts on liver and skeletal muscles to regulate blood glucose concentration. β cells in turn sense the alteration in plasma glucose and accordingly adjust their insulin secretion to maintain the plasma glucose concentration within normal range.

**Complex or Hierarchical Feedback Control**

When the feedback regulation involves second or third order feedback loop or both, the control mechanism is called complex or hierarchical control. This multiorper or complex control system is the usual mechanism for regulation of many hormone secretions:

1. In this system, the hormone secreted by first (upper) order gland stimulates secretion of second (middle) order gland.
2. Secretion (usually, trophic hormones) of middle order gland stimulates secretion of final (lower) order gland or target gland.
3. Secretion of target gland (target gland hormone) inhibits the secretion of first order or middle order glands (Flowchart 52.3).
4. Also, secretion of middle order gland (trophic hormone) inhibits secretion of first order gland.
5. This system operates mainly for control of hypothalamo-pituitary-target endocrine gland axis.
6. As this is an integrated system of control of endocrine functions, disorder at any level of hierarchy influences the function of other levels.

The major hormone axes regulated by hierarchical system of feedback control are:

- Hypothalamic-pituitary-thyroid axis
- Hypothalamic-pituitary-adrenal axis
- Hypothalamic-pituitary-gonadal axis.

For example, in hypothalamic-pituitary-adrenal axis, excess cortisol in plasma inhibits secretion of adrenal cortex by decreasing ACTH secretion from anterior pituitary or by inhibiting hypothalamic release of CRH.

**Loops of Negative Feedback Control**

Depending on the distance from which the hormone of the target gland inhibits the upper order glands, the inhibition is classified into long loop, short loop and ultrashort loop. For example, in the same hypothalamic-pituitary adrenal axis, cortisol inhibiting CRH release is the long loop of negative feedback, ACTH inhibiting CRH release is the short loop of negative feedback and CRH inhibiting its own release is the ultrashort loop of negative feedback (Flowchart 52.3).

**Positive Feedback**

This is a less common mechanism of regulation of hormone secretion. In this control system, increase in hormone concentration in plasma stimulates further secretion of that hormone so that the hormone concentration increases steadily to reach a peak plasma level:

1. The best example of positive feedback regulation is the LH surge that occurs just before ovulation. Normally, estrogen inhibits LH secretion; however, just before ovulation, increased estrogen concentration...
in plasma provides a positive feedback for LH release from anterior pituitary that results in LH surge (for details, refer ‘Menstrual Cycle’).
2. Other examples are oxytocin secretion during parturition, release of oxytocin during breastfeeding and release of melatonin in response to darkness.

**Neural Control**

Endocrine glands are usually innervated by both the components of autonomic nervous system:
1. **Stimulation of sympathetic or parasympathetic system** therefore alters the endocrine secretions. Secretion of catecholamines from adrenal medulla in response to sympathetic stimulation is an example.
2. However, the receptor types present in the endocrine tissue determine the final secretion from the gland. Besides, innervation of the endocrine tissues may also be cholinergic, serotonergic or dopaminergic depending on the neurotransmitter released at the nerve ending.
3. Secretion of hormones in response to various stimuli like visual, olfactory, gustatory, tactile, etc. is also neurally mediated. One of the examples is the milk ejection reflex in which suckling by the baby increases secretion of oxytocin that causes contraction of myoepithelial cells of the mammary gland.

**Rhythmic or Chronotropic Control**

Chronotropic control of hormone secretion is the regulatory mechanism operated by various rhythms of biologic phenomena that either cycle at regular intervals like circadian rhythm, sleep-wake cycle, seasonal rhythm and menstrual cycle, or appear at different phases of development like hormonal changes occurring in pre-pubertal children.

Influenced by chronotropic control mechanism, hormones are secreted in a definable and rhythmic pattern, which may be:
1. episodic or pulsatile lasting for few minutes to hours
2. diurnal lasting for several hours in a light-dark cycle
3. periodic lasting for many days
4. developmental occurring at different phases of development
5. seasonal, in different seasons.

**Examples of chronotropic control:**
1. **Example of episodic (pulsatile) hormone secretion** is the secretion of GnRH. Normally, GnRH is secreted in episodic bursts that cause circchral peaks of LH secretion (for details, refer, “Female Reproduction”).
2. **Example of diurnal hormone secretion** is the change in ACTH or cortisol at different times of day and night. Another example of day-night variation is melatonin secretion.
3. **Example of periodical secretion** is alteration in sex hormones or gonadotropins in different phases of menstrual cycle.
4. Alteration in secretion of gonadal hormones at puberty in both boys and girls is the example of developmental hormonal secretion.
5. **Example of seasonal variation** is change in hormone concentration in different times in a year that mostly occurs due to environmental changes. This is more prominent in birds.

**Mechanisms**

The variation in hormone secretion is due to many mechanisms such as change in secretory pattern influenced by photic stimuli (light-dark variation), change influenced by sleep (sleep-wake variation) or change subjected to environmental alteration (seasonal variation).

**Humoral Control**

Humoral control is the control by hormones and chemicals.

**Hormonal Control**

Many hormones influence secretion of other hormones. Examples are glucagon stimulating insulin secretion, angiotensin stimulating aldosterone secretion, somatostatin inhibiting growth hormone secretion and so on.

**Chemical Control**

Secretion of hormone is influenced by various chemical stimuli such as concentration of blood gasses, acids, ions and osmolality. Examples are hypokalemia inhibiting insulin secretion, hyperkalemia or hyponatremia stimulating aldosterone secretion, etc.

**Hormone Signaling**

The chemical signaling of hormone occurs through three pathways: endocrine, paracrine, and autocrine.

**Endocrine Signaling**

Hormone secreted from the endocrine gland reaches distant target tissues via bloodstream. Most of the hormones signal target tissues located far away from the gland via this route. Thus, cells of hormone secreting tissue communicate with cells of other tissues of the body via endocrine signaling. Hence, this type of intercellular communication is called endocrine communication.

**Paracrine Signaling**

Hormone secreted from endocrine tissue diffuses into extracellular space and signals the neighboring tissue. This is called paracrine signaling. For example, somatostatin secreted from D cells of pancreatic islets influences the secretion of insulin and glucagon from same islet cells (Flowchart 52.4).
Autocrine Signaling
Hormone secreted from an endocrine cell binds with the receptor located in the same cell that secretes the hormone. Thus, hormone modifies the function of its parent cell. The example of autocrine signaling is the platelet activating factor secreted from platelet, which activates the platelet.

Intercellular Communications
Cells communicate with each other by five major mechanisms: direct, neural, endocrine, paracrine and neurocrine (Table 52.2). Autocrine and juxtacrine communications are strictly not part of the intercellular communications, as in these two systems cells influence their own activities or the other cells in the vicinity:
1. Direct communication occurs between cells via gap junction (electrical synapses). Example is rapid transmission of impulse between cardiac myocytes via gap junctions.
2. Neural communication is the major mechanism of intercellular communication. Examples are neurons communicating through synapses.
3. Endocrine, paracrine and autocrine communications are described above in ‘Hormone signaling’.
4. Juxtacrine communication is the communication through cell adhesion to growth factors expressed on cell surface. For example, many cells having receptors for transforming growth factor \( \alpha \) (TGF\( \alpha \)) interact with each other by attaching themselves to the transforming growth factor \( \alpha \) (TGF\( \alpha \)) present on their cell surface.
5. Neurocrine communication is via secretion of chemicals at nerve ending. For example, cholinergic vagal fibers to oxyntic cells in stomach influence parietal cell function by releasing acetylcholine at their terminals, and non-cholinergic vagal fibers to G cells in the antrum of stomach influence G cell function by releasing gastrin releasing peptide (GRP) at their terminals.

Transport of Hormones
By definition, hormones are secretions of ductless glands, transported via blood stream to reach their target tissues. After entering the blood they either remain in free form or bind with a specific carrier protein. Usually, amine and protein hormones remain in unbound (circulate in free) form, and thyroxine and steroid hormones (and vitamin D) circulate in the bound form.

Transport of Amine and Peptide Hormones
Amino acid-derived and peptide hormones readily dissolve in the plasma and do not require special mechanism for their transport.

Transport of Steroid Hormones
Thyroxine, steroid hormones and vitamin D are relatively insoluble in plasma and circulate in the bound form. In blood, more than 90% of thyroid and steroid hormones are bound to plasma proteins. The transport proteins are specific for hormones (Table 52.3). However, few nonspecific proteins are also involved in the process of hormone transport.

Importance of Hormone Binding
Binding of hormone with carrier proteins influences important biological properties of hormones, especially, hormone action, metabolism, storage and removal:
1. Hormone action: The intensity of the hormone action depends on the extent to which hormone is bound to the proteins. Usually, hormones that bind to transport proteins remain 1 to 10% only in the free form, which is called as the biologically active hormone. Thus, about 90% of these hormones, i.e. the hormone in bound form constitutes the inactive pool of hormone. Any condition that decreases hormone binding by decreasing the concentration of proteins available for binding or by any other mechanism, increases the hormone...
activity as plasma level of free hormone rises; and conversely, condition that increases binding decreases hormone activity.

2. **Hormone reservoir**: Transport proteins also provide reservoir of hormones that is essential for buffering rapid change in hormone concentration in plasma.

3. **Hormone metabolism and clearance**: Binding with carrier protein influences metabolism and removal of hormone from circulation. This determines the half-life of the hormone. For example, the plasma half-life of thyroxine is 6 days as it is 99.9% protein bound, whereas half life of aldosterone is 25 minutes as only 15% of it is bound to protein.

4. **Diagnostic importance**: From diagnostic viewpoint, it is important to know both free and bound form of the hormone. Assay of total hormone concentration may sometimes be misleading as total concentration may be normal in the presence of actual hormonal deficiency or excess. For example, binding proteins may be increased in various conditions such as pregnancy, drug therapy, etc. that decrease the free form, and therefore lead to functional hormone deficiency though the total concentration of hormone remains normal. Therefore, free concentration of hormone (free hormone index), or the ratio of free form to bound form of hormone reflects the actual physiological state of hormone. Hence, often, in the diagnosis of hormonal disorder, measurement of free hormone index is preferred to total hormone estimation to evaluate the degree of dysfunction.

### Degradation and Disposal of Hormone

Liver and kidney are the major sites for extraction and degradation of hormones. Therefore, diseases of liver and kidney alter hormonal status of the body by impairing removal of hormones from the body. Hormone degradation also depends on the rapidity of uptake of the hormone by the target cells like receptor-mediated endocytosis of peptide hormones. Also, metabolic degradation of hormones occurs by various enzymes.

#### Physiological Importance

Hormone disposal is physiologically important for two reasons: measurement of hormone secretion and metabolic clearance rate.

1. **Measurement of hormone secretion**: Urine is the major route of excretion for many hormones, and few hormones are excreted in bile. Therefore, for many hormones, measurement of hormone metabolites in urine is a better indicator of the rate of production of hormones. For example, urinary excretion of metanephrine or VMA is an index of catecholamine secretion, which provides a simple and noninvasive test for assessment of adrenomedullary function.

2. **Estimation of metabolic clearance rate (MCR)**: Sometimes estimation of rate of metabolism is clinically useful for assessing hormone dysfunction. The rate at which the hormone is removed from the body is one of the indices of MCR. MCR is the hormone removed per unit time divided by the plasma concentration of the hormone.

\[
MCR = \frac{\text{Hormone removed per unit time (mg/min)}}{\text{Plasma conc. of hormone (mg/mL)}}
\]

MCR is reported as ml of plasma per min. Half-life of hormone and MCR are inversely related. Thus, shorter the half life, greater is the MCR.

### Estimation of Hormone Concentration

Measurement of concentration of hormone in biological fluids is often performed for confirmation of clinical diagnosis. Hormone estimation can be done by bioassay, radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA).

#### Bioassay

Bioassay is the assay of hormone’s ability to produce a characteristic biological response:

1. In this method, hormone is estimated in terms of units, which is defined as an amount sufficient to produce a response of specified magnitude under standard conditions.

2. Bioassay was the earlier method of assessment of hormone concentrations.

Alteration of Hormone

Some of the hormones are transformed in the peripheral blood, which is required for their full biological activity. Examples are the conversion of T₄ to T₃ and testosterone to dihydrotestosterone.
3. After the discovery of RIA and ELISA, bioassay is rarely used at present for the purpose.
4. Also, the method is slow and often expensive.

Radioimmunoassay (RIA)

RIA is usually used for estimation of hormones, proteins, drugs and vitamins in body fluids like plasma, urine and CSF. RIA is a type of competitive binding assays. It is based on the theory of competitive binding. In RIA, two components are used: a specific antibody (Ab) that is produced against the hormone to be assayed, and a radioactively labeled hormone (H):

1. When the hormone to be measured is a peptide, the molecule is commonly labeled with a radioactive iodine atom (¹²⁵I or ¹³¹I) that can be easily attached to the tyrosine residue of peptide chain, and if the hormone is a steroid (that lack tyrosine residue), labeling is done by radioactive carbon (¹⁴C) or hydrogen (³H).
2. The principle of RIA is that the labeled and unlabeled hormones compete for a limited number of antibody binding sites. The quantity of each hormone bound to antibody is the ratio of that present in solution. The hormone and the radioactive hormone bind to antibody, and the amount of radioactivity present as Ab-H' is determined.
3. The response produced by the standards is used to generate a standard curve and the response produced by the unknown samples is then compared to the standard curve to determine the amount of hormone present in the unknowns.
4. The major drawback of the RIA is that it measures immunoreactivity, not the biological activity of the hormone.
5. Therefore, recently RIA is modified to receptor assay (RRA), in which specific receptors of hormone instead of antibodies are used as hormone-binding reagent. In RRA, as the receptor binding (the hormone that binds to its own receptors) is assessed, it measures biologically active hormone.

Enzyme-linked Immunosorbent Assay (ELISA)

This is an enzyme-based colorimetric or fluorometric assay of hormones that does not produce radioactive wastes. Therefore, the environmental hazard is reduced. Moreover, as it is a solid-phase assay, it is automated to a large extent.

Hormone Actions

Most of the hormones have several effects on target tissues that are called as pleiotropic effects of hormones. For example, acting on liver, cortisol not only decreases glucose uptake, but also influences glycogenolysis, glyco genesis, neoglucogenesis, lipolysis, protein synthesis, etc. Similarly, many hormones have multiple actions on several other tissues simultaneously. For example, the same cortisol apart from acting on liver, also acts on other tissues like skeletal muscle, intestine, heart, brain, bones, blood cells etc for various other functions:

1. As hormones act on different body systems for different actions, some of the actions are complementary and some are antagonistic.
2. However, both complementary and antagonistic actions of hormones are meant for integration of body functions in normal conditions as well as in different other situations.

Complementary Actions

When actions of different hormones facilitate a function of the body in a particular situation, it is called complementary actions of hormone. Complementary actions may be for a short-term regulation or for a long-term modification:

1. The example for short-term complimentary action is the acute physical exercise, during which secretion of epinephrine, cortisol and glucagon contributes to defend plasma glucose concentration. Deficiency of one or more hormones in such a condition results in severe hypoglycemia.
2. The example of long-term complementary actions is the regulation of growth by growth hormone, thyroxine, insulin like growth factors and sex steroids.

Antagonistic Actions

When the action of a hormone on a target organ is opposed by another hormone, the process is called antagonistic action. The example is the effect of insulin and glucagon on liver to regulate plasma glucose concentration. Insulin lowers plasma glucose by inhibiting hepatic glycogenolysis and gluconeogenesis, whereas glucagon increases blood glucose by stimulating glycogenolysis and gluconeogenesis. Thus, glucose homeostasis depends on the balance of actions of insulin and glucagon and other hyperglycemic hormones. Therefore, antagonistic actions of hormones, is an important regulatory process of the nature to fine-tune the physiological activities of the body.

CHAPTER SUMMARY

**Key Concepts**

1. Regulation of hormone secretion occurs mainly by feedback control mechanism, in which negative feedback system is the usual process.
2. Hormone concentration in the blood depends mainly on the free hormone available (the quantity of the hormone not bound to binding proteins).
3. Also, the concentration remains elevated when the degradation of the hormone is less, in addition to increased production.
4. Paracrine signaling is for controlling of neighboring cells, and endocrine signaling is for control of all the cells including the distant cells.

**Important to Know (Must Read)**

1. In examinations, ‘Mechanism of regulation of hormone secretion’ may come as a **Long Question**.
2. Classification of hormones, Pathways of hormone synthesis, Types of feedback control of hormone secretion, Negative feedback mechanism of hormone control, Hormone signaling mechanisms, Intercellular communications, Types of hormone actions, are usual **Short Questions** in exams.
3. In **Viva**, examiner may ask… Define hormone, Classify hormones and give example of each category, Name the endocrine glands, How is endocrine system analogous with nervous and immune system, What is the basic principle of hormone synthesis, What are the pathways of hormone synthesis, What is the meaning of ectopic hormone secretion, In what conditions ectopic hormone secretion occurs, What is paraneoplastic syndrome, What is the meaning and role of a feedback system, What are types of feedback control of hormone secretion, and give example for each, What is negative and positive feedback mechanism of hormone control, give examples, What are the hierarchical systems of negative feedback process, What are the hormone signaling mechanisms and give example for each, What are the intercellular communications and give example for each type of communication, How are the hormones transported, What is the importance of hormone binding, What are the processes of hormone degradation, How are hormones estimated, What are types of hormone actions.
Mechanisms of Hormone Action

Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Understand the concept of receptor up-regulation and down-regulation.
2. Appreciate the role of G proteins in hormone action.
3. List the second messengers produced by first messengers (hormones).
4. List the important hormones that act through different second messengers.
5. Describe the mechanism of hormone action via adenylyl cyclase-cyclic AMP system, membrane phospholipid-phospholipase system, cyclic-GMP system and transcription of mRNA system.

The student **MAY** also be able to:
1. Explain the role of G proteins in health and disease.
2. Describe the effects of various second messengers on cells and tissues.

Receptors

Hormones to exert their effects on tissues bind with the **specific receptors** located in the target cell. The receptor may be present on the surface of the cell, in the cytoplasm or nucleus of the cell.

1. The binding of hormone with the receptor that forms hormone-receptor complex (HR complex), activates a series of signal generating mechanisms via a cascade of enzymatic reactions in the target cell.
2. The generated signal molecules increase in number in each step leading to manifold increase in final effect of the hormone on the cell. This is called **signal amplification**.
3. Normally, concentration of hormones in the body fluid is exceedingly low, which is usually in the range of $10^{-9}$ to $10^{-12} \, \text{mol/L}$. In spite of their very low concentration, hormones effectively alter cell functions through the process of signal amplification.
4. The peptide hormones bind to the cell surface receptors and activate a series of intracellular signal transduction systems.
5. Amine hormones also act via surface receptors.
6. Steroid and thyroid hormones bind to the intracellular receptors that regulate gene transcription.

Scientist contributed

The **Nobel Prize in Physiology or Medicine 1971** was awarded to American physiologist and endocrinologist, **Earl W Sutherland, Jr** “for his discoveries concerning the mechanisms of the action of hormones”. He worked extensively on the physiology of cyclic AMP.

Receptor Functions

The receptors located on the membrane are usually **large glycoproteins** with molecular weight of 50,000–200,000 dalton. They usually span the membrane seven times. Following binding of hormone with the receptor, **HR complex** is formed, which is **internalized by endocytosis**. Inside the cell, **HR complex is degraded by lysosomal enzymes**.

1. Usually, the receptor molecule is **recycled back to the cell membrane**. However, degradation of the receptor within the cell is not uncommon.
2. Mutation of receptors produces receptor diseases (Application Box 53.1).
Quantity and Sensitivity of Receptor

The receptor quantity and sensitivity are usually regulated by the concentration of the hormone that acts specifically on that set of receptors. Accordingly, there is up-regulation, down-regulation, and desensitization of receptors.

Up-regulation

When, concentration of a hormone decreases in plasma for a longer period, the number of receptors for that hormone usually increases in the target tissue. Also, sensitivity of receptor to the hormone increases. This is called up-regulation.

1. The exact mechanism by which deficiency of hormone results in increased recruitment of its own receptors is not clearly understood.
2. Up-regulation of receptors forms the physiological basis of denervation hypersensitivity.

Down-regulation

When, a hormone is present in excess in blood for a longer period, the number of receptors for that hormone in the target tissue decreases. This is called down-regulation.

Desensitization

When cells are chronically exposed to the excess concentration of a hormone, they become less responsive on subsequent exposures. The process is called desensitization. In this process, the sensitivity of receptors for the hormone decreases.

1. Chronic exposure to one hormone can also cause desensitization of receptors to other hormones.
2. If, desensitization occurs for the same hormone, the effect is called homologous desensitization, and if desensitization occurs for other hormones, the effect is called heterologous desensitization.

Application Box 53.1

Mutation of receptors: Receptor diseases are produced by mutation of receptors. Examples are Hirschsprung disease due to mutation of endothelin B receptors, familial hypothyroidism due to mutation of TSH receptors, color blindness due to mutation of receptors for cone opsins, X-liked nephrogenic diabetes insipidus due to mutation of V2 vasopressin receptors and so on.

G PROTEINS

Peptide hormones with the exception of IGF I and IGF II usually circulate freely as they do not have binding proteins for them in plasma. They bind with surface receptors on the target cells. Receptors are coupled with G proteins in the cell membrane.

1. G proteins belong to several families of intrinsic membrane proteins that link receptors to the nearby effector molecules in the membrane. Also, there are different subunits of each family of G proteins. In fact, specific subunit of G protein of a family relay specific signal from the receptors to the effectors that are usually specific ion channels or enzymes.
2. The effector molecules in turn generate second messengers that produce changes in cell functions when hormone binds with the receptors. Thus, G proteins convert the signal into biological activities.
3. These membrane proteins are called G proteins as they are attached to GDP. When the signal binds with the G protein, G protein exchanges GDP for GTP.
4. The GTP-protein complex influences subsequent signal transductions that results in generation of many intracellular signals, which mediate physiological effects of the hormone (Flowchart 53.1).
5. G protein has the inherent GTPase activity, which converts GTP to GDP. Therefore, once the hormone action is over, resting state of the G protein is restored.

Scientists contributed

Alfred Goodman Gilman (1941–2015) was an American pharmacologist and biochemist. He and Martin Rodbell shared the 1994 Nobel Prize in Physiology or Medicine for their discovery of G-proteins and the role of these proteins in signal transduction in cells. Martin Rodbell (1925–1998) an American biochemist and molecular endocrinologist discovered that ATP could reverse the binding action of glucagon to the cell receptor. He then noted that traces of GTP (guanosine triphosphate) could reverse the binding process almost one thousand times faster than ATP. This GTP, he found, stimulated the activity in the guanine nucleotide protein (later called the G protein), which, in turn, produced profound metabolic effects in the cell.
Types of G Proteins

Broadly, G proteins are classified into two categories based on their molecular size: small G proteins and large G proteins.

Small G Proteins

There are six different subfamilies of small G proteins. The major categories among them are Rab, Rac, and Ras families. A number of small G proteins contain lipid modifications that help them to adhere to membranes, whereas other small G proteins diffuse throughout the cytosol.

GAPs and GEFs

The GTPase activating proteins (GAPs) inactivate small G proteins by facilitating the hydrolysis of GTP to GDP in the central binding site. Guanine exchange factors (GEFs) activate small G proteins by facilitating exchange of GDP for GTP in the active site.

Functions of Small G Proteins

The small G proteins regulate many cellular activities.

The Rab family regulates rate of vesicle movement between cell organelles and the cell membrane.

The Rho/Rac family mediates interaction between cytoskeleton and the cell membrane.

The Ras family controls growth by regulating transmission of signals from the cell membrane to the nucleus.

Large G Proteins

These are the membrane proteins coupled to the receptors. Presently, five families of large G proteins have been discovered: Gs, Gi, Gq, Gv, and G13. In addition, there are three genes for G proteins: 20α, 6β, and 12γ genes. Therefore, a large number of subunits of G protein families are produced. Usually, G proteins are trimeric proteins consisting of three subunits. Therefore, they are called heterotrimeric G proteins. The subunits are called α, β, and γ subunits. Normally, α subunit is bound to GDP.

Mechanism of Action

When HR complex binds to the G protein couple receptors (GPCR), GDP is exchanged for GTP and α subunit is separated from βγ subunits of the G protein. This separation of α subunits from βγ subunits bring about physiological activities (Figs. 53.1A and B). The β and γ subunits do not separate from each other. The α subunit has the intrinsic GTPase activity that converts GTP to GDP. This results in reassociation of α subunit with the β and γ subunits of the G proteins. The GTPase activity of α subunit can be facilitated by regulators of G protein signaling (RGS).

The α subunit of three types of G proteins (Gs, Gi, and Gq) are physiologically most important. They are αs, αi, and αq subunits. Their activation produces following effects:

1. Activation of αs subunit activates the membrane enzyme adenylyl cyclase that promotes cAMP formation.
2. Activation of αi subunit inhibits the membrane enzyme adenylyl cyclase that decreases cAMP formation.
3. Activation of αq subunit activates membrane bound phospholipases like phospholipase C.

G Protein Coupled Receptors

G protein coupled receptors (GPCR) are membrane proteins that span the membrane seven times (Fig. 53.2). Hence, they are called serpentine receptors (seven-helix receptors). A large number of GPCR have been cloned recently. They have many diverse functions.

1. When a ligand binds with GPCR, conformational change occurs in GPCR that activates the large G protein attached to the cytoplasmic surface of the cell membrane.
2. Activation of a single GPCR can lead to activation of multiple large G proteins that transduces and amplifies the action of first messenger.

Robert Joseph Lefkowitz (1943) is an American physician (cardiologist). He was awarded the 2012 Nobel Prize for Chemistry with American Physiologist Brian Kobilka. Lefkowitz studies receptor biology and signal transduction and is most well known for his detailed characterizations of the sequence, structure and function of the β-adrenergic and related receptors and for the discovery and characterization of the two families of proteins which regulate them, the G protein-coupled receptor (GPCR) kinases and β-arrestins.

3. The GPCR bound to a ligand can be inactivated by phosphorylation of cytoplasmic side of the receptor to limit the process of cellular signaling.

There are many ligands (hormones/chemicals) for receptors coupled to G proteins (Table 53.1).

### G Protein Diseases

Mutation of G protein resulting in diseases is not uncommon. G protein responses may be increased or decreased by mutations.

#### Dysfunction due to Increased G Protein Responses

An example of increased G protein activity is somatotroph tumor causing acromegaly, in which mutation of Goαs decreases its intrinsic GTPase activity, therefore G protein activity is prolonged and more cAMP is produced. This leads to hyperplasia of somatotrophs of anterior pituitary producing acromegaly in about 40% of patients.

Another example is McCune-Albright syndrome, in which mutation of Goαs increases G protein activity producing areas of skin with hyperpigmentation and the state of hypercortisolism.

### Dysfunction due to Decreased G Protein Responses

An example of decreased G protein responses is type 1 pseudohypoparathyroidism, in which mutation of Goαs leads to failure of G protein to respond to parathyroid hormone. This results in features of hypoparathyroidism without actual decrease in parathyroid hormone.

#### SECOND MESSENGERS (Signal Transduction Pathways)

Hormones are considered as first messengers that bind with the receptors. The hormone (or the ligand) binding with receptors forms the complex called hormone-receptor (HR) complex. Formation of HR complex is the first step in the hormone action that eventually leads to formation of second messengers.

In general, the processes of second messenger formation are broadly categorized into 4 types (Table 53.2):

1. Activation of ion channels
2. Activation of G proteins
Chapter 53: Mechanisms of Hormone Action

3. Activation of intracellular or membrane enzymes
4. Activation of transcription process.

**Role of phosphorylation**: Phosphorylation is an important **post-translational event** in the cell signaling pathway. Phosphorylation in the cell is controlled by two group of proteins namely kinases and phosphatases.

1. **Kinases** catalyze the phosphorylation of tyrosine or threonine residues in proteins and **phosphatases** remove phosphates from proteins.
2. More than 300 protein kinases have been described (Table 53.3).
3. The process of phosphorylation-dephosphorylation of cellular proteins is important in control of some ligand signaling pathway, which is referred to as **phosphate timer**.

### Second Messengers

The intracellular signal molecules that are formed by a series of enzymatic reactions subsequent to the formation of HR complex are designated as **second messengers**.

1. Second messengers are formed depending on the hormone signaling of the effector cells.
2. The signal transduction pathways are activated depending on G protein activation of membrane enzymes (Table 53.4).
3. **The major second messengers are**: cyclic AMP, diacylglycerol (DAG), inositol triphosphate (IP₃), cyclic GMP, phosphoproteins, transcripted new mRNAs, and intracellular calcium.

### Second messengers are formed by activation of **four main transduction systems**:

1. **Adenylyl cyclase–cyclic AMP system**
2. **Membrane phospholipase–phospholipid system**
3. **Guanylyl cyclase–cyclic GMP system**
4. **Transcription of mRNAs**.

#### Cyclase–Cyclic AMP System

Cyclic adenosine monophosphate (cAMP) is an important **second messenger for many peptide and amine hormones**. It also causes **lymphocyte activation and mast cell degranulation**. Formation of cAMP and alteration in cell functions by it involve a series of events following interaction of hormone with receptor on the cell membrane (Fig. 53.3).

### Steps of Signal Transduction

The steps of signal transduction are as follows:

1. The hormone binds with the receptor present on the cell membrane and forms hormone-receptor complex (HR complex formation).
2. HR complex is formed that results in activation of G proteins (either αᵣ or αᵢ).
3. The membrane enzyme **adenyl cyclase is activated (if αᵣ is stimulated)**. Adenylyl cyclase is a membrane protein that spans the membrane 12 times. When the binding of hormone to receptor stimulates the stimulatory G protein (αᵣ subunit), adenylyl cyclase is activated. If the hormone binding with receptor stimulates the inhibitory G protein the (αᵢ subunit), adenylyl cyclase is inhibited. (Accordingly, in the next step, CAMP formation is either increased or decreased in the cell).
4. Adenylyl cyclase catalyzes the conversion of ATP to cyclic AMP.

5. The cAMP activates protein kinase A (PKA). 
**Protein kinase A** (PKA) has two catalytic and two regulatory subunits. cAMP separates catalytic from regulatory subunits. This separation of subunits leads to activation of PKA.

6. Free catalytic subunits phosphorylate the serine and threonine residues on many cellular enzymes and other proteins. This process of phosphorylation of intracellular proteins results in formation of various phosphoproteins.

7. New phosphoproteins induce cell functions (mediate the physiological effects of hormone). The PKA also migrates to the nucleus where it phosphorylates CREB (cAMP-responsive element-binding protein). CREB binds to DNA and influences transcription of a number of genes. Thus, cAMP also alters genetic functions of the cell.

### Termination of cAMP Actions
Actions of cAMP in the cell are terminated in two ways.
1. cAMP is degraded to 5′-AMP in the cell by the cytoplasmic enzyme phosphodiesterase (PDE).
2. Serine or threonine specific phosphatases dephosphorylate the proteins already phosphorylated by PKA.

### Clinical Importance
Not only, many hormones act through cAMP (Table 53.5), but also, toxins released by various pathogens produce...
Toxic features by altering cAMP concentration in the cell. **Cholera and pertussis toxins** are examples of stimulation and inhibition of cAMP respectively.

**Stimulation of cAMP**

In cholera, the highly infective acute diarrheal disease caused by Vibrio cholerae, the **cholera toxin** (especially, subunit A of the toxin) irreversibly transfers ADP-ribose from NAD to its specific target protein, the GTP-binding regulatory component of adenylate cyclase in intestinal epithelial cells. The ADP-ribosylated G protein **up-regulates activity of adenylate cyclase**. Therefore, cAMP production is increased. In intestinal epithelial cells, **cAMP decreases Na⁺ absorption and increases Cl⁻ secretion**. Increased NaCl content in the intestinal lumen osmotically retains water and produces **isotonic fluid diarrhea**. Tea and coffee stimulate cyclic AMP formation (Application Box 53.2).

**Inhibition of cAMP**

In pertussis (whooping cough), an acute respiratory tract infection caused by *Bordetella pertussis*, a variety of toxins are produced by the pathogen. A component of pertussis toxin decreases adenylyl cyclase activity by **activating inhibitory G protein**. This impairs the host's defense ability.

**Application Box 53.2**

Tea and coffee is good for heart: Normally, PDE degrades cAMP in the cells. Therefore, the agents that inhibit the action of PDE like caffeine and theophylline increase the concentration of intracellular cAMP. These chemicals increase myocardial contractility by increasing intracellular cAMP. Caffeine and theophylline are active principles in coffee and tea. Hence, moderate intake of tea and coffee is good for heart, and tea is considered better than coffee in this regard.

**Membrane Phospholipid-Phospholipase System (via IP₃ and DAG)**

This is an important system for transduction of hormone signals into physiological activities. In this system, binding of hormone with the receptor initiates the following cascade of reactions (Fig. 53.4).

1. **Hormone binding with receptor results in HR complex formation.**
2. **HR complex activates Gαq.**
3. **Activated Gαq activates the membrane enzyme phospholipase C.**

**Phospholipase C** (PLC) is attached to protein Gαq and is located on the inner surface of the membrane. There are eight isoforms of PLC. Usually, **PLC β₁ and β₂ isoforms** are activated by Gαq. They catalyze the cleavage of membrane phosphatidylinositols, the phospholipids present in the inner lamella of cell membrane.

**Fig. 53.4: Mechanism of hormone action through membrane phospholipid-phospholipase system.** (H: Hormone; R: Receptor; Gq: Gαq protein; PIP₂: Phosphatidylinositol bisphosphate; IP₃: Inositol triphosphate; DAG: Diacylglycerol; CaBP: Calcium binding proteins).
4. PLC β₁ or β₂ causes hydrolysis of phosphatidylinositols 4,5-bisphosphate (PIP₂) that generates two important signal molecules: inositol 1,4,5-triphosphate (IP₃) and diacylglycerol (DAG).
   - IP₃ releases calcium from endoplasmic reticulum.
   - DAG stimulates intracellular (submembrane) enzyme protein kinase C.

5. The increased protein kinase C activity activates many intracellular enzymes that bring about change in cell functions. Thus, two subsystems are formed in this pathway: the IP₃ subsystem and the DAG subsystem.

**In IP₃ Subsystem:**
5a. IP₃ binds with its receptors located on cytosolic surface of endoplasmic reticulum (ER). This binding facilitates release of Ca²⁺ from ER, which causes cytosolic Ca²⁺ to increase several-fold.
6a. Increased intracellular Ca²⁺ facilitates binding of Ca²⁺ with calcium-binding proteins (CaBP) like calmodulin, and also activates CaBP. Ca²⁺-calmodulin dependent protein kinases are also activated in this process.
7a. CaBP alters cell functions.

**In DAG Subsystem:**
5b. DAG stimulates the enzyme protein kinase C (PKC).
6b. PKC causes phosphorylation of a variety of intracellular proteins leading to formation of phosphoproteins.
7b. Phosphoproteins alter cell functions.

Examples of hormones that act via IP₃ and DAG are: norepinephrine acting via α₁ receptors, ADH acting via V₁ receptors, angiotensin II, TRH, etc.

2. The HR complex activates guanylyl cyclase in the membrane.

**Guanylyl cyclase** is the sub-membrane enzyme that forms part of the receptor. In fact, it is the cytoplasmic domain of the receptor. Therefore, binding of hormone with receptor automatically activates this enzyme. There are various isoforms of the guanylyl cyclase.

3. Guanylyl cyclase converts cytoplasmic guanosine triphosphate (GTP) to cGMP.

4. cGMP activates cGMP-dependent kinases and phosphatases that cause phosphorylation of different intracellular proteins. cGMP also directly opens ion channels. In rods and cones, cGMP operated mechanisms mediate physiologic effects.

**Ligands that act through cGMP:** The hormones that act through cGMP are ANP, nitric oxide (NO). The enterotoxin of E. Coli and GI polypeptide hormone guanylin also act through cGMP.

**Intracellular Receptor (Transcription of mRNA) System**

The receptors for thyroid and steroid hormones, 1,25-dihydroxycholecalciferol and retinoids are located inside the cell. The hormone diffuses through cell membrane into the cytoplasm and combines with the receptor, which is present either in cytoplasm or in nucleus. The receptor for glucocorticoid is present in cytoplasm, whereas the receptor for thyroxine and other steroid hormones is located in nucleus.
proteins are intracellular proteins and they are so named as their concentration increases on exposure of cells to heat and stress. Therefore, they are also called stress proteins. They protect cells from various stresses.

3. The binding of active HR complex to DNA facilitates transcription of mRNAs.
4. The mRNAs are then translated in the ribosomes to form new proteins.
5. Formation of new proteins in the cell alters cell function.

**Other Mechanisms of Signal Generation**

**Tyrosine Kinase Activation**

Some peptide hormones do not require G protein for inducing the signal transduction system. The hormone binds with the receptor, which has intrinsic tyrosine kinase activity. The receptor has three domains: extracellular, membrane and intracellular domains. The extracellular domain possesses the binding site for hormone and the intracellular domain possesses tyrosine kinase activity.

The steps of signal induction are as follows:

1. The binding of hormone with the receptor causes conformational change in the receptor that exposes the intracellular sites of the receptor for autophosphorylation (Fig. 53.8).
2. The kinase autophosphorylates tyrosine residue within the receptor and tyrosine residues on intracellular protein substrates.
3. The phosphorylation of tyrosine residue initiates cascade of phosphorylation reactions that phosphorlyates various enzymes like serine and threonine kinases, and phosphatases. Phosphorylated enzymes change cellular activities.

The hormones that act through tyrosine kinase are insulin, IGF I, IGF II, other growth factors like PDGF, and EGF, and M-CSF.

**JAK-STAT Pathway**

The other method of tyrosine kinase activation is that the hormone binding causes conformational change in the intracytoplasmic tip of the receptor that exposes the sites to which cytoplasmic tyrosine kinase binds.

1. The activation of tyrosine kinase such as Jannus tyrosine kinase (JAK) phosphorylates signal transducers and activator of transcription proteins (STAT proteins).
2. Activation of JAK-STAT pathway further activates intracellular enzymes that change cell function. Example of the hormone acting through JAK-STAT pathway is the growth hormone (for details of mechanism, refer “Growth Hormone”).

**Calcium–Calmodulin System**

This is the system of transduction of the hormone signal in which binding of hormone to a receptor on the cell

---

**Fig. 53.6:** Structure of steroid receptor. C and N at both end of the receptor depict carboxy terminal and amino terminal, respectively.

**Receptors**

The receptors for steroid hormones are monomeric phosphoproteins. They have amazing resemblance with the receptors for 1,25-dihydroxycholecalciferol, thyroid hormones, and retinoic acids. Receptors for all these diverse hormones are considered to be part of a single gene superfamily.

1. They have five domains (A to E), and the homology is mainly seen for the C domain, especially C1 sub-domain (Fig. 53.6). The estrogen receptor has an extra domain called F domain. The C1 sub-domain of the receptor is responsible for binding to DNA.
2. The receptors dimerize when they bind with DNA, which is essential for gene transcription.
3. The receptors have an amino terminal and a carboxy terminal.
4. The hormone binding domain is present close to the carboxy terminal.
5. A cysteine-rich DNA binding domain is located close to the hormone-binding domain.
6. When hormone binds with receptor, C1 DNA binding domain binds with DNA through two zinc fingers.

**Steps of Signal Transduction**

Binding of hormone with the receptor triggers following series of events:

1. The binding of hormone with the receptor causes conformational change in the receptor protein. The DNA binding domain of the receptor is exposed.
2. The hormone and active-receptor complex then moves to the DNA and binds with the enhancer elements (also called hormone response elements or steroid response elements; SRE) in the DNA. Normally, steroid receptors are bound to heat shock protein (HSP) that covers the DNA binding domain (Fig. 53.7). When hormone binds with receptors, the conformational change in receptor releases the heat shock protein from it, which exposes the DNA binding domain. Heat shock proteins are intracellular proteins and they are so named as their concentration increases on exposure of cells to heat and stress. Therefore, they are also called stress proteins. They protect cells from various stresses.
3. The binding of active HR complex to DNA facilitates transcription of mRNAs.
4. The mRNAs are then translated in the ribosomes to form new proteins.
5. Formation of new proteins in the cell alters cell function.
Increased intracellular calcium changes cell function by various mechanisms.
1. Thus, in this system, calcium is the second messenger for hormone action.
2. Calcium is also mobilized from the intracellular storage sites like mitochondria and endoplasmic reticulum (Fig. 53.9).
3. In many tissues, the secretion of calcium from the intracellular storage sites triggers opening of calcium channels in the cell membrane. This is called store-operated calcium influx. This further increases the calcium concentration in the cell and replaces calcium in endoplasmic reticulum and mitochondria.
4. Calcium then binds with many intracellular calcium binding proteins. One of the important calcium binding proteins is the calmodulin.

**Calmodulin-dependent Kinases**
Calmodulin is a polypeptide containing 148 amino acids and has four calcium binding domains. When calcium binds with calmodulin, it activates different calmodulin-dependent kinases. There are various calmodulin-dependent kinases in the cell. The important kinases are:
1. Myosin light change kinase that causes phosphorylation of myosin.
2. Phosphorylase kinase that causes phosphorylation of many intracellular proteins.
3. Other important kinases are calcium-calmodulin kinase I, II, and III. Kinases I and II are concerned with synaptic function and kinase III is involved in protein synthesis.
Likewise, there are many kinases that are involved in various cell functions.

**Calcium Binding Proteins**

The calcium binding proteins in the cells are calmodulin, troponin, and calbindin.

1. The troponin is the calcium binding protein present in the skeletal muscle involved in muscle contraction.
2. Calcineurin, a calmodulin-activated protein, is a phosphatase, which inactivates calcium channels through dephosphorylation. Calcineurin also participates in immunity by activating T cell.

**Rapid Actions of Steroids**

Usually steroids act through the intracellular receptor that causes translation and transcription of mRNA to form new proteins. As transcription of mRNA is a time-consuming process, actions (genomic actions) of steroids are normally delayed. However, some actions of steroid hormones manifest more rapidly than the transcription process. These are categorized as nongenomic actions of steroids.

1. For nongenomic actions, the hormone binds with the surface receptors that either changes membrane permeability to calcium or other ions, or stimulates formation of second messengers like cAMP in the cell. An example of nongenomic action is the rapid neuronal changes induced by steroid.
2. Thus, steroids also act through intracellular second messengers that are activated by other hormones.
3. This forms the physiological basis of interaction of steroid hormones with other hormones. For example, estrogen and dopamine interact at the second messenger level for nongenomic actions of estrogen.

---

**CHAPTER SUMMARY**

**Key Concepts**

1. Protein and amino acid hormones act by altering intracellular levels of cAMP, cGMP, IP$_3$, DAG, and Ca$^{2+}$. Few hormones act directly by altering ion channels in the membrane and many through the G proteins.
2. Steroid hormones and thyroid hormones act by altering cellular transcription and translation mechanisms.
3. Few hormones like insulin do not require G proteins. Binding with the receptor, activate the intrinsic tyrosine kinase activity of the receptor that triggers the induction of intracellular signaling pathway.
4. Up-regulation and down-regulation of receptors occurs with sustained decrease or increase in the level of hormone in the blood.
Important to Know (Must Read)

1. In examination, “Describe the mechanisms of hormone action”, “Describe the mechanism of hormone action via adenylate cyclase-cyclic AMP and membrane phospholipid-phospholipase pathways” may come as **Long Questions**.

2. Hormone signaling, G proteins, adenylate cyclase-cyclic AMP pathway of hormone action, Membrane phospholipid-phospholipase system, cGMP, Calcium-calmodulin system, Intracellular receptors, Hormone action via mRNA transcription mechanism, Hormone action via tyrosine kinase system, may be asked as **Short Questions**.

3. In **Viva**, examiner may ask… Up-regulation, Down-regulation, and Desensitization of receptors, Types, functions and dysfunctions of G proteins, list of second messengers, Steps and mechanism of action of cyclic AMP, Steps and mechanism of action of IP$_3$-DAG system, Steps and mechanism of action of cyclic GMP, Steps and mechanism of action of thyroid and steroid hormones, Steps following tyrosine kinase activation, Steps following tyrosine JAK-STAT pathway activation, Calmodulin-dependent kinases, Calcium binding proteins and their actions, Examples of hormones acting through the various pathways, and Rapid action of steroids.
CHAPTER 54
Hypothalamus and Hypothalmo‑pituitary Axis

LEARNING OBJECTIVES
On completion of study of this chapter, the student MUST be able to:
1. Appreciate the importance of hypothalamus as an endocrine organ.
2. List the hormones secreted from hypothalamus and mention their functions.
3. Understand the functional organization of hypothalmo‑pituitary axis (HPA).
4. Brief the role of HPA in the regulation of pituitary functions.

The student MAY also be able to:
1. Describe the functions of hypothalamic hormones.
2. Explain the function of HPA in the control of pituitary function.

HYPOTHALAMUS
Hypothalamus plays a vital role in the regulation of visceral functions. For its central location in the brain, hypothalamus is closely connected with the limbic system, autonomic nervous system and pituitary gland. Therefore, hypothalamus is the main neural structure for the integration of visceral homeostatic mechanisms. Through the regulation of pituitary secretions, hypothalamus plays a master role in the control of many endocrine functions of the body. As the hormones secreted from hypothalamus (especially to posterior pituitary) are synthesized in hypothalamic neurons, they are called as neurohormones.

Scientists contributed

Roger Charles Louis Guillemin (Born, 1924) and Andrew V Schally (Born, 1926)

Roger Charles Louis Guillemin received the National Medal of Science in 1976, and the Nobel prize in Physiology and Medicine for the year 1977 for his work on neurohormones (peptide hormones produced in the brain), sharing the prize with Andrew V Schally. Guillemin and Schally discovered the structures of TRH and GnRH in separate laboratories.

Hypothalamus as an Endocrine Gland
The hypothalamus plays an important role in the regulation of endocrine functions. It controls all the secretions from pituitary gland.
1. Through its connection with anterior pituitary gland, it controls:
   - thyroid functions (hypothalamo‑pituitary‑thyroid axis),
   - adrenocortical secretions (hypothalamo‑pituitary‑adrenocortical‑axis), and
   - gonadal functions (hypothalamo‑pituitary‑gonadal‑axis).
2. Via its influence on sympathetic output, hypothalamus controls secretions of adrenal medulla (hypothalamo‑sympatho‑adrenal‑axis).
3. It directly controls the secretions from posterior pituitary.
   Thus, hypothalamus regulates functions of major endocrine glands. Therefore, hypothalamus is apparently designated as the “master of endocrine orchestra”.

Integration with Neural Structures
Anatomically and physiologically, hypothalamus is situated at the center of the brain, below the corpus callosum and thalamus (Fig. 54.1). Therefore, hypothalamus collects and integrates information from various parts of
Section 6: Endocrine Physiology

Fig. 54.1: Location of hypothalamus in the brain.

Fig. 54.2: Connection of hypothalamus with other brain centers. Note, after receiving inputs from all these structures hypothalamus funnels these inputs to brainstem and pituitary for regulation of visceral functions.

the brain and funnels them through the pituitary gland for modification of endocrine functions. Thus, hypothalamus is the primary link between nervous and endocrine systems. It receives afferent signals from:
1. Reticular activating system
2. Thalamus
3. Neocortex
4. Eyes
5. Limbic system, especially from amygdala, septum, olfactory bulb, and hippocampus (Fig. 54.2).

These neural inputs convey the information regarding alertness, application of nociceptive stimuli, sleep-wakefulness, changes in environment, emotion, visual, olfactory and gustatory sensations and so on. After gathering these information, hypothalamus appropriately alters body functions partly through its influences on endocrine secretions and partly through its control on major neural outputs from brain like projections from brainstem cardio-respiratory centers, and autonomic and limbic outputs (Flowchart 54.1).

Hypothalamus, via its endocrine influences also controls thirst, appetite, energy store, body fat composition, immunity, behavior and visceral functions. Thus, hypothalamus through its extensive neuroendocrine connections, controls major body functions. Hence, diseases affecting hypothalamic nuclei result in many pathological syndromes.

Hypothalamic Hormones

Hypothalamic hormones are secreted from various nuclei of the brain (Fig. 54.3). Hypothalamic hormones can be classified broadly into three categories: anterior pituitary regulating hormones, posterior pituitary hormones and other hormones.

Anterior Pituitary Regulating Hormones

Hypothalamic hormones that regulate anterior pituitary secretions are known as releasing or release inhibiting hormones as they stimulate or inhibit the release of various hormones from this part of the pituitary. The hormones are: Thyrotropin releasing hormone, gonadotropin releasing hormone, corticotropin releasing hormone, growth hormone releasing and inhibiting hormones, and prolactin...
releasing and inhibiting hormones (Flowchart 54.2). These are peptide hormones that act on target cells mostly through cyclic AMP and IP3 or DAG as second messengers. They regulate secretions from anterior pituitary.

**A. Releasing Hormones**

**Thyrotropin Releasing Hormone (TRH)**

TRH is an oligopeptide containing 3 amino acids. 

**Source:** TRH is secreted from paraventricular nucleus of hypothalamus.

**Functions:**

1. TRH stimulates secretion of thyroid stimulating hormone (TSH) or thyrotropin from thyrotrophs of anterior pituitary.
2. It stimulates expression of genes for α and β subunits of TSH in thyrotrophs.
3. It also promotes secretion of prolactin and growth hormone (GH).

**Gonadotropin Releasing Hormone (GnRH)**

GnRH is a peptide containing 10 amino acids. 

**Source:** GnRH is secreted from the arcuate nucleus of hypothalamus.

**Functions:**

1. GnRH stimulates secretion of luteinizing hormone (LH); therefore, GnRH is known as luteinizing hormone releasing hormone (LHRH). It also stimulates secretion of follicular stimulating hormone (FSH). Together, it is known as gonadotropins releasing hormone as it stimulates secretion of both LH and FSH.
2. GnRH also stimulates secretion of GH.

**Corticotropin Releasing Hormone (CRH)**

CRH is a polypeptide having 41 amino acids. 

**Source:** CRH is secreted from paraventricular nucleus of hypothalamus.

**Functions:**

1. CRH stimulates the secretion of adrenocorticotropic hormone (ACTH) or corticotropin from corticotrophs of anterior pituitary.
2. It also stimulates the expression of proopiomelanocortin (POMC) gene in corticotrophs.
3. CRH promotes secretion of β- and γ-lipotropin and β-endorphins.

**Growth Hormone Releasing Hormone (GHRH)**

GHRH appears in two forms in humans, one containing 40 and other 44 amino acids. 

**Source:** GHRH is secreted from the arcuate nucleus of hypothalamus.

**Functions:**

1. GHRH stimulates secretion of growth hormone from somatotrophs of anterior pituitary.
2. It also stimulates the expression of GH gene in corticotrophs.
Section 6: Endocrine Physiology

**Prolactin Releasing Factor (PRF)**
The exact site of synthesis of PRF in hypothalamus is not known. It stimulates prolactin synthesis and secretion from lactotrophs of anterior pituitary.

**B. Release Inhibiting Hormones**

*Growth Hormone Inhibiting Hormone (Somatostatin)*
Somatostatin is a peptide having 14 amino acids. It is secreted from anterior periventricular nucleus of hypothalamus. It inhibits secretion of growth hormone, prolactin and TSH.

*Prolactin Inhibiting Hormone (PIH)*
PIH is the dopamine, which is secreted from arcuate nucleus of hypothalamus. It inhibits secretion of prolactin, TSH, and growth hormone from anterior pituitary.

**Posterior Pituitary Hormones**
ADH and oxytocin secreted from posterior pituitary are actually not formed in this gland. They are synthesized in supraoptic and paraventricular nuclei of hypothalamus and stored in posterior pituitary (for details, see below and refer the chapter on “posterior pituitary”).

**Other Hypothalamic Hormones**
Other hormones of hypothalamus are neuropeptide Y, orexins, MCH, ghrelin, MSH and CART. They are mainly involved in the control of ingestive behaviors and regulation of body weight and composition. Ghrelin is secreted mainly from GI tract, and less from hypothalamus.

*Neuropeptide Y*
This polypeptide hormone containing 36 amino acids is secreted from hypothalamus. The cell bodies of neurons that synthesize neuropeptide Y are present in the arcuate nucleus, and the axons project to the paraventricular nucleus.

1. It is the principal neurohormone that stimulates food intake. It has also been observed that neuropeptide Y secretion in hypothalamus increases during feeding and decreases during cessation of feeding (satiety).
2. Many neurotransmitters that stimulate food intake increase neuropeptide Y release and neurochemicals that inhibit feeding decrease neuropeptide Y release from hypothalamus.

**Orexins**
There are two types of orexins: orexin-A and orexin-B. Orexins are synthesized in the lateral hypothalamus. They stimulate food intake.

**Melanin-Concentrating Hormones (MCH)**
This is a polypeptide containing 19 amino acids. It is secreted by the pituitary, lateral hypothalamus, and zona incerta. There are receptors for MCH in the hypothalamus. It increases food intake.

**Cocaine and Amphetamine-Regulated Transcript**
The hypothalamic hormone CART (cocaine and amphetamine-regulated transcript) inhibits food intake.

**Applied Physiology**
Endocrine hypothalamic dysfunctions lead to abnormalities of hypothalamo-endocrine axes described above. This results in irregularities in anterior and pituitary secretions and many target organ dysfunctions. These are called hypothalamic syndromes (for details, refer the Chapter “Hypothalamic Functions” in Neurophysiology).

**HYPOTHALAMO-PITUITARY AXIS**
The hypothalamus is closely linked with pituitary gland both anatomically and functionally. The connection between hypothalamus and pituitary is called hypothalamo-pituitary axis. Hypothalamus is connected separately and differently with anterior and posterior pituitaries. The connection with anterior pituitary is by means of blood vessels (portal-hypophyseal vessels) and with posterior pituitary is through the neurons (hypothalamo-hypophyseal tract).
Chapter 54: Hypothalamus and Hypothalamo-pituitary Axis

457

Portal Hypophyseal Vessels

The connection between the anterior pituitary and hypothalamus is vascular. Anterior pituitary develops from the Rathke’s pouch, an evagination from the roof of the pharynx. The portal hypophyseal vessels directly connect between hypothalamus and anterior pituitary.

1. The blood vessels arise from capillaries on the ventral surface of hypothalamus (primary capillary plexus) that derive blood from superior hypophyseal artery (Fig. 54.4).

2. The capillaries drain into the sinusoidal portal hypophyseal vessels. These long portal hypophyseal vessels carry blood down the pituitary stalk to the anterior lobe of the pituitary where they end in another set of capillaries. Thus, the system of blood vessels begins with capillaries and ends with capillaries without passing through the heart. Therefore, they are examples of true portal system of blood vessels (a portal vessel starts and ends with capillaries without traversing through the heart).

3. The releasing hormones secreted from hypothalamus reach anterior pituitary via hypophyseal portal circulation. Therefore, these hormones are also called hypophysiotropic hormones.

4. Hypophysiotropic hormones are synthesized in small hypothalamic neurons (parvocellular neurons), the axon terminals of which contact the capillary network in the median eminence and infundibulum in hypothalamus that give rise to long portal vessels in the pituitary stalk.

5. Thus, hypophysiotropic hormones are transported to anterior pituitary via hypophyseal portal blood.

6. Short portal hypophyseal vessels communicate the capillaries of anterior pituitary with capillaries of posterior pituitary, which derives blood from inferior hypophyseal artery.

Hypothalamo-hypophyseal Tract

The connection between hypothalamus and posterior pituitary is neural. Posterior pituitary develops as an evagination of the floor of the third ventricle. It is formed by the terminals of the nerves, the cell bodies of which are present in the supraoptic and paraventricular nuclei of hypothalamus.

1. The cell bodies of these neurons are larger than the cell bodies of other hypothalamic neurons. Therefore, they are called magnocellular neurons.

2. The axons arise from these cell bodies and descend down to terminate on the capillary bed in the posterior pituitary. They form the hypothalamo-hypophyseal tract (Fig. 54.4).

3. Because of its neural origin and connections, posterior pituitary is known as neurohypophysis.

4. Most of the fibers originating from supraoptic nucleus terminate in the posterior pituitary whereas some of the fibers originating from the paraventricular nucleus in addition to their termination on posterior pituitary also terminate in the median eminence.
CHAPTER SUMMARY

**Key Concepts**

1. Hypothalamus is closely connected with limbic structures and secretes neurohormones.
2. It controls all pituitary secretions. Posterior pituitary hormones are formed in hypothalamus.
3. For its limbic connections, and control of pituitary functions, hypothalamus mediates body’s responses to emotion, stress and environmental changes.

**Important to Know (Must Read)**

1. **Long Questions** may not be asked from this chapter.
2. In examination, ‘Hypothalamic hormones, Hypothalamo‑hypophyseal tract, Hypothalamo‑pituitary axis’, are asked as **Short Questions**.
3. In **Viva**, examiner may ask... name of hormones secreted from hypothalamus, the hormones of anterior pituitary stimulated or inhibited by each hypothalamic hormone, Source and functions of TRH, GnRH, CRH, GHRH, PRF, PIH, and Somatostatin, name and functions of other hypothalamic hormones like Neuropeptide Y, Orexins, MCH, and CART, How is hypothalamo‑pituitary axis formed, What is the main difference between connections of hypothalamus with anterior pituitary and posterior pituitary. Dysfunctions associated with each hypothalamic hormones.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Appreciate the importance of anterior pituitary as an important endocrine gland and its role in regulation of body functions.
2. List the hormones secreted from anterior and name the cells that produce them.
3. Describe the regulation, mechanism of action, functions and dysfunctions of growth hormone (GH).
4. Understand the role of GH in regulation of growth and development.
5. Mention the functions and dysfunctions of other anterior pituitary hormones.

The student MAY also be able to:
1. Describe the regulation of GH secretion.
2. Explain the mechanism of action of GH.
3. Describe the details of the functions and diseases of GH.

Pituitary Gland: The Anterior Pituitary

The pituitary gland or hypophysis controls many aspects of human physiology starting from the birth (delivery of the fetus) and feeding of the baby to the growth and development of the individual to adulthood and reproduce. It controls various aspects of metabolism. It contributes to regulation of blood volume and pressure and body’s reaction to stress. Therefore, dysfunctions of pituitary gland result in various clinicopathological disorders.

Scientist contributed

Bernardo Alberto Houssay (1887–1971) was an Argentine physiologist who, in 1947, received one-half of Nobel Prize for Physiology or Medicine for his discovery of the role played by anterior pituitary in regulating the amount of blood sugar (glucose) in animals. He shared the prize with Carl Ferdinand Cori and Gerty Cori, who won for their discoveries of catalytic conversion of glycogen in carbohydrate metabolism. The animals used for pituitary related experiments are called as ‘Houssay animals’.

Functional Anatomy

Pituitary gland is situated at the base of the brain in sella turcica, a small cavity on sphenoid bone. It consists of two lobes: anterior and posterior lobes (Fig. 55.1). Though,
intermediate lobe of pituitary is present in many species, in human beings, it is rudimentary. Anterior and posterior lobes of pituitary are two separate and distinct glands.

1. The anterior pituitary is rich in various endocrine cells. Hence, anterior pituitary is called adenohypophysis.
2. The posterior pituitary contains neurons that secrete hormones. Hence, posterior pituitary is called neurohypophysis.

Development
Embryologically, anterior and posterior pituitaries develop from different sources:

1. Anterior pituitary develops as an evagination from Rathke’s pouch and neurohypophysis develops as part of developing hypothalamus that later merges with Rathke’s pouch.
2. Later, endocrine tissue of anterior lobe becomes purely glandular (adenohypophysis) and posterior lobe becomes neuroendocrine (neurohypophysis).

Blood Supply
Blood supply to pituitary is achieved by means of superior and inferior hypophyseal arteries:

1. The superior hypophyseal artery terminates in rich capillary network in the median eminence, from where long hypophyseal portal vessel arises and descends down the pituitary stalk to end in capillaries in the anterior lobe.
2. As the major hypophyseal vessels start and end with capillaries, the arrangement is called hypophyseal portal circulation.
3. The inferior hypophyseal artery supplies blood to the posterior lobe from where short hypophyseal portal vessels arise and terminate locally (Fig. 55.2).

Hormone Secretion
The anterior pituitary has extensive network of sinusoidal capillaries. The endothelium of capillaries is fenestrated:

1. The endocrine cells contain numerous granules that store hormones.
2. Hormones are secreted by exocytosis of these granules, following which they immediately enter circulation through the capillaries.

**ANTHORIAL PITUTARY**

**Hormones of Anterior Pituitary**

Six important hormones secreted from anterior pituitary are:

1. Growth hormone (GH) or somatotropin
2. Thyroid-stimulating hormone (TSH) or thyrotropin
3. Adrenocorticotropic hormone (ACTH) or corticotropin
4. Follicle-stimulating hormone (FSH) or gonadotropin
5. Luteinizing hormone (LH) or gonadotropin
6. Prolactin

Other hormones are: β-lipotropin (β-LPH), α-melanocyte-stimulating hormone (α-MSH) and interleukins.

**Structure**
Anterior pituitary hormones are polypeptides. LH, FSH, and TSH are glycoproteins containing two subunits: the α and β subunits, similar to that of hCG secreted from placenta. The α subunit of these hormones have similar amino acid pattern. Therefore, the β subunit confers specificity to the hormones.

Control of Secretion and Major Effects
Secretion of anterior pituitary is controlled by hypothalamic hormones (Fig. 55.3). Anterior pituitary hormones in turn control secretion of major endocrine glands of the body except pancreas. They also control growth and development and all aspects of metabolism (Flowchart 55.1). Therefore, diseases of anterior pituitary manifest with widespread and extensive abnormalities.

**Cell Types of Anterior Pituitary**
The cell types of anterior pituitary are divided into two broad categories: chromophobes and chromophils.

**Chromophil Cells**
The chromophil cells are subdivided into acidophils (α cells) and basophils (β cells):

1. The acidophils are the cells that stain with acidic dyes, and basophils are the cells that stain with basic dyes (Fig. 55.4).
2. There are five types of chromophil cells (Table 55.1):
Chapter 55: Pituitary Gland: The Anterior Pituitary

**Folliculostellate Cells**
Recently, **folliculostellate cells** have been identified in the anterior pituitary that secrete cytokines, especially IL-6.

**GROWTH HORMONE**
Growth hormone (GH) is secreted from **somatotrophs** that constitute about 50% of the total endocrine cells of the anterior pituitary. As GH promotes postnatal somatic growth, it is also known as **somatotropin**. It does not stimulate fetal growth. It maintains normal lean body and bone mass in adults. It has many metabolic effects.

**Structure**
Human GH is a polypeptide containing 191 amino acids. It has structural resemblance with human prolactin and placental lactogen.

**Flowchart 55.1:** Hypothalamic-pituitary-target organ axis. Plus sign (+) indicates stimulation and minus sign (−) indicates inhibition.
### Types, Secretion and Metabolism of GH

There are **two forms** of GH: **22 K GH** (molecular weight of 22000) that constitutes 90%, **20 K GH** (molecular weight of 20000) that constitutes 10% of the total circulating GH.

#### Synthesis of GH

GH is synthesized as a **larger prohormone** in rough endoplasmic reticulum. The prohormone consists of N-terminal signal peptide and 191 amino acid-peptide hormone. Subsequently, the **signal peptide** is removed when the prohormone traverses through the Golgi apparatus. Finally, the hormone is packaged and stored in the granules of somatotrophs.

#### Regulation of GH Synthesis

Two hypothalamic hormones control the synthesis of GH: GHRH and somatostatin. GHRH stimulates and somatostatin inhibits synthesis of GH. GHRH promotes GH synthesis by stimulating expression of **GH gene in the somatotrophs**. **TSH also stimulates** expression of GH gene. Therefore, patient with thyroid hormone gene deficiency also develops GH deficiency.

---

### Regulation of GH Secretion

The normal basal plasma GH concentration ranges from 0–5 ng/mL in adults. The rate of GH secretion primarily depends on the balance between the action of GHRH and somatostatin on somatotrophs of anterior pituitary:

1. GHRH stimulates and somatostatin inhibits GH secretion. GH in turn controls its own secretion by **feedback mechanisms** (Fig. 55.5).
2. GH has a **negative feedback effect** on GHRH and a positive feedback effect on somatostatin secretion. GH stimulates production of **insulin like growth factor I (IGF-1)** or somatomedin C, which in turn has a negative feedback effect on GH secretion.
3. IGF I has effects both at pituitary and hypothalamus levels. Various factors regulate GH secretion (Table 55.2) by influencing secretion of GHRH, somatostatin and IGF I.

Recently, a new growth hormone releasing factor (GHRF) secreted from hypothalamus has been identified, which profoundly modulates GH secretion. Ghrelin is proposed to be the new GHRF.

**GH secretion throughout life**: Exercise, stress, high protein meal and fasting facilitate GH secretion:

1. GH secretion **increases during infancy** and then the secretion is maintained throughout childhood.
2. GH secretion **increases enormously at puberty** (Fig. 55.6), which is associated with a sudden increase in height and general growth of the body. The final height of the individual is mainly determined by their inherent GH secreting capacity.
3. After puberty, GH secretion decreases to adult level and maintains till senescence. GH secretion is less in old age.

</table>
GH secretion in sleep: It is not clearly known why GH secretion occurs in episodes or bursts throughout the day when growth occurs slowly over months and years. The pulsatile secretion becomes more prominent in the midnight, especially within first few hours of deep sleep (Fig. 55.7). Approximately, 70% of total 24 hours GH secretion occurs during slow wave sleep (stages 3 and 4) (Application Box 55.1).

**Application Box 55.1**

Adequate sleep promotes growth: In a normal sleep, maximum time is spent in slow wave sleep. As GH secretion is maximum in slow wave sleep, individuals who sleep adequate usually remain healthy and those who sleep less do not gain weight. Especially, children (this is the growing phase of life) are advised to sleep more to attain normal growth. Those who have sleeplessness, they do not gain weight.

**Metabolism**

GH binds with a plasma protein, which is a fragment of the extracellular domain of GH receptor. The concentration of this plasma protein (GH receptor fragment) is therefore an index of the number of GH receptors in the tissue:

1. About 50% of the GH is bound to this protein that provides a reservoir of GH in the plasma.
2. GH is metabolized rapidly by the liver.
3. The half life of GH is about 6–20 minutes.
4. Normally, in adult, less than 3 ng/mL of GH is present in the plasma in basal conditions.
5. Though, only a small quantity of GH is excreted unaltered in urine, daily urinary output of GH reflects its 24 hours profile.

**Mechanisms of Action**

Growth hormone binds with the receptor called growth hormone receptor, which is a membrane polypeptide containing 620 amino acids. This receptor neither resemble any of the G protein-linked receptor, nor is it similar to receptors with intrinsic tyrosine kinase activity. Rather, it is a tyrosine kinase associated receptor that belongs to the member of cytokine receptor superfamily:

1. It has three domains: a large extracellular domain, a transmembrane domain, and a large cytoplasmic domain.
2. GH receptor has two subunits and there is binding site on each subunit.
3. When GH binds to one receptor subunit, the binding site on other subunit is attracted and subunits come close to each other. This produces a homodimer of GH receptor.
4. This dimerization is an essential component of receptor activation as it initiates the activation of a number of enzyme cascades including JAK-STAT pathway of hormone action (Fig. 55.8).
5. The hormone binding with receptor activates following four signaling pathways:

   a. JAK-STAT pathway: JAK-2 is the member of the family of cytoplasmic tyrosine kinases, known as Janus kinase. It is associated with but not an integral part of GH receptor. STAT is the signal transducers and activators of transcription, which belongs to a family of inactive cytoplasmic transcription factor:
      • Binding of GH with GH receptor activates cytoplasmic domain of it, which induces JAK kinase.
      • STAT on phosphorylation by JAK kinases migrate to the nucleus.
      • This results in induction of various genes that mediate hormone action.
      • Prolactin and other growth factors also act through the JAK-STAT pathway.

   b. SHC-Grb pathway: JAK 2 phosphorylates intracellular protein SHC which in turn activates Grb2 proteins. Grb2 proteins stimulate MAP kinase that induces various gene transcriptions.
c. **TK-IRS pathway**: Activation of JAK-tyrosine kinase causes **phosphorylation of IRS** (insulin receptor substrate) which in turn induces various intracellular enzymes.

d. **Phospholipase-C pathway**: HR complex also stimulates membrane enzyme **phospholipase C**, which results in production of DAG. **DAG initiates calcium influx** into the cell and probably, also initiates gene transcription.

### Physiological Actions of GH

Growth hormone is an anabolic hormone with profound **short-term metabolic effects** and **long-term growth-promoting effects**:

1. **Acute metabolic effects** of GH like lipolysis in adipose tissue, decreased glucose uptake by muscle and stimulation of gluconeogenesis by hepatocytes are due to its **direct actions** on target tissues.

2. Whereas, many **long-term effects** of GH are mediated by **somatomedins** (IGF-1 and IGF-2) produced by it. Growth promoting effects are also part of the direct effects of GH (Flowchart 55.2).

### Direct Actions of GH

**Effects on Growth**

The most striking and specific effect of GH is the *stimulation of linear growth*, which occurs due to its action on the epiphysial cartilage of long bones. GH stimulates **all aspects of metabolism of chondrocytes** (the cartilage forming cells). The major actions of GH on chondrocytes include:

1. Incorporation of **proline into collagen** and its conversion into **hydroxyproline** (Application Box 55.2).

2. Incorporation of sulfate into the proteoglycan chondroitin. The hydroxyproline and chondroitin together form the extracellular matrix of cartilage. Thus, GH **promotes cartilage matrix formation**.

3. Increased amino acid uptake and **protein synthesis**, and increased RNA and DNA synthesis in chondrocytes.

4. Increase in **size and number of chondrocytes**.

5. GH also acts directly on progenitor or stem cells such as **prechondrocytes** in growth plates of bone. It facilitates the **differentiation of prechondrocytes to chondrocytes**. All these actions result in **growth of epiphyseal cartilage** that increases the length of the bone and consequently promotes linear growth of the body. Thus, GH increases the height of the individual before closure of epiphysis.
Application Box 55.2

**Hydroxyprolinuria reflects GH activity:** Increased secretion of GH manifests as hydroxyprolinuria (excretion of hydroxyproline in the urine). Hydroxyproline is derived from collagen. As GH increases the soluble collagen synthesis, hydroxyproline is formed and excreted. Thus, hydroxyprolinuria is an index of GH activity. However, hydroxyprolinuria is also associated with diseases that cause collagen destruction.

**Other growth promoting effects of GH include:**

1. **On bone:** GH stimulates the activity of bone modeling units. It increases activity of both osteoclasts and osteoblasts. However, osteoblastic activity predominates, and therefore bone formation becomes more. The total bone mass and mineral content of bone increase.

2. **On skeletal muscle:** GH increases the growth of skeletal muscle by increasing protein synthesis and causing hypertrophy of skeletal muscle cell. It also promotes activity of satellite cells of skeletal muscle. Satellite cells are progenitor cells in skeletal muscles.

3. **On visceral organs:** GH also stimulates growth of many visceral organs like liver, kidney, heart, pancreas, intestine, etc., many endocrine organs, skin, and connective tissue. All these organs increase in size and function due to hypertrophy and hyperplasia in response to GH. Organs grow in size due to:
   - increased protein synthesis,
   - increased RNA and DNA synthesis and
   - increase in cell size and number.
   The general visceral functions like digestion and specific visceral functions like cardiac output and GFR improve.

4. **Pubertal and gonadal growth:** GH increases height during puberty. It also sensitizes gonads to the actions of LH and FSH. Thus, GH promotes prepubertal sexual maturation.

**Effects on Protein Metabolism**

The effects of GH on general somatic growth are primarily due to the protein anabolic effects. These include:

1. Positive nitrogen and phosphorus balance.
2. Increased amino acid entry into the cells in many tissues.
3. Increased RNA and DNA synthesis in the cell.
4. Increased protein synthesis.
5. Decreased plasma level of amino acid and urea that occur secondary to amino acid entry into the cells and increased protein synthesis.

**Effects on Carbohydrate Metabolism**

Growth hormone is a prodiabetogenic hormone as it causes hyperglycemia by following actions:

1. It increases release of glucose from liver by facilitating hepatic neoglucogenesis.
2. It decreases glucose uptake by skeletal muscle.
3. Decreases insulin sensitivity.

However, GH stimulates insulin secretion indirectly by increasing the ability of pancreas to various insulinogenic stimuli. IGF-I, secreted mainly from liver under the influence of GH has insulin like activity. Thus, indirectly GH also promotes growth, as insulin is a growth stimulating hormone.

**Effects on Fat Metabolism**

Growth hormone causes lipolysis and increases plasma level of FFA. By increasing FFA, it promotes ketogenesis. As it increases FFA and ketoacids in plasma, GH provides energy in various conditions of hypoglycemia and stress.

**Effects on Electrolyte and Water Metabolism**

Growth hormone influences concentration of various electrolytes by following mechanisms:
GH increases plasma Ca\(^{++}\) by increasing its absorption from GI tract. GH also potentiates the effect of vitamin D on the intestine.

2. GH causes Na\(^{+}\) retention. It decreases Na\(^{+}\) and K\(^{+}\) excretion in urine.

3. It maintains ECF volume indirectly by stimulating renin-angiotensin-aldosterone system, and suppressing the action of ANP (atrial natriuretic peptide) on kidney. Thus, GH decreases Na\(^{+}\) and water excretion.

4. It increases plasma phosphate level by increasing its reabsorption from proximal tubules of kidney.

**Effects Mediated through IGFs**

The effects of growth hormone on growth, cartilage, and protein metabolism depend partly on the production of insulin-like growth factors (IGFs) (see Flowchart 55.2). Initially, they were called somatomedins, as they were found to mediate the somatic effects of GH:

1. The principal circulating somatomedins are insulin-like growth factors-I (IGF-I, which is also called as somatomedin C) and insulin like growth factors-II (IGF-II).

2. IGF-I and II have similar actions as insulin and therefore, are called insulin like growth factors.

3. IGFs are polypeptide growth factors synthesized mainly in the liver.

4. They are also formed in cartilages and other tissues.

**Applied Physiology**

**IGF-I**

IGF-I is more potent in mediating the effects of GH than IGF-II. It is a polypeptide containing 70 amino acids:

1. **IGF-I receptor** is very similar to insulin receptor.

2. IGF-I is secreted independent of GH before birth. However, after birth, IGF-I secretion and actions are dependent on GH. Its plasma concentration is 10–700 ng/mL, which peaks at puberty. The concentration of IGF-I rises in childhood, attains peak at puberty and declines in old age.

3. It binds with plasma protein called insulin-growth factor binding proteins (IGFBP). There are six IGFBPs. **IGFBP-3 is the most prevalent** IGFBP, which serves as reservoir for IGFs in plasma.

4. IGF-I mainly causes skeletal and cartilage growth.

**IGF-II**

IGF-II is independent of GH action and plays an important role in the fetal growth. It is a polypeptide containing 67 amino acids:

1. IGF-II receptor is a mannose-6-phosphate receptor.

2. In adults, IGF-II genes are expressed only in the choroid plexus and meninges.

3. The plasma concentration of IGF II is 300–800 ng/mL.

**Hypersecretion of GH**

The hypersecretion of GH in adults (after fusion of epiphyses) results in acromegaly and in children (before fusion of epiphyses) results in gigantism.

**Acromegaly**

Acromegaly means enlargement of acral (peripheral) parts of the body. ‘Acromegaly’ is derived from the Greek words, ‘akron’ means top, and ‘megas’ means large). Hypersecretion of GH after the fusion of epiphysis results in acromegaly.

**Etiology**

Acromegaly occurs due to tumor of the somatotrophs of anterior pituitary:

1. Usually, tumor of the somatotrophs is associated with proliferation of lactotrophs also; therefore, prolactin secretion is increased in 20–40% of patients.

2. Acromegaly can also occur due to extra-pituitary causes like increased hypothalamic secretion of GRH (in hypothalamic tumors).

**Features**

- Enlargement of acral parts of the body, especially of hands and feet, prognathism (protrusion of lower jaw), acromegalic facies (overgrowth of malar, frontal and facial bones), increased amount body hair, osteoarthritis (due to skeletal changes), glucose intolerance, hirsutism, gynecomastia and lactation, increased heel pad thickness, and visual field changes (bitemporal hemianopia) are common features (Fig. 55.9).

1. Visceromegaly increases the size and function of the viscera. Macroglossia may be seen.

2. Enlargement of acral parts and skeletal deformities occur as bones enlarge in width. Bones cannot grow in length as epiphyses are already closed.

3. The visual defects are due to the effect of the pituitary tumor that enlarges the sella turcica and compresses on optic chiasma. This also causes headache.

**Management**

Disease is diagnosed by typical clinical presentation, demonstration of pituitary tumor by CT scan or MRI and demonstration of high GH level in plasma by estimation of the hormone. Surgical removal of tumor is the best option to cure the disease.

**Gigantism**

Hypersecretion of GH before fusion of epiphysis results in gigantism.

**Causes**

Pituitary tumor (of somatotroph) during childhood resulting in increased GH secretion causes gigantism. Hypothalamic tumor causing excess GHRH secretion can also produce the disease.
Features
Increased GH secretion before closure of epiphysis increases the epiphyseal growth of long bones. Therefore, the patient becomes abnormally tall, with giant stature (Fig. 55.10). Other features are same as acromegaly except the acromegalic facies.

Management
Disease is diagnosed by typical clinical presentation, demonstration of pituitary tumor by CT scan or MRI and demonstration of high GH level in plasma by estimation of the hormone. Surgical removal of tumor at the earliest cures the disease.

Hypossecretion of GH
Deficiency of GH results in dwarfism. This may occur due to four causes:
1. Decreased GRH deficiency (hypothalamic failure)
2. Decreased GH secretion (pituitary failure)
3. Decreased IGF synthesis by the liver (as seen in African pygmies)
4. Decreased or unresponsive GH receptors (Laron dwarfism).

Pituitary Dwarfism
A pituitary dwarf (dwarfism due to GH deficiency) is characterized by short stature and correspondingly delayed bone and sexual maturation (Fig. 55.10):
1. Decreased muscle and total body mass, decreased cardiac function and decreased bone density are common.
2. Mental power relatively remains normal in a pituitary dwarf, which helps in differentiating from a thyroid dwarf in whom mental retardation is an outstanding feature.

Fig. 55.9: Features of Acromegaly. Note the presence of acromegalic facies (malar and frontal prominence) and prognathism (enlarged and protruded mandible as shown in skull X-ray), enlarged acral parts of the body (increased hand and finger size as compared with a normal hand), osteoarthritis, macroglossia, increased heel pad thickness and increased size of visceral organs (visceromegaly).

Courtesy: Figure 10.1, page 757, Manual of Practical Medicine, by R Alagappan, 5th edition, 2014; Jaypee Brothers Medical Publishers (P) Ltd.
3. It is diagnosed by low level of GH or IGF-I in plasma.
4. Pituitary dwarfism is treated by administration of GH preparations (Clinical Box 55.1). Details of dwarfisms are discussed in the chapter “Physiology of Growth and Development” in Section 13.

Clinical Box 55.1
Recombinant human GH: Due to difference in structure, there is wide species variation in GH. Therefore, GH extracted from animals does not work in GH deficient patients. The amount of GH collected from human pituitaries at the time of autopsy is not adequate for treatment of GH deficient dwarfs. Presently, large quantity of human GH is produced by recombinant DNA technology that meets the need of the GH deficient children.

OTHER HORMONES

Prolactin
Prolactin is the hormone for milk synthesis. The term ‘prolactin’ refers to a hormone that favors lactogenesis (‘pro’ favoring, and ‘lactin’ lactogenesis). It also influences development of the mammary gland, reproductive functions and immune responses.

Source
Prolactin is secreted from the lactotrophs of anterior pituitary, which constitutes 10–25% of the total secreting cells of the gland. However, lactotroph population increases during pregnancy, lactation, and estrogen therapy.

Structure
This is a polypeptide hormone containing 198 amino acids with molecular weight of 23,000. It has considerable structural similarity with human GH.

Synthesis
Prolactin is synthesized like other peptide hormones, i.e. preproprolactin that forms proprolactin, which finally forms prolactin. After synthesis, the hormone is stored in the granules of the lactotrophs and on appropriate stimulation, secreted into circulation.

Regulation of Secretion
Prolactin secretion increases steadily during later part of pregnancy and attains peak at term. The increased prolactin secretion correlates with increase in plasma estrogen concentration during pregnancy:
1. In fact, estrogen causes hyperplasia of lactotrophs though it does not stimulate prolactin synthesis.
2. Estrogen also increases responsiveness of lactotrophs to other stimuli that increase prolactin synthesis and secretion.

Factors that Increase Prolactin Secretion
Prolactin releasing factor, TRH, pregnancy, estrogen therapy, nursing (breastfeeding), sleep, stress, angiotensin-II, oxytocin, dopamine antagonists, serotonin, and opioids promote prolactin secretion.

Factors that Decrease Prolactin Secretion
Dopamine and its agonists, somatostatin, prolactin and GABA inhibit prolactin secretion.

Recently, it has been found that a prolactin releasing factor is secreted from hypothalamus. However, the exact nature of the chemical is not yet known. TRH stimulates prolactin secretion. Dopamine has been identified as the prolactin inhibiting factor (PIF) secreted from hypothalamus (Clinical Box 55.2). Somatostatin also inhibits prolactin secretion. Prolactin stimulates secretion of dopamine and somatostatin, those in turn inhibit prolactin secretion. Thus, prolactin controls its own secretion by this feedback mechanism (Fig. 55.11).

Clinical Box 55.2
Dopamine is used in hyperprolactinemia: Dopamine is a potent inhibitor of prolactin secretion. Therefore dopamine is used in the treatment for conditions of hyperprolactinemia and dopamine antagonists are used in conditions of hypoprolactinemia.

Mechanism of Action
Prolactin binds with the prolactin receptors that are homologous with GH receptors in their extracellular domain. Binding of hormone with the receptor activates the cytoplasmic domain of the receptor, which in turn
Chapter 55: Pituitary Gland: The Anterior Pituitary

469

activates cytoplasmic tyrosine kinases (Fig. 55.12). Activation of JAK-STAT signal induction pathway stimulates formation of transcription factors that induces DNA and mRNA synthesis. Increased formation of mRNA promotes specific protein synthesis in the ribosomes, which in turn causes formation of casein, lipid and lactose, the ingredient of milk. Thus, milk production is stimulated.

Physiological Effects

Effects on Milk Synthesis and Secretion

The primary function of prolactin is to stimulate milk synthesis and secretion (therefore, the name pro-lactin). Therefore, prolactin secretion increases during lactation.

Effects on Breast Development

Prolactin causes hyperplasia of breast tissue before and after puberty. It also causes hyperplasia of breast tissue during pregnancy and lactation:

1. Together with estrogen, progesterone, cortisol and GH, it stimulates development (branching and proliferation of ducts) of the female mammary gland.
2. Along with estrogen and progesterone, especially during pregnancy, it increases the lobules of alveoli of the mammary gland in which milk is produced.
3. During lactation, together with insulin and cortisol, it increases milk synthesis and secretion in the mammary gland.

Effects on Reproduction

In Females

Increased prolactin concentration in plasma inhibits hypothalamic GnRH secretion. Therefore, the concentration of LH and FSH decreases during lactation:

1. This prevents ovulation and causes amenorrhea in lactating mothers (Clinical Box 55.3). This is called lactational amenorrhea.
2. Prolactin also controls some reproductive behaviors such as inhibition of libido in human beings and stimulation of maternal behavior (love, affection and protective behavior of the mother for the newborns).

In Males

In males, prolactin decreases spermatogenesis.

Clinical Box 55.3

Lactation prevents pregnancy: After delivery, pregnancy does not occur till active breast feeding continues. Lactation prevents pregnancy by maintaining high prolactin concentration that in turn inhibits GnRH secretion. Decreased GnRH inhibits ovulation. Therefore, conception does not occur till breastfeeding continues (physiological contraception during lactation). Breastfeeding has two important objectives: First, to provide best food for the baby, and second, to prevent pregnancy, so that automatically adequate spacing occurs between two children. The first one is important for the educated mothers as now-a-days breastfeeding is practiced less amongst them, the second one is essential for uneducated mothers.
Effects on Immunity

Prolactin is synthesized by immunocytes. The immunocytes number increases during pregnancy. It is believed that prolactin brings the immunologic balance required for acceptance of fetal tissue by the mother.

Effects on Liver

Prolactin increases synthesis of synlactin, an intermediary growth factor secreted from the liver. Synlactin is structurally analogous to somatomedin and functionally analogous to prolactin. Therefore, it is believed that prolactin indirectly stimulates growth.

Clinical Correlation

Amenorrhea–Galactorrhea Syndrome

Excess secretion of prolactin occurs in tumors of lactotrophs. Hyperprolactinemia causes amenorrhea and infertility. This also causes increased milk secretion in the absence of pregnancy and postpartum lactational state. Therefore, the condition is called amenorrhea-galactorrhea syndrome:

1. This is seen in hypothalamic or pituitary tumors that increase prolactin secretion.
2. The diagnosis is established by detecting high plasma prolactin level or by demonstrating tumor of lactotroph by CT scan or MRI.
3. The disease is treated by dopaminergic drugs that inhibit the secretion of prolactin. This restores fertility and libido.

Thyroid Stimulating Hormone

Structure

Thyroid stimulating hormone (TSH) is a glycoprotein hormone that controls the growth and function of thyroid gland. It mainly controls the secretion of thyroid hormones especially $T_4$ and $T_3$. It has two subunits: $\alpha$ and $\beta$. The $\alpha$ subunit is nonspecific as it is similar in structure with that of the LH and FSH because it is derived from the same gene for these hormones. It contains 96 amino acids. The $\beta$ subunit contains 110 amino acids and provides specificity to TSH. The molecular weight of TSH is 28,000.

Source

Thyroid stimulating hormone is secreted from the thyrotrophs of anterior pituitary that account for 3–5% of the cell population of the gland. These cells develop at about 13 weeks of gestation. Fetal thyroid gland starts secreting hormones in response to TSH almost during the same time in pregnancy.

Synthesis

Like other peptide hormones, TSH is synthesized as preprohormone, which is converted to prohormone. The $\alpha$ and $\beta$ subunits are synthesized separately from separate mRNA molecule:

1. Separate genes on different chromosomes code for synthesis of $\alpha$ and $\beta$ subunits.
2. The peptide chains of $\alpha$ and $\beta$ subunits undergo glycosylation in rough endoplasmic reticulum. The carbohydrate moiety, which is rich in mannose, is added to the prohormone molecule.
3. During packaging in the Golgi apparatus the carbohydrate unit undergoes modification by addition of sialic acid and sulphate to it, which allows two subunits to combine to form TSH molecule.
4. The TSH molecule is stored in the secretory granules of thyrotrophs. Thyrotrophs normally synthesize more $\alpha$ subunits than $\beta$ subunits. Therefore, secretory granules of thyrotrophs contain extra $\alpha$ subunits along with TSH, which is released into circulation along with the hormone at the time of secretion.

Regulation of Secretion

The normal plasma concentration of TSH is 0.3 to 5 µU/mL. The secretion of TSH is mainly controlled by two factors:

1. TRH, secreted from hypothalamus is the major stimulant for TSH secretion.
2. Somatostatin, released from hypothalamus inhibits TSH secretion.

The secretion of TRH is inhibited by $T_3$ and $T_4$ secreted from thyroid gland, by negative feedback mechanism (Fig. 55.13). Dopamine, another hypothalamic hormone also inhibits TSH secretion. TSH secretion exhibits some
diurnal variation with maximum secretion occurring in the night, which may be influenced by cortisol that inhibits both TRH and TSH secretion. Growth hormone also inhibits TSH secretion.

**Mechanism of Action**

TSH exerts its effects on thyroid cells by increasing concentration of intracellular cyclic AMP.

**Functions**

Thyroid stimulating hormone promotes growth of the thyroid gland and stimulates thyroid hormone synthesis and secretion. TSH acts almost in all the steps of thyroid hormone synthesis:
1. It facilitates iodide uptake and its organification in the thyroid gland. Iodide trapping is increased in few hours of TSH injections.
2. It enhances intermolecular coupling (coupling reaction), and thyroglobulin synthesis and secretion into the colloid.
3. It stimulates release of thyroid hormones and iodothyrosines from the gland.
4. It promotes endocytosis of colloid.
5. It increases blood flow to the thyroid gland.
6. It causes growth and hypertrophy of the thyroid gland.

**Applied Physiology**

Decreased secretion of TSH due to pituitary diseases results in thyroid atrophy and decreased secretion of thyroid hormones (secondary hypothyroidism or hypopituitary hypothyroidism). Chronic increase in TSH secretion results in hypertrophy of thyroid gland, called goiter.

**Adrenocorticotropic Hormone**

Adrenocorticotropic hormone (ACTH) is an important hormone that controls growth and secretion of adrenal cortex. It mainly influences the secretion of cortisol. ACTH plays vital role in physiology of stress and pathophysiology of stress disorders.

**Source and Structure**

Adrenocorticotropic hormone is secreted from corticotrophs of anterior pituitary that constitute 10–20% of its total cell population. ACTH is the smallest peptide hormone of anterior pituitary containing 39 amino acids. It has molecular weight of 4500.

**Synthesis**

Like other peptide hormones ACTH is synthesized as a preprohormone. It is synthesized in the corticotrophs as part of a larger molecule called pro-opiomelanocortin (POMC), which cleaves to form β-lipotropin, and ACTH in human beings (Fig. 55.14). In other species, POMC also forms β-endorphins. In the intermediate lobe of pituitary, POMC forms α-MSH (melanocyte stimulating hormone), especially in lower vertebrates. Intermediate lobe is rudimentary in humans. However, in humans, ACTH contains α-MSH sequence at its N-terminal, and therefore, it possesses intrinsic α-MSH activity.

**Circadian Rhythm of ACTH Secretion**

Normally, ACTH secretion occurs in irregular bursts. The pulsatile secretion of ACTH is due to several bursts of CRH (corticotropin releasing hormone) secretion in 24 hours. However, there is a prominent diurnal rhythm for ACTH secretion, in which secretion is more in the early morning, which constitutes about 75% of the total 24 hours secretion:
1. The secretion begins to rise at about 4 am and reaches a peak between 7 and 10 am and then falls slowly to basal level by noon (Fig. 55.15). Another small peak occurs in the evening between 4 and 6 pm.
2. The secretion is minimal when the person sleeps, especially in the midnight when the individual is in deep sleep. Again, ACTH secretion starts increasing at about 2 hours before awakening.
3. This diurnal variation in ACTH secretion is due to the natural sleep-wake cycle, controlled by inherent biological rhythm of suprachiasmatic nucleus of hypothalamus.
4. The pattern of secretion is reversed in individuals who sleep in the day and remain awake during night. The pattern of glucocorticoid secretion closely follows the ACTH secretion (for details, refer the chapter “Adrenal Cortex”).

**Regulation of ACTH Secretion**

Adrenocorticotropic hormone secretion from anterior pituitary is controlled by various factors. However, the
primary factor controlling the ACTH secretion is CRH secreted from hypothalamus. Many factors influence ACTH secretion by regulating CRH secretion from hypothalamus (Fig. 55.16). CRH in addition to its stimulation of ACTH secretion, also stimulates sympathetic activity, increases blood pressure and activates brainstem reticular activating system (causes arousal). Also, ADH is an important regulator of ACTH secretion.

**Factors that Increase ACTH Secretion**
Corticotropin releasing hormone, ADH, sleep-wake transition, stress (hypoglycemia, surgery, anesthesia, injury, infection, fever, etc.), anxiety, depression, α receptor agonist, β receptor antagonist, serotonin, acetylcholine, interleukins, and GI hormones.

**Factors that Inhibit ACTH Secretion**
Cortisol, ACTH, somatostatin, GABA, brain natriuretic peptide and opioids.

**ACTH and Stress**
Stress and hypothalamo-pituitary-adrenocortical axis are closely associated. Stress profoundly influences this neuro-endocrine axis. Increased ACTH secretion is an immediate response of the body to any form of stress. Therefore, stress is defined as a condition that results in increased ACTH level in plasma.
1. Due to increased ACTH secretion, glucocorticoid secretion increases rapidly. Inspite of increased cortisol secretion, ACTH secretion continues to remain high due to direct stimulation of hypothalamo-pituitary-adrenocortical axis by neurally mediated stimulation of hypothalamic paraventricular nucleus that secretes CRH.
2. In stress, higher brain centers stimulate hypothalamic nucleus to secrete CRH at a higher rate. Thus, stress induced CRH release overrides the negative feedback control of ACTH secretion.
3. If stress continues, glucocorticoid concentration remains high and mechanism of negative feedback control operates at a higher set point.

**Mechanism of Action**
ACTH acts primarily by increasing cAMP in the target cells.

**Functions**
1. ACTH stimulates synthesis and secretion of cortisol and other steroid hormones from adrenal cortex by stimulating growth of specific zone of the adrenal cortex. ACTH increases adrenocortical secretion by producing hypertrophy rather than hyperplasia of adrenal cells. The impact of ACTH is more on glucocorticoid secretion than on other steroids.
2. ACTH has intrinsic MSH activity; therefore, it stimulates growth and activity of melanocytes. This results in hyperpigmentation of the skin due to increased synthesis of melanin (Clinical Box 55.4).
3. The receptors for ACTH are also present in the GI tract and brain, where it acts as a local neurotransmitter.
4. ACTH influences immunity by controlling secretion of cytokines from lymphocytes. Cytokines also stimulate ACTH secretion.
Clinical Box 55.4

High ACTH level causes Hyperpigmentation: Patients with high ACTH level, which may be due to either Addison’s disease or ACTH secreting tumor of anterior pituitary, are hyperpigmented (appear black). In Addison’s disease, hyposecretion of cortisol increases ACTH production by negative feedback mechanism. ACTH promotes melanocyte activity as it has inherent MSH actions, and therefore causes skin hyperpigmentation.

LH and FSH

Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are called gonadotropins as they regulate growth and development of gonads, pubertal maturation and secretion of sex steroids.

Source and Structure

Gonadotropic hormones are secreted from gonadotrophs of anterior pituitary that constitute 10–15% of cell population of the gland. LH and FSH are glycoproteins. Both of them have α and β subunits.

1. The α subunit is nonspecific as it is similar to the α subunit of TSH and hCG.
2. The β subunit confers specificity to LH and FSH. The peptide chain of β subunit of FSH contains 111 amino acids and of LH contains 121 amino acids.
3. The carbohydrate moiety constitutes 15–25% of the hormones.
4. The molecular weight of LH is 28,000 and of FSH is 38,000.

Synthesis

Both LH and FSH are produced by the same gonadotrophs. There are separate genes that code the synthesis of α and β subunits of gonadotropins. The addition of carbohydrate moiety to the molecules allows variation in biological activity of LH and FSH in different conditions.

Regulation of Secretion

The regulation of LH and FSH is a complex phenomenon. The secretion of gonadotropins is pulsatile, periodic, diurnal, cyclic, and seasonal. However, secretion of both the hormones is mainly controlled by gonadotropin releasing hormone (GnRH) secreted from hypothalamus. GnRH secretion is influenced by various psychological, emotional and chemical factors. Among chemicals, important are norepinephrine that stimulates, and dopamine and endorphins that inhibit GnRH secretion.

LH and FSH secretion is regulated by feedback inhibition through gonadal hormones such as estrogen, testosterone, activin, inhibin, and follistatin (Clinical Box 55.5):

1. Testosterone in males and estrogen in females provide negative feedback signal to inhibit gonadotropin secretion from anterior pituitary (Fig. 55.17).
2. Inhibin, a hormone secreted by gonads inhibits GnRH and gonadotropin secretion.
3. Activin which is structurally similar to inhibin stimulates FSH synthesis and secretion.
4. Follistatin inhibits FSH secretion.
5. Prolactin inhibits LH and FSH secretion by inhibiting GnRH secretion from hypothalamus.

Clinical Box 55.5

Oral contraceptives: Oral contraceptives (estrogen and progesterone preparations) use negative feedback influence of gonadal hormones to interfere with LH and FSH secretion in both timing and concentrations. This prevents ovulation by interfering in balanced action of LH and FSH on ovary.

Functions

Luteinizing hormone and FSH exert their effects by increasing cyclic AMP concentration in the target cells.

CHAPTER SUMMARY

Key Concepts

1. Secretion of interior pituitary hormones is controlled primarily by hypothalamic hormones. Therefore, disorders of anterior pituitary hormones can occur in hypothalamic diseases.
2. Though visceral, metabolic and growth effects of GH are due to direct action of GH on target tissues, many of these effects are also mediated through somatomedins, that are mainly produces in liver. Therefore, liver diseases in childhood may considerably affect growth and development.

3. Secretion of ACTH is more in the early morning. Therefore, getting up early in the morning and do activities, help in keeping good health.

**Important to Know (Must Read)**

1. In examination, ‘Mechanism of action and functions growth hormone (GH)’ comes as a **Long Question**.

2. Mechanism of action of GH, Regulation of GH secretion, Insulin-like growth factors, Somatomedins, Acromegaly, Gigantism, Dwarfism, Prolactin, are usual **Short Questions** in exam.

3. In **Viva**, examiner may ask… Name the hormones secreted anterior pituitary, What is hypothalamopituitary axis, functions of GH, Direct action of GH, Actions mediated by somatomedins, Etiology, features and management of Acromegaly, Etiology, features and management of Gigantism, Types/causes of dwarfism and its treatment, Differences between pituitary dwarf and thyroid dwarf, Factors that increase and decrease GH secretion, Hormones of anterior pituitary and their target gland and major functions, Hormone secreting cell types of anterior pituitary, Factors affecting prolactin secretion, Functions of prolactin, How lactation prevents pregnancy, Amenorrhea-Galactorrhea syndrome, Functions of TSH and Functions of ACTH.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Name the hormones secreted from posterior pituitary.
2. Describe the mechanism of action, physiological effects and dysfunctions of ADH and oxytocin.
3. Understand the meaning and importance of a neurohumoral reflex.
4. Understand the pathophysiological basis of diabetes insipidus.

The student MAY also be able to:
1. Describe the synthesis, metabolism and regulation of posterior pituitary hormones.
2. Explain the detailed mechanisms of milk ejection reflex, parturition reflex and SIADH.

Posterior pituitary secretes two important hormones: ADH and oxytocin. These hormones are formed in supraoptic and paraventricular nuclei of hypothalamus and released into posterior pituitary. They are called neurohormones as they are synthesized and secreted by neurons into the circulation.

**ANTIDIURETIC HORMONE**

Antidiuretic hormone (ADH) plays an important role in regulation of blood volume and pressure.

**Structure, Synthesis and Secretion**

**Structure and Source**

ADH, also known as arginine-vasopressin (AVP) or vasopressin, is an oligopeptide containing nine amino acids. It is synthesized in the magnocellular cells of supraoptic and paraventricular nuclei of hypothalamus. The synthesis of ADH largely occurs in the supraoptic nucleus.

**Important Note**

Roger CL Guillemin received Nobel Prize in Physiology and Medicine for the year 1977 for his discovery of and extensive work on neurohormones (For details, refer to Chapter 54).

**Synthesis of ADH**

The hormone is synthesized in the cell bodies of the supraoptic and paraventricular nuclei of hypothalamus (Fig. 56.1). It is synthesized as preprohormone which becomes prohormone and then forms the hormone. The genes that cause ADH synthesis are located on chromosome 20. They code for synthesis of a larger molecule that includes a distinct larger protein called as neurophysin:

1. There are two neurophysins: neurophysin I, meant for oxytocin, and neurophysin II, meant for ADH. The neurophysins are almost identical.
2. The precursor molecule for ADH is prepropressophysin having 19 amino acids that contains ADH, neurophysin II and a glycoprotein (Fig. 56.2).

**Fig. 56.1:** Hypothalamic nuclei (supraoptic and paraventricular) synthesize and secrete posterior pituitary hormones (ADH and oxytocin). Note the Herring bodies at the end of these neurons in posterior pituitary.
3. Prepropressophysin is cleaved enzymatically to release ADH, neurophysin II and glycoprotein molecules.
4. The glycoprotein and ADH are packaged in the Golgi apparatus as secretory granules along with the neurophysin II.
5. **Neurophysin serves as carrier protein** to transport the hormone from the cell body to the axon terminals. The secretory granules are called as **Herring bodies** that are transported to axon terminal by slow axoplasmic flow. The axon terminals of the neurons are located in the posterior pituitary.

**Regulation of Secretion**

ADH secretion is primarily controlled by **two important stimuli**: plasma osmolality and ECF volume.

**Plasma Osmolality**

Increased plasma osmolality above 285 mOsm/kg increases ADH secretion proportionate to the osmolality rise (Fig. 56.3):

1. The increased osmolality is sensed by **hypothalamic osmoreceptors** that increases the synthesis of ADH in supraoptic and paraventricular nuclei and increase ADH release from posterior pituitary. ADH causes water retention and brings osmolality back to normal.
2. Osmolality of plasma is a very **sensitive regulator** of ADH secretion. Even, **change in 1% osmolality** leads to appreciable increase in plasma ADH level.
3. The hypothalamic osmoreceptors are located in the anterior hypothalamus.

**Blood Volume and Pressure**

Decrease in blood pressure and blood volume stimulates ADH secretion:
1. Percentage **fall in mean arterial pressure** (MAP) causes linear increase in ADH release (Fig. 56.4).
2. **Decreased ECF volume** also stimulates ADH secretion. However, change in osmolality is a stronger stimulus than the change in volume of plasma. Hypovolemia sensitizes ADH response to hyperosmolality (Fig. 56.5).
3. Effect of hypovolemia on blood volume and blood pressure is partly mediated by activation of **renin-angiotensin system** (RAS).
4. Angiotensin II (AII) formed by stimulation of RAS acts on **subfornical organ** (SFO) and **organum vasculosum of lamina terminalis** (OVLT) that are part of thirst center to stimulate thirst and water intake. SFO, OVLT, area postrema and posterior pituitary are **circum ventricular organs** that are located outside blood-brain barrier.

**Factors Affecting ADH Secretion**

**Factors that Increase ADH Secretion**

Increased plasma osmolality, decreased ECF volume, decreased blood pressure, angiotensin II, pain, nausea and vomiting, emotion, hypoglycemia, standing, increased temperature and stress increase ADH secretion.
Stimuli that Inhibit ADH Secretion
Decreased plasma osmolality, increased ECF volume, decreased temperature, ethanol, cortisol, ANP, thyroxine and α-adrenergic agonist decrease ADH secretion.

Metabolism
ADH is rapidly inactivated in kidneys and liver. In humans, the biologic half-life of ADH is about 18 min.

Mechanism of Action
ADH acts on kidney to conserve water and on blood vessel to regulate blood pressure. There are receptors for ADH on these organs:

ADH Receptors
There are two types of ADH receptors: V₁ and V₂.

V₂ Receptors
V₂ receptors are located on the kidney tubules. ADH increases permeability of the tubular cells by acting on the V₂ receptors.
1. It acts by increasing the cyclic AMP concentration on the target cells. Cyclic AMP activates protein kinase, which causes phosphorylation of different membrane and cellular proteins.
2. This leads to transport of vesicles or endosomes by the microfilaments and microtubules from the cytosol to the luminal membrane of the epithelial cells of the tubule.
3. The endosomes contain water channels (aquaporins). Thus, water channels are incorporated into the cell membrane of epithelial cells on the luminal side of the tubules. This increases the permeability of the collecting duct (CD) and distal convoluted tube (DCT) to water (Flowchart 56.1). The water channels are called aquaporins.
4. Aquaporin 2 is responsible for water reabsorption from DCT by ADH.

Aquaporins
13 types of aquaporins have been identified till date: AQP0 to AQP12. Aquaporins 1, 2 and 3 are found in kidney, aquaporin 4 is found in brain and aquaporin 5 is present in salivary and lacrimal glands and in respiratory tract. Aquaporin 9 has been described in human leucocytes. According to recent observations, aquaporins are distributed in all tissues of the body.

V₁ Receptors
For its vasoconstriction effect, ADH acts on V₁ receptors present in the smooth muscles of blood vessels. There are two types of V₁ receptors: V₁A and V₁B. The V₁A receptors cause constriction of smooth muscles of blood vessels. ADH increases calcium concentration in the smooth muscles by activating the membrane enzyme phospholipase C that causes hydrolysis of phosphatidylinositol (increases intracellular Ca²⁺ concentration). Via its action through V₁B receptors (that are also called V₃ receptors), ADH increases CRH and ACTH secretions.
Flowchart 56.2: Restoration of fluid volume of the body by ADH in volume depletion state.

- Diarrhea, vomiting, etc.
- Loss of water
- Increased plasma osmolality
- Decreased ECF volume
- Decreased BP
- Osmoreceptors in hypothalamus
- Low pressure (or volume) receptors in atria and veins
- High pressure (arterial) receptors
- Decreased vagal activity
- ADH secreting neurons in hypothalamus
- Increased plasma ADH
- Water reabsorption from kidney
- Restoration of ECF volume
- NTS in medulla

NTS: Nucleus tractus solitarius.

Scientist contributed
The Nobel Prize in Chemistry 2003 was awarded to Peter Agre “for the discovery of water channels” called aquaporins that revolutionized the mechanism of water absorption by many cells, tissues and organs in the body, including the process in the renal tubules.

Peter Agre (Born, 1949)

Functions of ADH
1. ADH acts mainly on DCT and collecting duct of renal tubule to increase water reabsorption. It is secreted in conditions of hypovolemia, hypotension and hyperosmolality. It is an important hormone for restoration of ECF volume in conditions of depletion like acute diarrhea, vomiting, etc. (Flowchart 56.2).
2. Acting on blood vessels, ADH causes vasoconstriction. Thus, in higher concentration it increases blood pressure. However, water conservation occurs at physiological concentration whereas vasoconstriction occurs at supraphysiological concentration of ADH.
3. ADH facilitates memory by acting as a neurotransmitter in memory areas of the brain.
4. It causes contraction of smooth muscles of spermatic cord. Therefore, it facilitates ejaculation of sperm. This action is mediated via V1 receptors.
5. ADH increases CRH release and therefore increases ACTH secretion. It also directly stimulates corticotrophs to secrete ACTH. This action of ADH is mediated via V1 receptors.
6. ADH acts on area postrema to decrease cardiac output.
7. It causes glycogenolysis in liver.
8. ADH acts as a neurotransmitter in some areas of brain and spinal cord.

Applied Physiology

Diabetes Insipidus
Deficiency of ADH causes diabetes insipidus (DI), a syndrome characterized by production of abnormally large volume of dilute urine. Usually, it occurs due to hypothalamic or posterior pituitary dysfunctions:
1. The main clinical features are polyuria and polydipsia. Polyuria occurs due to ADH deficiency that promotes water diuresis. Polydipsia occurs secondary to dehydration caused by polyuria.
2. Polyuria and polydipsia are also features of diabetes mellitus. However, the main distinguishing characteristic is the difference in osmolality of the urine; in diabetes insipidus urine is dilute (pure water loss) and urine osmolality is <300 mOsm/L, whereas in diabetes mellitus the urine is hyperosmolar due to loss of glucose in urine (>1200 mOsm/L). In diabetes insipidus, the urine is tasteless (insipidus, means tasteless), whereas in diabetes mellitus urine is tasty due to presence of more glucose in it (mellitus, means sweet taste).
There are two types of DI: nephrogenic (kidneys fail to respond to ADH) and neurogenic (deficiency of ADH secretion). Neurogenic DI is also called central DI.

Nephrogenic DI
Etiology and Types
In nephrogenic DI, ADH secretion is normal, but kidney is unresponsive to it due to receptor deficiency or abnormality. It may be acquired or genetic:
1. Acquired causes are usually due to drugs such as demeclocycline, rifampicin, aminoglycoside, lithium, cisplatin and amphotericin B. Other acquired causes are ischemia resulting in acute tubular necrosis, metabolic disorders such as hypercalcemia and hypokalemia, and infiltrative diseases like neurosarcoidosis and amyloidosis.
2. Genetic disorders are X-linked recessive defect in which V2 receptor gene is deficient and autosomal defect in which aquaporin gene is deficient.

Treatment
Chlorpropamide is used for treatment of the disease as it increases the renal response to ADH.

Neurogenic DI
Etiology and Types
This occurs in diseases of CNS in which hypothalamus, hypothalamo-hypophyseal tract or posterior pituitary are...
affected. Accordingly, the disease is referred to as, central, neurohypophyseal or pituitary DI. It occurs in head injury, tumors such as craniopharyngioma and suprasellar pituitary tumors, infections such as meningitis and encephalitis, vascular lesions such as Sheehan’s syndrome and aneurysm of internal carotid artery, and congenital or genetic defects. ADH secretion is deficient in these conditions.

Treatment
Uncomplicated pituitary DI is cured completely by treatment with DDAVP, a synthetic analogue of AVP that acts selectively on V₂ receptors to increase water reabsorption from tubular fluid. Injection of vasopressin is useful. Clofibrate therapy also improves the condition.

Syndrome of Inappropriate ADH Secretion
Excessive secretion of ADH occurs in a clinical syndrome called as SIADH (syndrome of inappropriate ADH secretion). The term SIADH is used as ADH secretion is inappropriately high relative to serum osmolality.

SIADH is seen in:
1. Head injury
2. Ectopic production of ADH by some malignant tumors such as carcinoma of lungs, pancreas, ovary and bladder.
3. Neurologic diseases like multiple sclerosis, Guillain-Barré syndrome, brain abscess, meningitis, encephalitis, etc.
4. Drugs such as desmopressin, chlorpropamide, high dose of oxytocin, vincristine, phenothiazine, carbamazepine, etc.

In SIADH, not only there is dilutional hyponatremia due to increased absorption of large quantity of water from kidney, but also there is natriuresis (loss of sodium in urine) secondary to decreased aldosterone secretion activated by expansion of ECF (Application Box 56.1). If SIADH is due to brain diseases, the condition is called cerebral salt wasting, and if due to lung diseases the condition is called pulmonary salt wasting.

Application Box 56.1
Vasopressin escape: In lung cancers and other malignant tumors, ADH secretion is very high. In such conditions, the water retaining action of ADH is counteracted by a process called vasopressin escape that limits the degree of hyponatremia. This escape phenomenon occurs due to down regulation of aquaporins production in collecting duct. Thus, urine output increases despite high ADH levels in plasma, which indicates that the kidney has escaped from the effects of vasopressin (hence, the term ‘vasopressin escape’).

OXYTOCIN
Structure, Synthesis and Secretion
Source and Synthesis
Oxytocin is an oligopeptide containing nine amino acids. The hormone is synthesized in magnocellular neurons of hypothalamus. Oxytocin is mainly synthesized in the paraventricular cells of hypothalamus though synthesis also occurs in supraoptic nucleus (see Fig. 56.1):
1. After synthesis, oxytocin is secreted into the posterior pituitary where it is stored.
2. The precursor molecule is prepro-oxyphysin that contains oxytocin, neurophysin I and a glycoprotein. Otherwise, the steps of synthesis and secretion of oxytocin are similar to that of ADH, as described above.

Regulation of Secretion
Oxytocin secretion occurs in response to two important physiological stimuli:
1. Suckling at the time of breastfeeding, and
2. Cervical dilatation at the time of parturition.

Genital stimulation in females during coitus increases oxytocin release. Stressful stimuli facilitate oxytocin release. Oxytocin secretion is inhibited by alcohol.

Functions
Oxytocin mediates two physiological reflexes: 1. milk ejection reflex and 2. parturition reflex.

Milk Ejection Reflex
Discharge or expulsion of milk from the breast of the mother into mouth of the baby when baby suckles during breastfeeding, is called milk ejection reflex.

Receptors
Tactile receptors in and around the nipple.

Reflex Arc
Nipple is stimulated by suckling of the baby:
1. The afferent neural impulses are transmitted from the nipple to the spinal cord and from there via spinothalamic tract to the brainstem (Fig. 56.6).
2. In the midbrain, the information reaches paraventricular nucleus of hypothalamus via collaterals arising from the ascending sensory pathway. The neurons terminating on hypothalamus are cholinergic.
3. These fibers stimulate oxytocin secreting magnocellular neurons of hypothalamus.
4. Via hypothalamopituitary axis, oxytocin is released from posterior pituitary and enters circulation.
5. Oxytocin causes contraction of myoepithelial cells of the milk-laden alveoli of the mammary gland. Therefore, milk is forced from the alveoli into the ducts and from there to the mouth of the infant.

Effects
Due to initiation of this reflex, milk from the mother’s breast is forcefully discharged into the mouth of the baby. Therefore, the reflex is called milk ejection reflex.
Physiological Significance

This is an example of neurohumoral reflex (Application Box 56.2). Ovulation that occurs during mating in some animals like rabbit is also an example of neurohumoral reflex.

Application Box 56.2

A neurohumoral reflex: Normally, a reflex is purely a neural phenomenon, the reflex arc having neurons in both afferent and efferent limbs. When, a hormone forms part of the efferent limb, the reflex becomes a neurohumoral reflex. Thus, the neurohumoral reflex involves both neurons and hormones in the reflex pathway. Therefore, milk ejection by oxytocin is a neurohumoral reflex.

Parturition Reflex

Oxytocin causes contraction of uterine muscle:
1. Toward term, oxytocin secretion gradually increases and reaches its peak just before parturition. Also, number of oxytocin receptor increases in the uterine muscle.
2. Due to increased plasma level of oxytocin and increased sensitivity of uterus to oxytocin, uterus contracts vigorously leading to expulsion of the fetus.
3. Thus, oxytocin initiates and completes parturition. Parturition reflex is also a neurohumoral reflex.

Other functions of oxytocin are as follows:
1. Oxytocin receptors are also present in the ovary. It is believed that oxytocin facilitates degeneration of corpus luteum at the end of the menstrual cycle.
2. Oxytocin secretion increases in males during orgasm, though the exact physiological significance of it is not known. At the time of ejaculation in male, possibly oxytocin causes contraction of smooth muscles of vas deferens that helps in propelling sperms toward the urethra.
3. In females, following ejaculation of sperms into female genital tract, oxytocin causes contraction of nonpregnant uterus to facilitate sperm transport into fallopian tubes. Though sperm transport to the fallopian tube for fertilization depends on motility of sperm, uterine contraction facilitates the process.

Applied Physiology

Oxytocics (preparations of oxytocin) are used routinely for:
1. Induction of labor, if labor pain does not start effectively at term.
2. Oxytocic infusion is given to facilitate the progress of labor.
3. It is routinely injected immediately following delivery of placenta, to prevent excessive postpartum hemorrhage, in which uterus contracts severely in response to oxytocin and bleeding vessels are compressed in the contracted uterus that prevents bleeding.

CHAPTER SUMMARY

Key Concepts

1. Hormones of posterior pituitary are synthesized in hypothalamic neurons. Therefore, they are called neurohormones. Therefore, the reflexes caused by ADH and oxytocin are called neurohumoral reflex.
2. Osmolality is a better stimulus than hypotension and hypovolemia for secretion of ADH.
3. SIADH occurs in paraneoplastic syndrome.

Important to Know (Must Read)

1. In examination, 'Mechanism of action, and function of hormones of posterior pituitary/ may come as a Long Question.
2. In examination, ADH, Oxytocin, Diabetes insipidus, Neurohumoral reflex, may be asked as Short Questions.
Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:

1. Appreciate the role of thyroid hormones in the integration of various body functions.
2. Name the hormones secreted from thyroid gland.
3. Briefly describe the steps of thyroid hormone synthesis.
4. Comprehend the role of TSH in regulation of thyroid hormone secretion.
5. Know the important aspects of thyroid hormone metabolism.
6. Describe the mechanism of action and physiological effects of thyroid hormones.
7. Understand physiological basis of dysfunctions in hyperthyroidism and hypothyroidism.
8. Learn the physiological basis of thyroid function tests.

The student **MAY** also be able to:

1. Describe the synthesis of thyroid hormones.
2. Explain the mechanisms of action of thyroid hormones.
3. Describe the regulation of thyroid hormone secretion.
4. Describe the thyroid function tests.

Thyroid is an important endocrine gland that primarily governs the rate at which metabolism occurs in the individual cells. Thyroid hormones profoundly influence normal growth and development of the individual. They are essential for mental and psychological development in infancy and early childhood. Though, thyroid hormones are not very essential for immediate maintenance of vital functions of life, their deficiency causes severe deficit in mental and physical growth, and extreme decrease in body metabolism. Thyroid gland also influences calcium metabolism by secreting calcitonin from its parafollicular cells.

Scientist contributed

Emil Theodor Kocher (1841–1917) was a Swiss surgeon, medical researcher and physiologist who, in 1909, received Nobel Prize in Physiology and Medicine for his outstanding contribution in physiology, pathology and surgery of the thyroid gland. His studies on goiter began the systematic work on the functions of thyroid. Among his many accomplishments are the introduction and promotion of aseptic surgery and scientific methods in surgery, specifically reducing the mortality of thyroidectomies below 1% in his operations. He was the first Swiss citizen and the first surgeon to ever receive a Nobel Prize.

FUNCTIONAL ANATOMY

General Aspects

Development

Thyroid gland develops from the floor of primitive pharynx during third week of gestation. Along with thyroglossal duct, it migrates from floor of the tongue to the neck. Therefore, ectopic thyroid gland may be located at the base of the tongue, which is called as lingual thyroid. Normally, thyroid hormone synthesis begins at about 11th week of gestation.

Location

Thyroid gland is present on the anterior aspect of the neck. It is located anterior to trachea, between the cricoid cartilage and the suprasternal notch. It consists of two lobes that are connected by a band of thyroid tissue called isthmus. Sometimes an extra thyroidal tissue arises from the isthmus, which is known as pyramidal lobe. The weight of thyroid gland in a healthy adult is between 15 and 20 g. Four tiny parathyroid glands are located posteriorly at each pole of thyroid gland (Clinical Box 57.1).
Section 6: Endocrine Physiology

Clinical Box 57.1
Surgical precautions: During thyroid surgeries, utmost care is taken not to remove parathyroid glands that are embedded in thyroid tissue; otherwise that leads to acute hypoparathyroidism (hypocalcemic tetany) following thyroidectomy. Also, recurrent laryngeal nerves traverse beneath the lateral borders of the thyroid gland on both sides. Therefore, care is also taken to prevent damage to this nerve to avoid vocal cord paralysis during thyroid surgery.

Blood Supply
Thyroid gland has rich blood supply, which is maximal among all endocrine organs. Blood flow per gram is even more than that of kidneys. The blood supply to thyroid gland is derived from superior and inferior thyroid arteries that originate from external carotid and subclavian arteries respectively (Fig. 57.1). Thyroid veins drain into external jugular and innominate veins.

Innervation
Thyroid gland is innervated by autonomic nerves. The fibers for sympathetic innervation originate from cervical ganglia and fibers for parasympathetic innervation travel in vagus nerve. Autonomic innervation regulates delivery of TSH and iodide to the gland by controlling vasomotor tone. Sympathetic innervation plays important role as it has direct influence on functions of thyroid cells.

Histology
Thyroid gland is formed by aggregates of acini or follicles (Fig. 57.2). The thyroid follicles are spherical in shape and are formed by a single layer of epithelial cells that surround a central thick solution called colloid, which is a viscus-gel like substance containing thyroglobulin in it.

SYNTHESIS, SECRETION AND METABOLISM OF THYROID HORMONES

The principal hormones synthesized and secreted by thyroid gland are:

1. $T_4$ (thyroxine)
2. $T_3$ (triiodothyronine).
3. $RT_3$ (reverse-triiodothyronine), secreted in small quantity.
4. Calcitonin

$T_4$, $T_3$, and $RT_3$ are secreted from thyroid follicles and calcitonin is secreted from the parafollicular cells (C cells) of thyroid gland.

Normally, $T_3$ is more active than $T_4$, though $T_4$ is secreted in more quantity from thyroid gland. $T_3$ is converted to $T_3$ in the peripheral blood and tissues. Therefore, $T_4$ is mainly a prohormone. $RT_3$ is physiologically inactive.

The raw materials required for thyroid hormone synthesis are the iodine and tyrosine. Therefore, iodine
deficiency or excess produces thyroid dysfunction. Before discussing thyroid hormone synthesis, it is desirable to know the basics of iodine metabolism.

**Iodine Metabolism**

Iodide uptake is the first and crucial step in the thyroid hormone synthesis.

1. About 500 µg of iodine is ingested daily in the food, which is converted to iodide and absorbed from GI tract.
2. Ingested iodine binds with albumin and unbound iodine is mainly excreted in urine.
3. However, daily ingestion of 150 µg of iodine in an adult maintains normal thyroid function. The normal plasma concentration of iodide is 0.3 µg/dL. Thyroid gland is the principal organ that takes up iodine to form thyroid hormone.
4. Normally, about 120 µg of iodide is taken up by the thyroid gland per day for thyroid hormone synthesis.
5. Kidney is the principal organ that excretes iodide in the urine.
6. The thyroid gland secretes 80 µg of iodine in the form of T₃ and T₄, and 40 µg of iodine directly into ECF per day (Fig. 57.5).
7. T₃ and T₄ are primarily metabolized in liver. Daily, liver releases about 60 µg of iodine into the ECF and 20 µg of iodine into bile, which is excreted in stool.
8. On average, 480 µg of iodine is excreted in the urine and 20 µg is excreted in the stool.

**Iodine deficiency** is prevalent in developing countries and in mountainous regions all over the world. When iodine intake is less than 50 µg per day, thyroid hormone synthesis decreases. The consequent increase in TSH results in goiter, hypothyroidism and cretinism.

**Thyroid Hormone Synthesis**

**Steps of Thyroid Hormone Synthesis**

The thyroid hormone synthesis involves following steps:

1. Iodide trapping
2. Conversion of iodide into iodine
3. Thyroglobulin synthesis
4. The coupling reaction
5. Proteolysis of thyroglobulin
6. Secretion of thyroid hormones

**Iodide Trapping**

Thyroid gland takes up iodide by active mechanisms. The active transport of iodide from circulation into the colloid of the thyroid follicles is known as iodide trapping or iodide pump.

1. The transport process is a secondary active transport. Na⁺ and I⁻ are co-transported into the thyroid cell by means of Na⁺-I⁻ symporter (NIS) or cotransporter (Clinical Box 57.2). NIS can cause 20 to 40 times intracellular iodine accumulation, compared to the concentration of iodine in plasma.
2. TSH induces expression and retention of NIS in the basolateral membrane of thyrocytes where it facilitates sustained iodine uptake.
3. The Na⁺ is pumped back into the interstitium by Na⁺-K⁺ pump (Fig. 57.6).
4. The RMP of thyroid cell is −50 mV and iodide is negatively charged. Therefore, iodide is pumped into the cells against the electrical gradient.
5. The iodide concentration inside the colloid is usually very high. Therefore, iodide is also pumped against its own chemical gradient.

6. ATP is used in iodide uptake by thyroid cells. This enables the follicular cells to accumulate more iodide than its concentration in blood.

7. The other tissues that accumulate iodide are salivary gland, placenta, choroid plexus, mammary gland, gastric mucosa, and ciliary body; however, they do not form thyroid hormones. Iodide trapping is stimulated by TSH.

---

**Clinical Box 57.2**

NIS deficiency: Mutation of NIS (Na⁺-iodide symporter) gene, an autosomal recessive condition results in decreased thyroid uptake and causes congenital hypothyroidism.

---

**Conversion of Iodide into Iodine**

Iodide that is actively transported into the colloids of thyroid follicles is immediately converted to iodine by means of oxidation. This oxidation of I⁻ to I, also known as organification (Clinical Box 57.3) is facilitated by the enzyme thyroid peroxidase.
Clinical Box 57.3

Pendred syndrome: An iodine transporter called pendrin is located on the apical surface of the thyroid cells that transports iodine actively from thyroid cells into the colloid. Pendrin is an anion exchanger (Cl⁻–I⁻ exchanger). Mutation of pendrin gene leads to Pendred syndrome, which is characterized by defective organification of iodine, goiter and sensorineural deafness.

Thyroglobulin Synthesis
Thyroglobulin is the glycoprotein with two subunits and the molecular weight of 660,000. It contains 123 tyrosine residues. It is synthesized in the endoplasmic reticulum of thyroid cells, packaged in Golgi apparatus and then, secreted into the colloid by exocytosis. This secretion is facilitated by thyroid peroxidase. The thyroid hormones are synthesized in the thyroglobulin molecule and remain bound with the thyroglobulin till they are secreted.

Binding of Iodine to Thyroglobulin
Once reactive iodine is formed (by oxidation of iodide to iodine), it binds immediately with the tyrosine molecule, which is attached to thyroglobulin molecule at 3 position. This binding of iodine to thyroglobulin is facilitated by thyroid peroxidase.

Coupling Reaction
Binding of iodine with tyrosine at 3 positions forms mono-iodotyrosine (MIT), which is again iodinated in the 5 position to form diiodotyrosine (DIT). Two DIT molecules undergo oxidative condensation to form thyroxine (T₄). This is called coupling reaction. There are two theories of coupling reaction: intramolecular coupling and intermolecular coupling.

Intramolecular Coupling
In this process, coupling occurs with both DIT molecules attached to thyroglobulin.

Intermolecular Coupling
In this process, DIT that forms the outer ring is detached from the thyroglobulin.

The coupling reaction is also facilitated by thyroid peroxidase. The condensation of MIT with DIT forms triiodothyronine (T₃). When condensation of DIT occurs with MIT, reverse-T₃ (RT₃) is formed. Normally, distribution of MIT, DIT, T₄, and T₂ in the thyroid cell is 23%, 33%, 35%, and 7% respectively. RT₃ is present in very minor quantity.

Secretion of Thyroid Hormones
The thyroid cells ingest colloid by endocytosis.
1. The lysosomal enzymes digest the peptide bonds between iodinated residues and thyroglobulin. This is called proteolysis of thyroglobulin molecule.
2. This results in formation of free T₄, T₃, DIT, and MIT in the cytoplasm. The iodinated tyrosines are deiodinated by the microsomal enzyme iodotyrosine deiodinase.

3. The T₄ and T₃ are then released from thyroid cells into the general circulation.
4. The iodine released by deiodination of MIT and DIT is usually reutilized by the gland for further synthesis of thyroid hormone.
5. This provides more supply of iodine for thyroid hormone synthesis in comparison to the iodine available by iodide pump.
6. MIT and DIT are not secreted by the thyroid gland.

Thus, thyroid cells serve three important functions:
1. They actively accumulate iodide from blood for synthesis of thyroid hormones.
2. They synthesize thyroglobulin molecules and secrete them into the colloid.
3. They digest the colloid and free thyroid hormones from thyroglobulin molecules to secrete them into the circulation.

Structure of T₃ and T₄
Thyroxine contains four iodine atoms, each one at 3, 5, 3’ and 5’ positions, whereas triiodothyronine contains three iodine atoms at 3, 5 and 3’ positions of the thyronine ring structures (Fig. 57.7). For the positions of iodine atoms in thyroid hormones, thyroxine and triiodothyronine are abbreviated as T₄ and T₃ respectively.

Metabolism of Thyroid Hormones

Normal Concentration
In a normal individual, total plasma T₄ concentration is about 8 µg/dL, and plasma T₃ is about 0.15 µg/dL. In circulation, most of the thyroid hormones bind with the plasma proteins. About 99.9% of T₄ and 99.8% of T₃ are bound to
plasma proteins. Therefore, the free T4 level in plasma is about 2 ng/dL, and free T3 is about 0.3 ng/dL (Application Box 57.1).

**Application Box 57.1**

**Measurements of free and bound forms:** Concentration of thyroid hormone is measured by RIA. As physiological effects of thyroid hormones depend on their free-form level in plasma, and the free hormone component influences feedback control of hypothalamo-pituitary-thyroid axis, in thyroid dysfunctions, mainly the free hormone concentrations are measured. However, it is ideal to measure both total and free level of hormones in blood for diagnosing thyroid dysfunctions.

**Protein Binding**

Thyroid hormones bind with three types of plasma proteins:
1. Thyroxine binding globulin (TBG)
2. Thyroxine binding prealbumin (TBPA), also called transthyretin.
3. Albumin.

Normally, T4 binds mainly with TBG and TBPA, and T3 binds with albumin and TBG.

**TBG**

TBG is a glycoprotein synthesized by liver. Its molecular weight is 54000. Each TBG molecule has a single binding site on it for a molecule of thyroid hormone.
1. About 70% of T4 and 45% of T3 are bound to TBG.
2. TBG level in plasma increases in pregnancy and in patients receiving estrogen, major tranquilizers, clofibrate, etc.
3. Plasma TBG level decreases in patients receiving glucocorticoids, androgens, danazol and L-asparaginase (cancer chemotherapeutic drug). Salicylates, phenytoin (anticonvulsant), mitotane (cancer chemotherapeutic drug) and 5-fluorouracil inhibit binding of T3 and T4 to TBG.

**TBPA**

TBPA, though named as prealbumin is not an albumin, rather a globulin. Recently, TBPA has been designated as transthyretin. The binding of T3 with TBPA is very less (less than 1%), whereas about 20% of T4 binds to it.

**Albumin**

T3 mainly binds with albumin. About 55% of T3 and 10% of T4 bind with albumin.

The concentration of free T3 and T4 depends on the concentration of plasma proteins that bind these hormones.
1. When, concentration of thyroid binding proteins increases in plasma, the free level of thyroid hormones decreases. However, the decreased hormone level provides feedback signals to secrete more TSH, which in turn increases secretion of thyroid hormones.

2. The opposite phenomenon occurs when level of plasma binding protein decreases in plasma.
3. Thus, initial change observed in thyroid hormones due to change in plasma proteins is a temporary effect. Therefore, thyroid activity remains normal (euthyroid state) in patients with altered binding proteins.

**Importance of protein binding:**
1. Protein-bound forms of T3 and T4 serve as reservoir of these hormones. This can replenish the circulating hormone, when due to some reasons or the other, the secretion is decreased or metabolism is increased suddenly and temporarily.
2. Protein binding protects the hormone against metabolic degradation. Therefore, the half-lives of circulating T3 and T4 are more (1 day for T3 and 7 days for T4).
3. Circulating free form concentration provides feedback effect on regulation of hormone secretion.

**Peripheral Conversion**

The major product of thyroid gland secretion is T4.
1. Normally, about 35% of secreted T4 is converted to T3 in the circulation by the enzyme 5’-deiodinase (Flowchart 57.1) present in liver and kidney, and this accounts for about 85% of circulating T3.
2. T3 mainly acts on the target cells. Therefore, physiologically T3 is considered as the most active hormone.
3. About 45% of T4 is also converted to RT3 by the enzyme 5-deiodinase, which accounts for 95% of circulating RT3. However, RT3 is physiologically inert.
4. As 5’-deiodinase is present in high concentration in pituitary and cerebral cortex, the ratio of T3/T4 is very high in these structures. Remaining about 20% is conjugated with sulphates and glucuronides.

**Effect of Diet**

Fasting decreases conversion of T4 to T3. Therefore, T3 concentration in plasma decreases in fasted individuals. However, conversion of T4 to RT3 is facilitated. Therefore, RT3 is increased and T4 remains normal in fasting. In starvation (chronic and severe fasting), RT3 returns to normal, but T3 continues to remain low. In overfeeding, opposite happens; T3 is increased and RT3 is decreased.
Section 57: Thyroid Gland

Flowchart 57.2: Metabolism of thyroxine.

Effect of Drugs

Various drugs inhibit deiodinase, and therefore, they decrease $T_3$ and increase $RT_3$ level in plasma.

Effects of Diseases

In many nonthyroidal conditions such as chronic febrile illness, trauma, burns, liver and kidney failure, myocardial infarction, selenium deficiency, advanced stage of cancers and other cachectic states, activity of deiodinases is suppressed. Therefore, level of $T_3$ decreases in these conditions. However, $T_3$ becomes normal when patient recovers.

Peripheral Degradation

Thyroid hormones are metabolized mainly by enzymes deiodinases (Flowchart 57.2).
1. There are three types of deiodinases: Type 1 ($D_1$), type 2 ($D_2$) and type 3 ($D_3$).
2. All the deiodinases contain a special amino acid selenocysteine. This rare amino acid makes the enzyme potent to catalyze oxidoreductive reactions. In fact, the selenium in the amino acid is essential for their enzyme activity.
3. $D_1$ is present in liver, kidney, thyroid and pituitary. $D_2$ is present in skeletal muscle, brain, pituitary gland, placenta and brown fat. $D_3$ is present in brain and reproductive tissues.
4. $D_1$ and $D_2$ are 5’-deiodinase that convert $T_4$ to $T_3$ and maintain the intracellular $T_3$ in their target tissues.
5. $D_3$ promotes conversion of $T_4$ to $RT_3$.
6. Especially in brain, $D_2$ maintains the supply of $T_3$ to the neurons. $T_3$ is degraded to diiodothyronines by deiodinases that are present in the liver and kidney.
7. In liver, $T_2$ and $T_3$ are metabolized by conjugation with sulphates and glucuronic acid. The conjugated forms are secreted in the bile into the intestine to reenter the enterohepatic circulation. Thus, iodine is lost minimally, about 4% in stool.
8. In many tissues, $T_4$ is also metabolized to tetradiodoacetic acid (tetrac).

Regulation of Secretion

Secretion of thyroid hormones is regulated by a feedback control mechanism. Hypothalamus secretes thyrotropin releasing hormone (TRH), which stimulates thyrotrophs of anterior pituitary to secrete thyroid stimulating hormones (TSH). TSH stimulates thyroid gland to secrete $T_3$ and $T_4$.
1. The plasma concentration of free $T_3$ and $T_4$ provides feedback signal for regulated release of TRH and TSH (refer to, Fig. 55.17; Chapter 55).
2. When thyroid hormones decrease in plasma, TSH secretion increases, and conversely, when thyroid hormones increase, TSH secretion decreases.
3. This counter regulation of TSH by thyroid hormones is partly attributed to their inhibitory effect on thyrotrrophs to directly inhibit TSH secretion and partly to their effects on hypothalamus to inhibit the secretion of TRH.
4. Thus, concentration of TSH is a better index of thyroid activity. Dopamine, somatostatin and glucocorticoid also inhibit TSH secretion from the anterior pituitary.

TSH

Structure and Secretion

TSH is a glycoprotein containing 211 amino acids. It has two subunits: $\alpha$ and $\beta$.
1. The $\alpha$-subunit of TSH is structurally similar to the $\alpha$-subunits of LH, FSH, and hCG (Application Box 57.2).
2. Therefore, the specificity of TSH is conferred by its $\beta$-subunit.
3. Normally, TSH is secreted at the rate of 110 µg/day and its plasma concentration is about 2 µU/mL.
4. Secretion of TSH is usually pulsatile. The mean secretion starts increasing at about 9 PM, reaches its peak at midnight and then decreases slowly. The secretion is less during the day.

Functions of TSH

TSH stimulates thyroid hormone synthesis and secretion by influencing almost all the steps involved in it.
1. This includes iodide trapping, iodide binding, synthesis of $T_3$ and $T_4$ (coupling reaction), secretion of thyroglobulin into the colloid and endocytosis of colloid.
2. TSH also increases blood supply to the thyroid gland.
3. TSH increases the size and number of follicles. Therefore, chronic rise in TSH causes thyroid hypertrophy or goiter (for details of TSH, refer Chapter “Anterior Pituitary”).

TSH Receptor and Other Receptors

The receptor for TSH on thyroid cells is a glycoprotein receptor with an extended glycosylated extracellular domain. It is a G protein-coupled receptor having typical seven transmembrane segments.
1. It activates adenylyl cyclase via Gs protein.
2. It also acts via phospholipase-C pathway.

Apart from having TSH receptors, thyrocytes also have receptors for IGF-1, EGF, TNF-α and γ-interferon and other growth factors.

1. IGF-1 and EGF promote growth and TNF-α and γ-interferon inhibit growth of thyroid tissue.
2. Cachexia in chronic inflammation could be due to decreased thyroid activity mediated by action of inflammatory cytokines (TNF-α and γ-interferon) on thyrocytes.

**Application Box 57.2**

Placental tumors can cause hyperthyroidism: As α-subunit of hCG is identical to the α-subunit of TSH, the hypersecretion of hCG stimulates thyroid activity. Major source of hCG is placent. Therefore, mild to moderate hyperthyroidism is observed in tumors of placental origin like choriocarcinoma.

---

**PHYSIOLOGICAL EFFECTS OF THYROID HORMONES**

### Mechanism of Action

The mechanism of action of thyroid hormones is similar to that of steroid hormones. They act by binding with the intracellular receptors. With few exceptions like adult brain and gonads, receptors for thyroid hormones are present in all tissues and organs. Though the developing neurons in infants and children are highly sensitive to thyroid hormones, it is not clear why the adult neurons are not so sensitive.

The steps of mechanism of action are as follows:

1. T₃ and T₄ enter the cells of the target organs by carrier mediated (energy dependant) transport.
2. Inside the cell, most of the T₄ is converted to T₃, which then binds with the thyroid-hormone receptors (TR) present on nucleus. The thyroid receptor protein binds to thyroid-hormone response elements (TRE) in the DNA via zinc fingers.
3. Binding of T₃ with thyroid hormone receptor-TRE elements cause translation of DNA that in turn increases the transcription of mRNA (Fig. 57.8).
4. Increased mRNA causes increased intracellular protein synthesis that stimulates cellular growth and maturation, increases intracellular enzyme synthesis, increases mitochondria formation and respiratory enzyme synthesis, and increases Na⁺-K⁺ ATPase activity.
5. The increased Na⁺-K⁺ ATPase activity increases cellular oxygen consumption and increased mitochondrial activity increases general metabolism of the cell.

**Thyroid-Hormone Receptors (TR)**

There are two human TR genes: α and β. The α receptor gene is located on chromosome 17 and β receptor gene is located on chromosome 3.

---

1. Each of them synthesizes two different mRNAs. Therefore, two different receptor proteins are formed: TRα₁, TRα₂, TRβ₁ and TRβ₂. TRα₁, TRβ₁ and TRβ₂ bind with T₃.
2. TRα₁ and TRβ₁ are widely distributed in tissues.
3. TRα₂ does not bind with T₃, though widely distributed and its function is not clearly known. TRβ₂ is found only in the brain.
4. There are many activators and repressors of TR, which makes thyroid hormones, exert their diverse effects in various tissues. T₃ binds more rapidly and avidly to TR. Therefore, T₃ is more potent than T₄.
5. In myocytes, especially in heart T₃ is not formed from T₄. However, T₃ directly enters myocyte to combine with nuclear receptors and promotes expression or inhibition of genes.

**Physiological Actions**

In general, thyroid hormones control basal energy metabolism, and development of CNS and normal body growth in childhood.
General Effects on Basal Metabolism

The metabolism of a cell depends on the rate of its oxygen consumption. Oxygen is essential for oxidative phosphorylation of ADP to ATP that takes place in mitochondria.

1. Thyroid hormones increase the basal rate of oxygen consumption and therefore, the basal metabolism of the tissues. This increased metabolism increases the rate of heat production. This is called calorogenic or thermogenic actions of thyroid hormones.

2. The cellular metabolism is also activated by increased Na⁺-K⁺ ATPase activity. Increased oxygen consumption by the cells parallels their increase in Na⁺-K⁺ ATPase activity and in some of the tissues, inhibition of Na⁺-K⁺ pump decreases oxygen consumption.

3. T₃ also stimulates the transcription of genes for both α and β subunits of Na⁺-K⁺ pump. Therefore, it is strongly perceived that increased oxygen consumption stimulated by thyroid hormones is mediated by Na⁺-K⁺ ATPase activity, at least partly.

Target tissues: The increased consumption of oxygen by thyroid hormone is observed in all tissues of the body, which is prominent especially in skeletal muscle, liver, heart, kidney and connective tissues. However, exceptions are anterior pituitary, adult brain, gonads (testis and ovary), uterus, lymph nodes, and spleen that show little thermogenic response. Receptors for thyroid hormones are almost absent in adult brain.

Basal metabolic rate: In the resting stage, oxygen consumption in human is about 250 mL/min. In hyperthyroid state, it increases to about 400 mL/min. Therefore, the basal metabolic rate (BMR) increases to about +80% in hyperthyroidism. Conversely, in hypothyroidism BMR decreases to as low as -40%. Increased BMR increases body temperature.

Mitochondrial mechanism: Metabolism is increased by thyroid hormones not only by increased oxygen consumption and Na⁺-K⁺ ATPase activity, but also by increase in synthesis of mitochondrial cytochromes and promote cytochrome oxidase activity.

1. Thus, thyroid hormones regulate the number of respiratory unit in each cell and their capacity to carry out oxidative phosphorylation.

2. Thyroid hormones also stimulate synthesis of uncoupling protein 1 (UCP-1) that contributes significantly to oxidation of nutrients and heat production.

3. The tissue expression of UCP-2, and UCP-3 are also increased by thyroid hormones.

Effects Secondary to Metabolic or Thermogenic Actions

Increased body metabolism increases nitrogen excretion. Therefore, increased food intake should be associated with hypermetabolic states to prevent catabolism of endogenous protein and fat. Thus, significant weight loss occurs promptly in increased thyroid activity, without adequate nutrient supplementation.

1. Increased metabolism increases body temperature.

2. This causes vasodilation that decreases peripheral resistance and consequent changes occur in hemodynamics.

3. Increased metabolism also increases the requirement for vitamins. Therefore, vitamin deficiency is common in increased thyroid activity.

Effects on Nervous System

Thyroid hormones are essential for development of the central nervous system, especially during infancy and early childhood. Development of brain occurs maximally in last six months of fetal life and first six months of postnatal life. During this period, thyroid hormones initiate and facilitate the process of differentiation and maturation of brain cells.

Thyroid hormones are required for following neural functions:

1. Growth of cerebral and cerebellar cortices, and basal ganglia.

2. Proliferation of axons and branching of dendrites.

3. Development of synaptic connections.

4. Development of neurotransmitter systems in CNS. Thyroid hormones induce formation of enzymes essential for neurotransmitter synthesis.

5. Increase in number of receptors on different brain tissues for various neurotransmitters in the brain.

6. Myelination of neurons. Thyroid hormones stimulate galactosyl sialyl transferase activity, which is essential for myelin formation.

7. Synthesis of proteins and various enzymes like succinic dehydrogenase that are required for energy generation in neurons.

9. General alertness and responsiveness to various stimuli.

10. Speed and amplitude of stretch reflexes.

11. Memory, learning and intellectual capacities.

Deficiency of thyroid hormones during infancy results in irreversible retardation in CNS development (Clinical Box 57.4). This is why thyroid deficiency in newborn should be detected early and treated promptly.

Cerebral blood flow, glucose and oxygen utilization by brain remains normal in adult hypothyroidism and hyperthyroidism. Thyroid hormones enter the brain in adults and found in gray matter of various parts of the brain. Also, T₄ is converted to T₃ by astrocytes in brain. After thyroidectomy, D₂ type 2 deiodinase activity in brain increases enormously, which is reversed in 3 to 4 hours following injection of T₃.
Clinical Box 57.4

Mental retardation in hypothyroid children: Thyroid hormones are essential for normal mentation. Therefore, mental retardation is an important feature of a thyroid deficiency in infancy and early childhood (thyroid dwarf). This differentiates it from a pituitary dwarf in whom mental activities are apparently normal. Decreased stretch reflex activities, especially decreased reaction time of Achilles tendon reflex (ankle jerk) is diagnostic in hypothyroidism.

Effects on Growth and Development

Thyroid hormones are essential for normal growth and musculoskeletal maturation.

1. Thyroid hormones promote expression of gene for growth hormone (GH) in somatotrophs of anterior pituitary.
2. They facilitate the effect of GH on tissues.
3. They stimulate linear growth of bones, and endochondral ossification and maturation of epiphyseal bone centers.
4. They enhance the activity of chondrocytes in cartilage.
5. They increase osteoid activity and bone remodeling.
6. They cause eruption and development of teeth.
7. They promote epidermal growth, and growth of nails and hairs.
8. They stimulate synthesis of structural and enzymatic proteins.

In hypothyroid children, bone growth is slowed and epiphyseal closure is delayed.

On tissues: Thyroxine causes alteration in the characteristics of mucopolysaccharides in the subcutaneous tissue. It decreases synthesis and promotes degradation of glycosaminoglycans (mucopolysaccharides).

Cardiovascular Effects

Thyroid hormones increase heart rate and myocardial contractility. Therefore, they increase the cardiac output.

1. Heart rate: Thyroid hormones increase the number of β receptors on the nodal tissues (SA and AV nodes) of the heart and also increase the sensitivity of β receptors to catecholamines. Thus, thyroid hormones increase the heart rate. Tachycardia is a common feature of hyperthyroidism (Clinical Box 57.5).
2. Myocardial contractility: Myocardial contractility increases by following mechanisms:
   i. Thyroid hormones induce myosin heavy chain (MHC) expression in the cardiac muscle. Especially, the α-MHC activity is increased, which has more actin and calcium-activated ATPase activity.
   ii. Thyroid hormones increase the expression of β receptors, G proteins and Na⁺-K⁺ ATPase in myocardiual cells.
   iii. They also increase the calcium-ATPase activity of the sarcoplasmic reticulum in cardiac muscle, which facilitates sequestration of calcium.

All these factors increase the force of contraction that in turn increase stroke volume.

MHCs in heart muscle: Normally, heart muscle contains two MHCs: α and β MHCs. The α MHC has high myosin ATPase activity, and β MHC has low myosin ATPase activity. Thyroid hormones stimulate α MHC and inhibit β MHC activities. In hyperthyroidism, expression of α MHC gene is enhanced and of β MHC gene is suppressed. However, in myocytes, thyroid hormones inhibit phospholamban, adenylyl cyclase, T₃ nuclear receptor and Na⁺-Ca⁺ exchanger, in addition to its inhibition of β MHC.

3. Systolic pressure: Increased heart rate and stroke volume result in increase in cardiac output (Flowchart S7.3). Thus, systolic blood pressure increases significantly.

4. Diastolic pressure: Via its calorigenic action, thyroid hormones increase body temperature that causes thermogenic cutaneous vasodilation and decreases peripheral resistance. Thus, diastolic pressure decreases.
Chapter 57: Thyroid Gland

5. **Pulse pressure and circulation time**: The net effect on blood pressure is increased pulse pressure. Wide pulse pressure is a prominent feature of hyperthyroidism. Increased cardiac output and vasodilation makes the circulation hyperdynamic. Therefore, circulation time is shortened.

**Clinical Box 57.5**

**Tachycardia in sleep**: Tachycardia is an important feature of hyperthyroidism. Tachycardia due to other causes (anxiety, tension, etc.) usually disappears during sleep or heart rate falls significantly. In thyroid excess, tachycardia persists even during sleep. **Sleeping tachycardia is an important diagnostic feature of thyrotoxicosis.** Sometimes atrial arrhythmias such as flutter or fibrillation are also seen in hyperthyroidism, especially in elderly people.

**Effects on Intermediary Metabolism**

Thyroid hormones by increasing oxygen consumption of tissues increase oxidation of substrates in general. They also increase the supply of substrates for metabolism by increasing their absorption from GI tract. By activating genes encoding enzymes of various metabolic pathways, thyroid hormones amplify all intermediary metabolisms.

**On Carbohydrate Metabolism**

Thyroid hormones increase absorption of glucose from intestine.
1. They increase hepatic glucose output by inducing gluconeogenesis. They also stimulate hepatic glycogenolysis. Therefore, plasma glucose level increases.
2. However, thyroid hormones increase the turnover of glucose by increasing its uptake and oxidation. Therefore, the net effect is no substantial change in plasma glucose concentration.
3. In hyperthyroidism, though plasma glucose level rises fast after a carbohydrate meal, it decreases rapidly.
4. Thus, sustained hyperglycemia or glucose intolerance is not a usual feature of hyperthyroidism. However, some patients develop glucose intolerance or even diabetes in the long run.

**On Fat Metabolism**

Thyroid hormones stimulate lipolysis.
1. Thus, thyroxine increases release of free fatty acids and glycerol from adipose tissues. Glycerol is utilized for gluconeogenesis.
2. Thyroid hormones also increase turnover of lipids, by facilitating their oxidation.
3. They stimulate synthesis of cholesterol and simultaneously promote its oxidation and biliary excretion.
4. Hepatic uptake of cholesterol is increased by increased expression of LDL receptors in liver.
5. Therefore, the net effect is significant decrease in plasma cholesterol and total lipid.

**On Protein Metabolism**

Thyroid hormones promote proteolysis in skeletal muscle, increasing the release of amino acid. They increase protein turnover by promoting protein degradation.

**On Metabolic Actions of Other Hormones**

Thyroid hormones potentiate the metabolic actions of catecholamines, glucagons, cortisol and growth hormone, especially their gluconeogenic and lipolytic effects.

**Effects on Sympathetic Nervous Systems**

Thyroid hormones increase the rate of metabolism, heat production, heart rate and neuromuscular functions; the features that are similar to the effects of sympathetic stimulation (Clinical Box 57.6).
1. They also synergize the metabolic effects of catecholamines like lipolysis, glycogenolysis, and gluconeogenesis.
2. In fact, they do not increase the release of catecholamines; rather increase the expression and sensitivity of β receptors in various tissues like heart, skeletal muscle and adipose tissues to catecholamines.
3. Recently, it has been observed that T₃ stimulates the production of thermogenin, a protein in the brown adipose tissue that partly mediates the thermogenic action of catecholamines.

**Clinical Box 57.6**

**Hypersympathetic state**: The features of hyperthyroidism mimic the features of sympathetic stimulation like increased metabolism, increased body temperature, nervousness, increased motor activity, and excessive sweating. Use of sympathetic blockers such as propranolol that blocks β receptors alleviates many features of hyperthyroidism. β blockers have some degree of inhibitory effects on conversion of T₄ to T₃; and therefore, mildly decrease plasma T₃ level.

**Effects on Respiratory System**

Thyroid hormones increase oxygen utilization of tissues. Therefore, the demand for oxygen also increases.
1. Thyroxine meets this demand by stimulating the rate of respiration, minute ventilation, and ventilatory responses to hypercapnia and hypoxia.
2. Thus, arterial PO₂ increases that increase the supply of oxygen to tissues.
3. Thyroid hormones stimulate erythropoiesis by increasing the synthesis of erythropoietin. Thus, the supply of oxygen to the tissues is also increased.

**Effects on GI Tract**

Thyroid hormones enhance the motility GI tract. Therefore, **hyperdefecation** is a feature of hyperthyroidism and constipation is a feature of hypothyroidism. Thyroid hormones also increase appetite and food intake, and reabsorption of glucose from GI tract.
**Effects on Skeletal Muscle**

Thyroid hormones increase the expression of MHC genes in the skeletal muscle. Therefore, hypothyroidism is associated with muscle cramp and weakness. However, muscle weakness also occurs in hyperthyroidism, which may partly be due to increased protein catabolism in the muscle. Myopathy occurs in chronic hyperthyroidism (thyrotoxic myopathy).

**Effects on Reproductive System**

In both males and females, thyroid hormones play an important role in the regulation of reproductive functions.

1. In women, they cause follicular maturation and ovulation. Thyroid abnormalities in women result in irregularities in menstrual cycle, such as menorrhagia (increased menstrual loss) in hypothyroidism and oligomenorrhea (decreased menstrual loss) in hyperthyroidism.

2. In males, they promote spermatogenesis. T₃ promotes differentiation of prepubertal testicular Sertoli cells.

**Effects on Kidney**

Thyroid hormones increase kidney size and promote growth of renal tubular epithelial cells. They increase renal blood flow and GFR. Tubular reabsorption of electrolytes, glucose and water is also increased by thyroid hormones. Increased water reabsorption increases blood volume.

In summary, thyroid hormones have widespread effects on metabolism, growth and development and control of many systemic functions (Table 57.1)

---

### APPLIED PHYSIOLOGY

#### Hyperthyroidism

Hyperthyroidism occurs due to hypersecretion of thyroid hormones from thyroid gland or from extrathyroidal tissues, which may be broadly divided into primary and secondary varieties.

**Primary Hyperthyroidism**

When hyperthyroidism occurs due to pathology of the thyroid gland, the condition is called primary hyperthyroidism. The common causes are:

1. Adenoma of thyroid
2. Multinodular goiter
3. Metastatic carcinoma of functioning thyroid gland
4. Graves’ disease
5. Activating mutation of TSH receptors
6. Iodine excess (Jod-Basedow phenomenon)

**Secondary Hyperthyroidism**

When hyperthyroidism occurs due to the pathology outside thyroid gland, the condition is called secondary hyperthyroidism, which may be due to a tumor of the pituitary gland or of extrathyroidal tissue.

#### Pituitary Causes

Tumor of thyrotrrophs of anterior pituitary (secretes excess of TSH).

#### Extrathyroidal Causes

Chronic excess administration of thyroid hormones (iatrogenic), tumor of ectopic thyroid tissue (lingual thyroid), hCG secreting tumors such as choriocarcinoma.

#### Features of Hyperthyroidism

Features of hyperthyroidism in descending order of frequency are:

**Symptoms**

Hyperactivity and irritability, heat intolerance, fatigue, tremor, sweating, palpitation, nervousness, hyperphagia (due to increased appetite), weight loss in spite of hyperphagia, hyperdefecation (due to increased GI motility), loss of libido, and oligomenorrhea (in females).

**Signs**

Sinus tachycardia, atrial fibrillation, systolic hypertension and increased pulse pressure, fine tremor, thyroid swelling (goiter), increased body temperature (warm and moist skin), muscle weakness (proximal myopathy), protrusion of eyeball with retracted lid (exophthalmos) (Fig. 57.9), periorbital edema, and gynecomastia (in males).

**Increased BMR** to as high as +100 is an important and diagnostic laboratory finding of hyperthyroidism.

Diagnosis of Hyperthyroidism
Diagnosis is made by estimation of $T_3$, $T_4$, and TSH in plasma.
1. Typically, in primary hyperthyroidism, $T_3$ and $T_4$ are high and TSH is low.
2. In secondary hyperthyroidism due to pituitary cause, TSH is high along with high $T_3$ and $T_4$.

Physiological Basis of Treatment
Administration of antithyroid drugs is the mainstay of treatment of hyperthyroidism. They usually inhibit iodide trapping mechanism or binding of iodide with the tyrosine molecule.

Antithyroid drugs are thionamides, anions, high dose of iodides, nonspecific beta-blockers and radioiodines.

Thionamides
These are thioureylenes, a group of compound related to thiourea. The commonly used thionamides are propylthiouracil, carbimazole and methimazole (active metabolite of carbimazole). The mechanisms of action of thionamides are:
1. They inhibit the function of thyroid peroxidase.
2. They inhibit oxidation and organification of iodide. Thus, they inhibit iodination of monoiodotyrosine and coupling reaction.
3. They reduce the level of thyroid stimulating antibodies.
4. Propylthiouracil reduce the rate of conversion of $T_4$ to $T_3$ by inhibiting $D_2$-deiodinase activity.

Anions
These are chlorate, perchlorate, pertechnetate, periodate, b iodate, etc. They are monovalent anions that compete with iodide for transport into the thyroid via NIS (Na$^+$-I symporter). Thus, they prevent iodide trapping. Thiocyanate is also an anion that inhibits iodide transport, but is less potent.

High Dose of Iodide
Iodide is essential for thyroid hormone synthesis. However, in very high dose it prevents organic binding by itself, and therefore, prevents thyroid hormone synthesis. This inhibition is called Wolff-Chaikoff effect. High dose of iodide also inhibits the effect of TSH on the gland by decreasing cAMP production in the cell, and by inhibiting proteolysis of thyroglobulin.

Propranolol
It is a nonspecific β-blocker. By preventing the action of catecholamines on β receptors, propranolol ameliorates many of the hyperthyroid features. It decreases heart rate, cardiac output, nervousness etc. and is very helpful in the early stages of the disease.

Radioiodine
It causes progressive destruction of thyroid cells and achieves euthyroid state. The dose should be appropriately adjusted to prevent development of hypothyroidism.

However, from the above-listed drugs, most commonly used drugs are propylthiouracil, methimazole and perchlorate.

Special States of Hyperthyroidism

Thyrotoxicosis
Thyrotoxicosis is not synonymous with hyperthyroidism. It is a state of thyroid hormone excess that occurs due to severe hyperthyroidism as seen in Graves’ disease, toxic multinodular goiter and toxic adenoma. This can also occur without hyperthyroidism as seen in thyroiditis or due to excess administration of thyroid hormones (thyrotoxicosis factitia).

Graves’ Disease
Graves’ disease is a condition in which there is diffuse enlargement of thyroid gland, which is usually associated with exophthalmos.
1. This is an autoimmune disease that occurs due to development of autoantibodies against TSH receptors. The antibodies formed against the TSH receptors activate the receptors. Therefore, thyroid gland becomes hypertrophied and hyperactive.
2. There is marked stimulation of secretion of thyroid hormones. Therefore, plasma level of $T_3$ and $T_4$ is very high.
Hypothyroidism

3. **TSH concentration is less** as excess thyroid hormones inhibit TSH secretion.

4. **Exophthalmos** occurs due to swelling of extraocular muscles and proliferation of connecting tissue within the bony walls of the orbit that pushes the eyeball forward.

5. **The disease is treated by** using antithyroid drugs, by decreasing thyroid hormone synthesis, or by reducing the amount of thyroid tissue (with treatment of radioactive iodine like $^{131}$I or by subtotal thyroidectomy).

**Thyroid Storm**

A patient suffering from hyperthyroidism becomes **suddenly extremely ill** with features like high fever, profound tachycardia, restlessness, and sometimes circulatory collapse. This is called thyroid storm. It usually develops when a hyperthyroid patient **undergoes major surgery, or experiences a major trauma or illness**. This is a medical emergency that requires immediate fluid replacement and steroid therapy with antithyroid drugs.

**Hypothyroidism**

**Hypothyroidism in Adult**

Hypothyroidism in adult is usually known as **myxedema**.

**Etiology**

Hypothyroidism, according to the cause may be classified into two categories: Primary and secondary.

**Primary Hypothyroidism**

When hypothyroidism develops due to the diseases or causes that primarily affect thyroid gland, is classified under primary hypothyroidism. The common causes are:

1. Autoimmune hypothyroidism: for example, Hashimoto’s thyroiditis.
2. Iatrogenic: Excess use of radioiodine ($^{131}$I), thyroidectomy, etc.
3. Iodine deficiency
4. Drugs: Excess of iodine, excess use of antithyroid drugs, lithium, etc.
5. Congenital hypothyroidism

**Secondary Hypothyroidism**

When hypothyroidism develops primarily due to a defect outside the thyroid gland, the condition is called secondary hypothyroidism. Usually, it occurs due to a defect either in the pituitary or in the hypothalamus.

1. **Pituitary hypothyroidism**: Pituitary resection, pituitary tumors affecting thyrotrophs, and Sheehan’s syndrome (postpartum necrosis of pituitary). Hypothyroidism occurs due to decreased TSH secretion.
2. **Hypothalamic hypothyroidism**: Brain injury involving hypothalamus, tumors of hypothalamus, etc. in which secretion of TRH is less.
3. Features of hypometabolism similar to hypothyroidism could occur due to resistance of peripheral tissues to thyroid hormones, called **thyroid hormone resistance** (Clinical Box 57.7).

**Clinical Box 57.7**

**Thyroid hormone resistance**: Recently, the condition of thyroid hormone resistance has been described, in which the tissues (usually peripheral tissues and anterior pituitary) become resistant to the effects of $T_3$ and $T_4$. Features of hypothyroidism may not develop, as in this condition mutation of thyroid receptor gene occurs only for $TRb$, whereas $TRa$ remains unaffected. Also, levels of $T_3$ and $T_4$ are maintained that overcome the resistance to some extent. But, features of hypometabolism similar to hypothyroidism occur in peripheral tissues. However, TSH level of plasma remains inappropriately high, which is not suppressed by exogenous thyroxine. The **patients with resistance in pituitary** have hypermetabolism, elevated $T_3$ and $T_4$ and normal nonsuppressible TSH level. The **patients with peripheral tissue resistance** have hypometabolism despite normal levels of $T_3$ and $T_4$. These patients require large doses of thyroid hormone to maintain their BMR. It has been observed that the **attention deficit hyperactive disorder** in children is more associated with thyroid hormone resistance.

**Features of Hypothyroidism**

Following are the features in descending order of frequency:

**Symptoms**

Cold intolerance, weakness and easy-tiredness, dry-thick skin, loss of hair, poor memory and inability to concentrate, constipation (due to decreased GI motility), weight gain in spite of poor appetite, thick and husky voice (typical hoarse voice that helps physician to **diagnose the disease over phone**), yellow skin (occurs due to carotenemia, as thyroxine causes conversion of carotene to vitamin A; therefore deficiency of it causes deposition of carotene), alopecia, psychosis (myxedema madness) menorrhagia (in females), galactorrhea and infertility (Fig. 57.10).

**Signs**

Cool extremities with dry coarse skin, dry hair, bradycardia, puffy face, with edematous hands and feet (myxedema), diffuse alopecia, goiter, bradycardia, hypertension (diastolic), anemia, decreased reaction time of tendon reflexes (especially, delayed Achilles tendon reflex relaxation), carpal tunnel syndrome and periorbital edema.

**BMR decreases** to about −40, and plasma cholesterol is usually elevated.

**Diagnosis of Hypothyroidism**

In primary hypothyroidism, $T_3$ and $T_4$ levels are decreased, but TSH is increased by feedback mechanism. In hypopituitary or hypothalamic hypothyroidism, the TSH concentration is less, in addition to decreased $T_3$ and $T_4$. The TSH response to TRH is usually normal in hypothalamic hypothyroidism, whereas it is increased in hypothyroidism caused by thyroid disease.
**Treatment of Hypothyroidism**

Thyroid hormone replacement is the mainstay of treatment. \( T_4 \) is instituted at a dose (usually 10 to 15 µg/kg/day) to maintain its normal level in plasma.

**Hashimoto’s Thyroiditis**

It is a chronic form of autoimmune thyroiditis in which antibodies are formed against the thyroglobulin and thyroid peroxidase. Therefore, thyroid cells are damaged and hypothyroidism develops. Fine needle aspiration cytology (FNAC) demonstrates sheet of Hürthle cells with lymphoid infiltrate.

**Hypothyroidism in Children (Cretinism)**

Cretinism is the hypothyroidism in children. When hypothyroidism develops from or before birth, the patients are called cretins.

**Causes**

Maternal iodine deficiency during pregnancy, maldevelopment of thyroid gland during fetal life, inborn errors of thyroid hormone synthesis, antithyroid antibodies in mother that crosses placenta and enters fetal circulation, and hypopituitarism in fetal life are usual causes of cretinism.

**Features**

Patients are dwarf and mentally retarded. Typically, they have potbelly and protrusion of tongue (Fig. 57.11). Other features of hypothyroidism are also present.

**THYROID FUNCTION TESTS**

Thyroid function tests include measurement of hormones in plasma, estimation of plasma TSH, measurement of binding proteins, TRH response test, radioactive iodine uptake, thyroid scanning, detection of thyroid antibodies, and determination of cholesterol level in blood.

**Classification**

A. **Isotopic tests:**
   a. Estimation of \( T_3 \) and \( T_4 \)
   b. Estimation of free \( T_3 \) and free \( T_4 \)
   c. TRH stimulation test
   d. Thyroid scan
   e. \(^{125}\text{I} \) uptake studies, TSH stimulation and \( T_3 \) suppression tests. These are seldom done at present.

B. **Non-isotopic tests:**
   a. Demonstration of thyroid autoantibodies
   b. Imaging procedures of the neck. USS, CT and MRI
   c. Biopsy of thyroid: fine needle aspiration cytology (FNAC) or open biopsy.

**Measurement of Thyroid Hormones**

\( T_3 \) and \( T_4 \) concentration in plasma are usually measured by RIA or sometimes by ELISA test. In primary hyperthyroidism, the thyroid hormone levels are increased, but typically the TSH is reduced due to feedback inhibition. In primary
**Plasma TSH Estimation**

Measurement of plasma TSH is an important diagnostic tool for the detection of thyroid abnormalities. In *primary hypothyroidism* TSH label is high but, in secondary hypothyroidism TSH as well as T3 and T4 are low. In *primary hyperthyroidism*, TSH is low. But, in hyperthyroidism due to pituitary causes, TSH, T4 and T3 are high.

**Measurement of Binding Proteins**

Usually, T3 uptake by the resin is measured. The T3 resin uptake indicates the free binding sites on the TBG.

1. In this test, radioactive iodine labeled-T3 is added to the patient’s serum. The labeled-T3 occupies the free binding sites on TBG.
2. Then, a resin is added to the tube, which absorb the excess of labeled-T3. The amount of labeled-T3 absorbed by the resin (T3 resin uptake) is directly proportional to the amount of thyroid hormones present in the serum and is inversely proportional to the free binding sites on the TBG.
3. When the hormone level is high as in hyperthyroidism, the free binding site on TBG is less.
4. Therefore, more T3 is taken up by the resin. In hypothyroidism, due to more of free binding sites on the TBG, T3 resin uptake is low.

**TRH Response Test**

This is a useful test for diagnosing both hypo- and hyperthyroidism. Normally, administration of TRH increases TSH production and therefore, the secretion of T3 and T4. An *abnormal response* is seen in hyperthyroidism because the negative feedback effect of high T4 overrides the stimulant effect of TRH. In hypopituitarism in which pituitary cannot respond to TRH, the TRH response test is also abnormal. An *exaggerated response* is observed in primary hypothyroidism because the negative feedback effect of T4 is reduced.

**Detection of Thyroid Antibodies**

Detection of antibodies against thyroid glands is essential for diagnosing Graves’ disease and Hashimoto’s thyroiditis, as these are autoimmune dysfunctions. In these diseases, specific antibodies are detected in plasma.

In Graves’ disease thyroid stimulating immunoglobulin known as LATS (long acting thyroid stimulator) is increased in plasma. LATS *mimic TSH* by binding to TSH receptors on thyroid gland and stimulates more secretion of thyroid hormones. In this condition, the thyroid secretion is not under the feedback control as TSH is not the actual stimulator for the hormone secretion.

In Hashimoto’s thyroiditis, antibodies against thyroglobulin are detected in circulation.

**Plasma Cholesterol Estimation**

Cholesterol level in plasma is *high in hypothyroidism* and low in hyperthyroidism. This is not diagnostic because change in plasma cholesterol occurs in many diseases. However, plasma cholesterol level is a useful index for monitoring the effectiveness of therapy in thyroid diseases, especially in hypothyroidism. Moreover, hyperlipidemic complications such as coronary artery disease are common in hypothyroidism.

**Estimation of BMR**

BMR is invariably *high in hyperthyroidism* and low in *hypothyroidism*. Though BMR determination is not performed now-a-days, and it is also not diagnostic, its alteration is highly suggestive of thyroid dysfunctions.

**Thyroid Scintiscanning**

Scintiscanning offers a *visual display* of the size and shape of the thyroid gland. It is employed in following situations.

1. It provides an objective assessment of the morphology of the gland.
2. It locates ectopic foci of the thyroid tissue.
3. The functional activity of the thyroid nodules (hot or cold nodules) can be evaluated.
4. In the investigation of masses in the neck or mediastinum, scintiscanning is useful to detect their nature (e.g: retrosternal thyroid).
5. Metastasis from thyroid carcinoma can be visualized.

Originally 131I was used for visualizing the thyroid, the scan being done after 24 hours of administration. At present *technetium pertechnetate*, which has a half life of 6 hours is used for this purpose. With technetium scanning it can be done soon after the injection of the radioisotope.

Additional laboratory investigations include hematological tests and estimation of the levels of serum calcium, sodium, CPK and proteins.

**Fine-Needle Aspiration Cytology**

This biopsy of FNAC is a very *valuable preoperative procedure* done routinely. A correct diagnosis can be obtained in over 80% of cases. False negative results occur...
more frequently than false positive ones. The diagnosis accuracy of FNAC is about 95%, specificity 92% and sensitivity is around 83%.

**Ultrasound/CT/MRI**

Ultrasound scanning provides an accurate indication of the size and is useful for differentiating cystic from solid lesions. CT and MRI are useful in the evaluation of retrosternal and retrotracheal extension of the gland, compression of trachea, extent of intrathoracic extensions of thyroid malignancy and infiltration to adjacent structures. MRI gives better delineation of soft tissue involvement like infiltration of nerves.

**Achilles Tendon Reflex**

Decreased relaxation time of Achilles tendon reflex is an important clinical assessment to suspect hypothyroidism.

---

**CHAPTER SUMMARY**

**Key Concepts**

1. Thyroid hormone is the key hormone for body metabolism. In hyperthyroidism there is substantial increase in BMR. Most of the features of hyperthyroidism are due to increased BMR and secondary to increased BMR. Opposite phenomena happens in hypothyroidism.

2. Thyroxine is highly essential for brain development in first year of life. Hypothyroidism in early infancy leads to severe mental retardation. Therefore, thyroxine deficiency if present in newborn, should be detected and treated immediately after birth.

3. Thyroxine profoundly increases body metabolism and HR. Therefore, heat intolerance and tachycardia even during sleep (sleeping tachycardia) are highly indicative of hyperthyroidism.

**Important to Know (Must Read)**

1. In examination, Steps of thyroid hormone synthesis, mechanism of action and physiological actions of thyroid hormone, is usually asked as a Long Question.

2. Mechanism of action of thyroxine, Synthesis and regulation of secretion of thyroxine, Actions of thyroxine on the cardiovascular system, nervous system and general effects on basal metabolism, Hyperthyroidism, Graves’ disease (Features and Physiological basis of treatment) Hypothyroidism (Etiology, features, diagnosis and treatment), Cretinism (Causes, features and treatment), and Thyroid function tests, can come as Short Questions in exam.

3. In Viva, examiner may ask… Name of hormones secreted from thyroid gland, Actions of Thyroxine, specially on the cardiovascular system, nervous system and general effects on basal metabolism, Steps of thyroid hormone synthesis, specially mechanism of iodide trapping, role of Na\(^+\)-I\(^–\) cotransporter, Pendred syndrome, Synthesis and secretion of thyroglobulin, Intramolecular and Intermolecular coupling, Proteins binding to T\(_4\) and importance of protein binding, Factors affecting peripheral conversion of T\(_4\), Regulation of thyroxine secretion, Mechanism of action of thyroid hormone, Functional anatomy of thyroid gland especially blood supply and histology of thyroid follicles, Surgical precautions during thyroid surgery, Functions of TSH, Features of Hyperthyroidism, Diagnosis of hypothyroidism, Graves’ disease, Thyrotoxicosis, Hashimoto’s thyroiditis, Mechanism of action/ Physiological basis of different antithyroid drugs like Thionamides group (Propylthiouracil, Carbimazole, Methimazole), Anions, Iodide in high dose, Radiiodine, Propranolol etc., Etiology, features, diagnosis and management of Hypothyroidism, Etiology, features and management of cretinism, and Classify thyroid function tests and explain few important tests.
ADRENAL GLAND

General Features

There are two adrenal glands, each one located at the upper pole of each kidney (Fig. 58.1). The adrenals consist of two distinct endocrine glands, one surrounding the other: the inner adrenal medulla, surrounded by the outer adrenal cortex that consists of three layers (Fig. 58.2).

1. The outer zone of adrenal gland, i.e. the adrenal cortex forms about 80–90% of the total gland, the inner zone, i.e. the adrenal medulla consists of 10–20% of the gland.
2. Developmentally and functionally, these glands are two separate endocrine organs. Adrenal cortex develops from the mesodermal tissue and secretes steroid hormones.
3. Adrenal medulla develops from neuroectodermal tissue related to sympathetic ganglia, and therefore secretes catecholamines.

Blood Supply

Weight of each adrenal gland is about 5–10 g. The gland is highly vascular and receives blood from three sources: branches of aorta, renal arteries, and phrenic arteries. The arterial blood enters the sinusoidal capillaries in the cortex and then drains into the medullary venules. This arrangement exposes the medulla to the high concentration of corticosteroids secreted from the cortex.

General Importance

The adrenal glands are essential for survival. In general, they play important role in following physiological processes of the body:
1. Homeostasis of energy stores
2. Control of fluid volume and extracellular environment of cells
3. Supply of substrates for generation of ATP in the cells
4. Regulation of intermediary metabolisms
5. Control of immunological mechanisms
6. Regulation of functions of various organ systems.
Therefore, an adrenalectomized animal unlike its normal counterpart, cannot survive prolonged fasting and stress, and dies due to hypoglycemia, inadequate ATP generation in the cells and inefficiency to maintain fluid volume and composition (circulatory collapse). However, the adrenocortical hormones are essential for survival of the being. Though, adrenomedullary hormones are not essential for immediate survival, they help prepare the individual to deal with emergencies.

**ADRENAL MEDULLA**

Unlike hormones of adrenal cortex, adrenomedullary hormones are not very essential for survival. However, they help the individual to cope with emergencies. Adrenal medulla, by secreting catecholamines assist the individual to prepare for fight or flight responses and also assist in meeting the metabolic requirements of the body in hypoglycemic emergencies in addition to their effects on other systemic functions.

**Scientist contributed**

John Jacob Abel (1857–1938), a German scientist, who later worked in USA, was pioneer in the study of endocrine secretions, especially on adrenal medulla. His outstanding works on the blood pressure-raising constituents of the adrenal medulla led to the identification and synthesis of catecholamines, and further to the development of many derivatives of catecholamines. Similarly, his studies on pituitary gland resulted in the isolation of its oxytocic, pressor and diuretic principles. He also pioneered with crystalline insulin. With Leonard G. Rowntree he introduced kidney and liver function tests.

**Cell Types**

Adrenal medulla is the inner zone of the adrenal gland, which constitutes about 20–30% of its mass. Essentially, adrenal medulla represents an enlarged and specialized sympathetic ganglion in which the postganglionic fibers are embedded and modified to become the endocrine cells. The tissue of adrenal medulla weighs about 1 g in adults.

**ADRENOMEDULLARY HORMONES**

The major hormones secreted from adrenal medulla are catecholamines:

1. Epinephrine
2. Norepinephrine
3. Dopamine.

The gland consists of clumps and strands of chromaffin cells, interspersed with venous sinuses. The cells are called chromaffin cells as they have greater affinity for chromium stains. They contain numerous granules that are present in the vesicles that store catecholamines (Fig. 58.3).

There are two types of endocrine cells in the adrenal medulla: epinephrine-secreting and norepinephrine-secreting.

1. **Epinephrine-secreting type:** In humans, 90% of cell types in adrenal medulla are epinephrine-secreting type. The granules in these cells are larger and less dense. Granules completely fill the vesicles.

2. **Norepinephrine-secreting type:** They constitute 10% of the cell mass of adrenal medulla. The granules in these cells are small and very dense. The granules do not fill the vesicles in which they are present.

The types of cells that secrete dopamine are not known, but are believed to be very less in number. Chromaffin cells receive sympathetic preganglionic cholinergic innervation and on stimulation discharge their content into venous sinuses. Small group of chromaffin cells are present near abdominal sympathetic ganglia. These are called paraganglia. They also secrete catecholamines.
In addition to secretion of catecholamines, the gland also secretes following peptides:
1. Adrenomedullin
2. Enkephalins
3. \( \beta \)-endorphin
4. Neuropeptide-Y
5. Chromogranin

Epinephrine secreting cells secrete opioid peptide. Most of the circulating metenkephalins are secreted from adrenal medulla.

The major secretion from adrenal medulla in human is epinephrine. About 85% of adrenomedullary secretion is epinephrine, 10–12% is norepinephrine and 1–3% dopamine, whereas secretion from sympathetic noradrenergic nerve ending is almost entirely norepinephrine.

**Effect of Sympathetic Stimulation**

Adrenal medulla is stimulated with the activation of sympathetic system. Therefore, sympathetic stimulation not only increases norepinephrine secretion from its nerve endings that slowly enters circulation, but also directly increases epinephrine secretion from adrenal medulla that rapidly enters circulation. Thus, sympathetic activation increases the level of both epinephrine and norepinephrine in blood.

**Synthesis, Secretion, and Metabolism of Catecholamines**

**Synthesis and Secretion**

Catecholamines are synthesized from the amino acid phenylalanine and tyrosine (Flowchart 58.1).

1. Conversion of tyrosine to Dopa is catalyzed by tyrosine hydroxylase and dopa to dopamine by dopamine decarboxylase.
2. Norepinephrine is formed by hydroxylation and decarboxylation of tyrosine and epinephrine is formed by methylation of norepinephrine by phenylethanolamine-N-methyltransferase (PNMT).
3. After synthesis, the hormones are stored in the granules of chromaffin cells before they are secreted into venous blood.

**Effects of Glucocorticoid**

The enzyme PNMT is induced by glucocorticoid at higher concentration. It may be noted that, the concentration of glucocorticoids is normally high in blood bathing adrenal medulla as blood from cortex drains into medulla before entering general circulation. Therefore, in adrenocortical deficiency, epinephrine synthesis is also reduced. Also, glucocorticoid promotes normal growth of adrenal medulla.

**Effects of 21β-hydroxylase**

During fetal life, the adrenocortical enzyme, 21β-hydroxylase stimulates development of adrenal medulla. Therefore, fetal deficiency of 21β-hydroxylase results in dysplasia of adrenal medulla, and if enzyme deficiency is not corrected promptly after birth, circulating catecholamines remain permanently low.

**Regulation of Secretion**

Catecholamine secretion from adrenal medulla increases in following conditions.
1. Exercise
2. Hypoglycemia
3. Trauma (Physical injury)
4. Anger and anxiety
5. Pain
6. Cold

The main mechanism of secretion in these conditions is sympathetic stimulation. Hypoglycemia is a strong stimulus for catecholamine release. When blood glucose is less than 60 mg%, CNS receptors monitoring plasma glucose are activated. They stimulate the neural pathways that activate sympathetic fibers to release norepinephrine and adrenal medulla to release mainly epinephrine. These catecholamines in turn increase plasma glucose level.

**Metabolism**

The normal plasma concentration of free hormone in recumbent posture is as follows:

- Norepinephrine: 300 pg/mL
- Epinephrine: 30 pg/mL
- Dopamine: 35 pg/mL

On standing, the hormone level increases by 50–100%. The circulating epinephrine is mainly derived from adrenal medulla and norepinephrine from the sympathetic nerve endings, whereas dopamine is derived equally from adrenal medulla and autonomic nerve endings.

1. About 70% norepinephrine and epinephrine, and 90% of dopamine are conjugated to sulfate. They have very short life span. Half-life is about 1–3 minutes.
2. They are metabolized primarily in the liver and kidney.

**Degradation**

The steps of degradation of epinephrine and norepinephrine are summarized in Flowcharts 58.2A and B respectively. Only 2–3% of catecholamines are excreted unchanged in urine. About 50% of secreted catecholamines appear in urine as metanephrine and normetanephrine, and 35% as 3-methoxy-4-hydroxy-mandelic acid, also called as VMA (Application Box 58.1).

The steps of degradation of dopamine are listed in Flowchart 58.3.

**24 h urinary excretion:** The normal daily urinary excretion of catecholamines and their metabolites are as follows:

- Metanephrine plus normetanephrine: 300 µg
- VMA: 400–600 µg
- MOPG: 200 µg
- Norepinephrine: 30 µg
- Epinephrine: 6 µg

**Application Box 58.1**

VMA is the index of sympathetic activity: Urinary excretion of VMA and MOPG reflect activity of sympathetic nervous system as they are mainly derived from norepinephrine. Epinephrine contributes relatively less to the production of VMA and MOPG. Therefore, the activity of adrenal medulla is assessed primarily by measurement of plasma epinephrine or free urinary epinephrine.

**Mechanism of Action**

Catecholamines act on α and β receptors. There are three types of β receptors: β₁, β₂, and β₃, and two types of α receptors: α₁ and α₂.

1. The α₁ and α₂ receptors have three subtypes each. Epinephrine and norepinephrine act on both α and β receptors.
2. However, in general, epinephrine acts more on β receptors and norepinephrine on α receptors. β₁, β₂, and α₂ are structurally similar.
Physiological Actions of Catecholamines

Catecholamines have profound effects on carbohydrate and fat metabolisms. They supply energy at the time of emergency and prepare the individual for either Fight or flight responses. They also control many autonomic and visceral functions.

Effects on Intermediary Metabolism

On Carbohydrate Metabolism

Catecholamines act on liver to increase glucose production by following mechanisms:

1. Catecholamines stimulate hepatic glycogenolysis by activating the key enzyme glycogen phosphorylase, which causes hydrolysis of stored glycogen. They also activate glycogenolysis in the skeletal muscle.

2. They stimulate gluconeogenesis from lactate and amino acids in the liver.

3. They also inhibit glycogen synthesis by inhibiting glycogen synthase enzyme complex.

4. Epinephrine inhibits insulin mediated glucose uptake by the skeletal muscle and adipose tissue.

5. Catecholamines also stimulate glucagon and inhibit insulin secretion from pancreas.

All these effects are primarily aimed to increase plasma glucose concentration.

On Fat Metabolism

Catecholamines promote lipolysis.

1. Epinephrine activates hormone sensitive lipase in the adipose tissue that causes hydrolysis of triglycerides and increases plasma FFA. FFA provides an alternative substrate for energy metabolism.

2. Catecholamines also promote β oxidation of FFA in muscle and liver to form ketone bodies.

3. Catecholamines are therefore prodiabetogenic and proketogenic hormones.

On Thermogenesis

Epinephrine is more potent than norepinephrine in most of the metabolic effects. Epinephrine increases BMR by 10–15%. It increases nonshivering thermogenesis and diet-induced thermogenesis. Therefore, epinephrine plays an important role in body adjustment mechanisms in response to cold.

During Hypoglycemia

Secretion of catecholamines increases in profound hypoglycemia, as occurs during strenuous exercise or fasting.

1. Catecholamines induce glycogenolysis and gluconeogenesis to combat hypoglycemia.

2. Lipolysis-induced release of FFA is used as alternative fuel.

3. In such situation, catecholamines also stimulate secretion of glucagon and inhibit insulin release.

Various metabolic effects of catecholamines mediated through different receptors are summarized in Table 58.2.

Fight or Flight Response

Norepinephrine and epinephrine have widespread effects on cardiovascular, respiratory and gastrointestinal systems, and intermediary metabolisms to prepare the individual to fight or flight at the time of emergency.

1. They increase cardiac output, promote blood flow to organs, increase ventilation, stimulate energy supply, relax the smooth muscle of GI tract and urinary

(PLC: Phospholipase C; AC: Adenylate cyclase).
system, and cause piloerection; all these effects are intended to either Fight with the enemy to finish or escape fast from the enemy to protect.

2. This is called Fight or flight response, which is exclusively mediated by sympathetic stimulation and catecholamines released from adrenal medulla (for details, refer Chapter “Sympathetic System”).

**Effects on Cardiovascular System**

Both epinephrine and norepinephrine increase force and rate of contraction of the heart that are mediated by $\beta_1$ receptors. Catecholamines also increase cardiac excitability and conductivity.

**Effects of Epinephrine**

1. Epinephrine increases heart rate and force of myocardial contraction, and therefore, causes adequate increase in cardiac output. Due to increased cardiac output systolic pressure increases.

2. It causes selective arteriolar constriction in renal, splanchnic and cutaneous vascular bed. However, epinephrine produces vasodilation in the skeletal and hepatic circulation via $\beta_2$ receptors. The vasodilation effect of epinephrine overrides the vasoconstriction effect and therefore, total peripheral resistance falls. Consequently, the diastolic pressure decreases mildly.

3. Thus, pulse pressure widens. This occurs especially during sympathetic stimulation that takes place during exercise.

4. The primary aim of all these changes is to divert blood from splanchnic and cutaneous circulation to the exercising (active) muscles, while maintaining the cerebral and coronary blood flow.

5. This also occurs during stress. These changes ensure delivery of substrate for energy production to the vital organs during Fight or flight situations (Application Box 58.2).

**Effects of Norepinephrine**

1. Norepinephrine produces vasoconstriction in most of the organs via $\alpha_1$ receptors that increases peripheral resistance and therefore, diastolic blood pressure rises.

2. Norepinephrine also produces some degree of tachycardia and increases myocardial contractility; therefore, systolic blood pressure also increases.

3. However, hypertension produced by norepinephrine stimulates baroreceptors in the carotid sinus and aortic arch (activates baroreceptor reflex) that causes reflex bradycardia, and overrides cardioacceleratory effects.

4. Therefore, the net effect is decrease in heart rate and cardiac output inspite of increased peripheral resistance (Fig. 58.4).

**Application Box 58.2**

Chronic catecholamine secretion is not good: In shock or circulatory failure, sympathetic stimulation that causes catecholamines secretion benefits the individual. However, if secretion of catecholamine is prolonged, then the effect on the body is deleterious, because renal vasoconstriction decreases kidney blood flow and compromises kidney function. Also, decreased splanchnic circulation impairs visceral functions. Chronic sympathetic stimulation may even result in intestinal paresis or hepatic failure.

**Effects on Other Systems**

**GI System**

Catecholamines inhibit gastric secretion and motility.

**Respiratory System**

Catecholamines cause bronchial dilation (prevent expiratory airway obstruction) so that gas exchange improves. They also stimulate respiration.
On Eye
They cause pupillary dilation; therefore vision for distant objects improves. This helps to see the surroundings clearly that helps the endangered individual.

On Endocrine Glands
Catecholamines stimulate ADH release through β receptors. They also increase renin secretion from the JG apparatus of kidney. Catecholamines increase thyroid hormone secretion and promote peripheral conversion of T₄ to T₃ which is mediated by β₂ receptors.

On Kidney
Catecholamines increases Na⁺ reabsorption from kidney. Catecholamines also redistribute renal blood flow. They increase renin formation that causes angiotensin and aldosterone synthesis and secretion, which in turn increases Na⁺ and water retention.

On Electrolyte Balance
Catecholamines stimulate the entry of K⁺ into the muscle cell. Therefore, they decrease plasma K⁺ (prevent hyperkalemia). Catecholamines also increase plasma Na⁺ concentration.

Effects of Dopamine
1. It produces renal and mesenteric vasodilation.
2. It causes vasoconstriction in other parts of the body.
3. It has positive inotropic effects (via β₁ receptors), increases cardiac output.
4. It increases systolic pressure, whereas diastolic pressure does not change significantly.
5. It causes natriuresis, by inhibiting Na⁺-K⁺ ATPase in proximal tubule.
   As dopamine increases systolic pressure and at the same time maintains kidney functions, it is very useful for the treatment of traumatic and cardiogenic shocks.

Applied Physiology

Clinical Uses of Catecholamines
Agonists and antagonists of catecholamines are widely used in clinical practice.
1. The agonists are used as nasal decongestant, appetite inhibitor, and for stimulation of general body functions.
2. The antagonists (both α and β receptor antagonists) are also used for the treatment of hypertension.
3. The antagonists (β receptor blockers) are also used for the treatment hyperthyroidism, especially to prepare the patient before thyroid surgery to decrease the heart rate.
4. Catecholamines are used for the treatment of shock.
5. Dopamine is used for treatment of traumatic and cardiogenic shock.

Pheochromocytoma
Pheochromocytoma is a tumor of adrenal medulla that occurs due to hyperplasia of chromaffin cells. Also, proliferation of chromaffin cells of paraganglia is associated with this condition. Most of pheochromocytomas produce both epinephrine and norepinephrine. Therefore, concentration of epinephrine and norepinephrine is very high. However, few pheochromocytomas produce either epinephrine or norepinephrine.

Features
The most common feature is sustained hypertension.
1. The disease is associated with increased metabolic rate, profuse sweating, extreme tachycardia and high BP, hyperglycemia, and loss of appetite and body weight.
2. In this disease, though there is continuously high secretion of catecholamines, typically there are episodes of excess catecholamine release.
3. The burst of catecholamine secretion usually occurs following rapid change in posture or the regular physiological events that stimulate sympathetic system.
4. This manifests with severe headache, tachycardia, palpitation, extreme anxiety, perspiration, either pallor or flushing, severe rise in blood pressure and a feeling of impending death.

Diagnosis
Diagnosis is established by detecting increased concentration of catecholamines in blood when the patient is in recumbent and at rest. Urinary excretion of metanephrine and VMA also increases.

Treatment
Treatment is by surgical removal of the tumor. The systematic improvement occurs with administration of α blockers.

Role of Catecholamines in Stress
Stress activates CRH and ADH secreting neurons of hypothalamus.
1. CRH in turn increases adrenergic discharge. Adrenergic stimulation increases plasma catecholamine concentration.
2. All these hormones together increase glucose concentration in plasma. Catecholamines increase glycogenolysis and cortisol promotes gluconeogenesis.
3. They also shift glucose utilization from peripheral tissues to the neural tissue.
4. Epinephrine increases supply of FFA to the heart.
5. Catecholamines increase cardiac output and blood pressure and promote supply of substrate to the tissue.
   During acute stress, a general state of arousal and vigilance is maintained by catecholamines. In chronic stress,
reproductive functions, sexual activity, and feeding are suppressed that are also mediated by catecholamines. A variety of cytokines are secreted during stress. The hypothalamic-pituitary-adrenal axis works in adaptation to stress. They generally activate the lifesaving mechanisms.

OTHER ADRENOMEDULLARY PEPTIDES

Adrenomedullin

Adrenomedullin is a polypeptide hormone. It is synthesized from proadrenomedullin. It is also formed in other tissues like brain and kidney.

Functions
1. Adrenomedullin decreases blood pressure by causing vasodilation, which is due to the increased production of EDRF by it.
2. It inhibits aldosterone secretion, and therefore, decreases ECF volume.
3. It, along with proadrenomedullin decreases peripheral sympathetic activity.

Chromogranin

This is a granular protein present in the secretory granules of chromaffin cells. The protein makes the dense core vesicles denser. The dominant chromogranin in human is chromogranin B.
1. Chromogranins are secreted along with catecholamines from the granules.
2. Therefore, measurement of their concentration in plasma indicates the secretory activity of chromaffin cells and indirectly the rate of catecholamine secretions.

Other Hormones

Enkephalins, endorphins, and neuropeptide Y are discussed elsewhere in the book.

CHAPTER SUMMARY

Key Concepts
1. Adrenal medulla is a neuroendocrine gland, a modified sympathetic postganglionic tissue. Therefore, sympathetic stimulation results in instantaneous increase in catecholamines level in plasma.
2. Though, epinephrine and norepinephrine act on both α and β receptors, in general, epinephrine acts more on β receptors and norepinephrine on α receptors.
3. Increased level of urinary VMA is an index of increased sympathetic activity.
4. Though sympathetic activation is essential in stressful situations to maintain energy metabolism and cardiovascular parameters, chronic stress (sustained sympathetic stimulation) is not good for body as it leads to depletion and degeneration.

Important to Know (Must Read)
1. In examination, “Describe the synthesis, metabolism and physiological effects of adrenaline and noradrenaline” may come as a Long Question.
2. In examination, Fight or flight response, Pheochromocytoma, Difference in the effects of adrenaline and noradrenaline on cardiovascular system, Effects of catecholamines on intermediary metabolism can be asked as Short Questions.
3. In Viva, examiner may ask… List the hormones secreted from adrenal medulla, Why VMA is an index of sympathetic activity, What is Fight or flight response, Cause, features, diagnosis, and treatment of Pheochromocytoma, Why chronic catecholamine secretion is not good, Types of catecholaminergic receptors, Which catecholamine act more on which receptor, Mechanism of action of catecholamine on different receptors, Effects of catecholamines on cardiovascular system, Effects of catecholamines on intermediary metabolism, Effects of catecholamines on other systems, Effects of Dopamine, Clinical uses of catecholamines, Mechanism of action of catecholamines, Steps of synthesis of adrenomedullary hormones, Factors regulating secretion of catecholamines, Names of other adrenomedullary hormones, Functions of adrenomedullin, and Functions of chromogranin.
CHAPTER 59

Adrenal Cortex

Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Correlate the histological specialization of different layers of adrenal cortex and medulla for secretion of specific hormones.
2. List the hormones secreted from different layers of adrenal cortex.
3. Give the steps of synthesis of different adrenocortical hormones.
4. Understand the deficiency of adrenocortical enzymes causing a specific dysfunction or syndrome.
5. Describe the regulation of secretion, mechanism of action and functions of glucocorticoids.
6. Describe the regulation of secretion, mechanism of action and functions of mineralocorticoids.
7. Appreciate the physiological importance of cortisol, and indications & contraindication of cortisol use in clinical medicine.
8. Understand the physiological basis of dysfunctions caused by excess or deficiency of glucocorticoids and mineralocorticoids.
9. Outline the functions and dysfunctions of adrenal sex steroids.

The student **MAY** also be able to:
1. Describe the steps of synthesis and regulation of secretion of adrenocortical hormones.
2. Explain the mechanism of action of glucocorticoids and mineralocorticoids.
3. Describe the role of cortisol in stress.
4. Describe the functions and dysfunctions of adrenal sex steroids.

The adrenals consist of **two distinct endocrine glands**, one inside the other. The inner **adrenal medulla** is surrounded by the outer **adrenal cortex** that consists of three layers (Figs. 59.1A to C). The outer zone of adrenal gland, i.e. the adrenal cortex forms about 80–90% of the total gland, the inner zone, i.e. the adrenal medulla consists of 10–20% of the gland. Developmentally and functionally, these glands are **two separate endocrine organs**. Adrenal cortex develops from the mesodermal tissue and secretes steroid hormones. Adrenal medulla develops from neuroectodermal tissue related to sympathetic ganglia, and, therefore, secretes catecholamines.

**FUNCTIONAL ANATOMY**

Adrenal cortex, the outer zone of the adrenal gland constitutes 80–90% of the gland. In fetus, adrenal cortex is larger in size in which **fetal adrenal cortex constitute 80%** of the gland and the future permanent adrenal cortex makes only 20% of the gland.

**Scientists contributed**

EC Kendall (1886–1972)  
T Reichstein (1897–1996)  
PS Hench (1896–1965)

The **Nobel Prize in Physiology or Medicine 1950** was awarded jointly to American biochemist and endocrinologist Edward Calvin Kendall, Swiss biochemist and endocrinologist Tadeus Reichstein, and Jamaican biochemist and endocrinologist Philip Showalter Hench “for their discoveries relating to the hormones of the adrenal cortex, their structure and biological effects”.

1. At term, the fetal adrenal cortex **undergoes rapid degeneration** and almost disappears in early infancy.
2. The remaining permanent cortex remains and constitutes **postnatal adrenal cortex**.
3. During fetal life, the **fetal adrenal cortex synthesizes and secretes sulfate conjugates of androgens** that
are converted to estrogens and progesterone in the placenta, which is essential for maintenance of pregnancy (see below).

**Hormones and their major functions:** Adrenal cortex secretes three categories of hormones: glucocorticoids, mineralocorticoids and sex hormones (Table 59.1).

1. The glucocorticoids are important for their metabolic, permissive, anti-inflammatory and immunosuppressive effects.
2. Mineralocorticoids are important for their role in extracellular fluid volume and electrolyte balance.
3. The sex steroids contribute to establish and maintain secondary sexual characteristics.

Of adrenocortical hormones, glucocorticoids and mineralocorticoids are the indispensable hormones.

**Histology**

Adrenal cortex consists of three layers: the outer zona glomerulosa that secretes mineralocorticoids, the middle zona fasciculata that secretes glucocorticoids and sex steroids, and the inner zona reticularis that secretes sex steroids and glucocorticoids (Figs. 59.1A to C).

**Zona glomerulosa:** This is the outermost and thinnest layer of the gland. It constitutes 20% of the adrenal cortex and consists of small clumps of cells that contain numerous mitochondria. It secretes mineralocorticoids, mainly aldosterone.

**Zona fasciculata:** This is the middle and widest layer of the adrenal cortex. It constitutes 80% of the adrenocortical mass. It consists of columnar cells that form long cords. The cytoplasm is loaded with vacuoles and lipid droplets. The mitochondria are large and contain numerous vesicular cristae. Cells of this layer secrete glucocorticoids (mainly cortisol and corticosterone) and sex steroids.

**Zona reticularis:** This is the innermost layer of the adrenal cortex and constitutes about 10% of its mass. It contains network of intercalated cells. The mitochondria are large and have vesicular cristae. There are no vacuoles and fat droplets. Cells of this layer secrete sex steroids like androgens and estrogens, and to some extent also glucocorticoids.

**SYNTHESIS OF ADRENOCORTICAL HORMONES**

Adrenocortical steroid hormones are synthesized from cholesterol. Cholesterol used for synthesis of steroid hormones in the adrenal cortical cells, are made available from two sources:

1. From blood, and,
2. Synthesized de novo.

**From blood:** Most of the cholesterol used for biosynthesis of steroid hormones are derived from cholesterol esters attached to the LDL (LDL-cholesterol) in circulating blood. Cells of adrenal cortex actively take up cholesterol from plasma by endocytosis of LDL molecules.

1. There are abundant LDL receptors on adrenocortical cells. In the cytoplasm, the cholesterol is esterified immediately and then stored as cholesterol esters in the lipid droplets (Fig. 59.2).
2. Whenever required for synthesis of hormones, cholesterol ester is converted to free cholesterol by the action of the cytosolic enzyme cholesterol ester hydrolase.
3. Cholesterol is then transported to mitochondria by a carrier protein, called sterol carrier protein 2. Sterol carrier protein 2 facilitates entry of cholesterol into mitochondria for hormone synthesis.

**From the cell itself (de novo synthesis):** Cholesterol is synthesized de novo in the cytosol of adrenocortical cells from acetate by the action of the enzyme HMG CoA reductase.

**Figs. 59.1A to C:** (A) Location of adrenal gland; (B) Parts of adrenal gland as seen in cross-section of the gland; (C) Histology of adrenal gland. Note, zona fasciculata constitutes more than 80% of adrenal cortex.
1. Formed cholesterol is then converted to cholesterol ester by the action of acyl-CoA-cholesterol acyltransferase (ACAT). Cholesterol ester is then stored in the lipid droplet, to be used later for hormone synthesis. Though, cells of the adrenal cortex can synthesize cholesterol de novo, under basal conditions plasma cholesterol is the major source for adrenocortical hormone synthesis. However, when hormone synthesis is stimulated by ACTH, the stored cholesterol in the cytosol of adrenocortical cells and newly formed cholesterol in the cytosol become the important source for hormone synthesis. In such conditions, plasma cholesterol without undergoing esterification directly enters mitochondria for biosynthesis of hormones. 

Cytochrome P-450 enzymes: The synthesis of hormones from cholesterol involves cytochrome P-450 enzymes, also known as CYPs (Table 59.2). These are the enzymes that catalyze hydroxylation of steroids. They are located in the membranes of endoplasmic reticulum and mitochondrial cristae.

Steps of Cortisol Synthesis

Steps of cortisol synthesis are depicted in Flowchart 59.1. In the mitochondria, pregnenolone forms 17-hydroxy-pregnenolone by the enzyme 17α-hydroxylase. 17-hydroxy-pregnenolone then moves into endoplasmic reticulum, where it is converted to 17-hydroxyprogesterone by 3β-hydroxysteroid dehydrogenase, which in turn hydroxylated to 11-deoxycortisol by 21β-hydroxylase. ACTH facilitates cortisol synthesis by increasing the supply of cholesterol and by converting the cholesterol to pregnenolone.

Steps of Corticosterone Synthesis

Steps of corticosterone synthesis are depicted in Flowchart 59.2. The cholesterol is converted to pregnenolone by the mitochondrial enzyme cholesterol desmolase. Pregnenolone then moves to endoplasmic reticulum where it is dehydrogenated to form progesterone by the enzyme 3β-hydroxysteroid dehydrogenase. Progesterone is hydroxylated by the 21β-hydroxylase to form 11-deoxycorticosterone, which then moves back to mitochondria to form corticosterone by the enzyme 11β-hydroxylase.
Synthesis of Mineralocorticoids

Mineralocorticoids are formed in the zona glomerulosa of adrenal cortex. Aldosterone is the major mineralocorticoid synthesized in humans.

The steps of aldosterone synthesis are depicted in Flowchart 59.3.

1. Aldosterone synthase is found only in the cells of zona glomerulosa of adrenal cortex.
2. Therefore, aldosterone synthesis is limited to the zona glomerulosa. Zona glomerulosa lacks the enzyme 17α-hydroxylase. Hence, synthesis of glucocorticoid and sex steroid does not occur in this layer of adrenal cortex.

Synthesis of Sex Steroids

In adrenal cortex, sex steroids are formed mainly in the zona reticularis. However, zona glomerulosa also contributes to it. The major sex steroids formed are dehydroepiandrosterone and androstenedione. The steps of androstenedione synthesis are depicted in Flowchart 59.4.
1. Dehydroepiandrosterone is converted to dehydroepiandrosterone sulfate by the enzyme sulfokinase. Though, androstenedione is synthesized from dehydroepiandrosterone, it can also be formed from 17-OH-progesterone.
2. Androstenedione is then converted to testosterone, which later forms estradiol.

The steps of estradiol synthesis are depicted in Flowchart 59.5.

In woman, adrenal gland supplies about 50–60% of the androgenic hormones. The adrenal androgen is not important in males because the testes produce testosterone. Similarly, the conversion of androgen to estrogen in the adrenal cortex in females is not important because ovaries secrete estrogen. However, after menopause secretion...
Section 6: Endocrine Physiology

Effects of Enzyme Deficiency

Deficiency of adrenocortical enzymes results in various syndromes. The congenital deficiency of the adrenal enzymes results in decreased cortisol secretion. Decreased level of cortisol in plasma stimulates ACTH secretion. As the ACTH has growth promoting (trophic) effects on cells of adrenal cortex, the gland size increases. Therefore, the conditions are called **congenital adrenal hyperplasia**. Deficiency of 21\(\beta\)-hydroxylase and 11\(\beta\)-hydroxylase are common.

**Deficiency of 21\(\beta\)-Hydroxylase**

Deficiency of 21\(\beta\)-hydroxylase accounts for **90% of the cases of congenital adrenal hyperplasia**. Deficiency of 21\(\beta\)-hydroxylase decreases the production of glucocorticoids and mineralocorticoids. Decreased cortisol level in...
plasma increases the production of ACTH, which facilitates the production of pregnenolone from cholesterol. Surplus pregnenolone is diverted for the excess production of androgens. Therefore, the condition is mainly characterized by virilization.

1. This leads to characteristic adrenogenital syndrome in females. The features of this syndrome are hirsutism, small breasts, male escutcheon, heavy arms and legs, enlarged clitoris (Clitromegaly), and receding hairline.

2. In severe cases, genitalia of genetic females are masculinized (female pseudohermaphroditism).

3. Many of them develop hyponatremia (salt losing form of congenital virilizing adrenal hyperplasia). Hyponatremia occurs due to urinary loss of Na⁺, which occurs due to lack of mineralocorticoid activity.

4. Hyponatremia causes hypovolemia and hypotension.

**Deficiency of 11β-hydroxylase**

In 11β-hydroxylase deficiency, increased production of androgen is associated with increased secretion of 11-deoxycortisol and 11-deoxycorticosterone. The 11-deoxycorticosterone is a mineralocorticoid. Thus, excess mineralocorticoid activity increases retention of Na⁺ and water. Therefore, patient develops hypertension in addition to virilization (hypertensive form of congenital virilizing adrenal hyperplasia).

In all virilizing forms of adrenal hyperplasia, glucocorticoid therapy is preferred. Exogenously administered glucocorticoid fills the endogenous cortisol deficit, and also suppresses the production of ACTH. Thus, ACTH induced excess production of sex steroid is decreased.

**Deficiency of 17α-hydroxylase**

This is a rare condition. It results in decreased production of sex steroids. Therefore, female external genitalia are present. However, as the production of aldosterone and corticosterone is normal, elevated level of mineralocorticoids result in hypertension and hyperkalemia.

**3β-hydroxysteroid Dehydrogenase**

This is also a rare condition, in which production of dehydroepiandrosterone is increased. There is some degree of masculinization in females. But, as dehydroepiandrosterone is a weak androgen, it does not cause full masculinization of the genitalia in male babies. Therefore, hypospadias (urethral opening on the undersurface of the penis) develops.

**Cholesterol Desmolase Deficiency**

Deficiency of the cholesterol side-chain cleaving enzyme decreases production of all adrenocortical hormones as it converts cholesterol to pregnenolone, the first step in steroidogenesis. The condition is fatal during fetal life. The production of placental progesterone depends on fetal adrenocortical production of androgen. Progesterone is essential for pregnancy to continue. Thus, deficiency of this enzyme results in termination of pregnancy. However, this condition is very rare.

**Metabolism of Adrenocortical Hormones**

**Normal Secretion**

The daily secretion and plasma concentration of adrenocortical hormones are listed in Table 59.3.

**Plasma Protein Binding**

Adrenocortical steroids usually bind with proteins, such as transcortin and albumin.

**Transcortin Binding**

About 80% of adrenal steroids, especially cortisol and corticosterone bind with a plasma protein called transcortin, or corticosteroid binding globulin (CBG). The transcortin is a glycoprotein produced by liver. The normal plasma concentration of transcortin is 3 mg/dL.

1. The concentration increases in pregnancy and estrogen therapy. When transcortin level increases, the quantity of hormone binding to it increases that in turn decreases free cortisol level.

2. The decreased free hormone increases ACTH secretion, which consequently increases cortisol secretion. However, a new state is reached at which the bound form is increased, but the free form remains normal.

3. Thus, the total hormone concentration increases without changing the concentration of the free form. Therefore, in pregnancy features of cortisol excess do not appear inspite of increased total cortisol level.

**Albumin Binding**

About 10–15% of cortisol is bound to albumin. Thus, only 5–10% of cortisol is free in the plasma.

Because of its protein binding, the half life of cortisol is more (60–90 mins), its concentration as free hormone in plasma is less and its excretion in urine is less. As binding of aldosterone to protein is less, the half life of aldosterone is less (about 20 minutes).

**Metabolic Degradation**

Cortisol is metabolized in liver, where it is reduced to dihydrocortisol and tetrahydrocortisol glucuronides.
tetrahydroglucuronide derivative cortisol and corticosterone are water soluble, and therefore is rapidly excreted in urine (Flowchart 59.6).

1. The free cortisol circulating in the plasma is filtered by kidney and about 50 mg is excreted in the urine. The measurement of urinary metabolite of cortisol provides a reliable index of cortisol secretion.
2. The excretion of 17-hydroxycorticoids represents about 50% of the total daily cortisol secretion. Normally 2–12 mg of 17-hydroxycorticoids is excreted per day.
3. The precursors of cortisol (progesterone and 17-OH-progesterone) are metabolized to pregnanediol and pregnanetriol.
4. In adult females, urinary excretion of these metabolites reflects the activities of ovarian-adrenal axis. However, their increased urinary concentration in prepubertal girls indicates specific congenital defect in cortisol secretion (due to disease of the adrenal cortex, not the ovary).

17-Ketosteroids

17-Ketosteroid derivative is formed in the liver from cortisol. However, corticosterone does not form 17-ketosteroid. Dehydroepiandrosterone, the major adrenal androgen is a 17-ketosteroid. Testosterone is converted to 17-ketosteroid.
1. Etiocicholanolone, a metabolite of adrenal androgens and testosterone, forms 17-ketosteroid.
2. 17-ketosteroid is excreted in the urine. Normally, 5–10 mg of 17-ketosteroids in women, and 8–20 mg of 17-ketosteroids in men is excreted in urine per day.
3. About 70% of this amount excreted is normally derived from adrenal cortex and 30% from the gonadal androgens.
4. When they accumulate in blood, they cause episodic fever known as etiocholanolone fever.

Regulation of secretion, mechanism of action, functions and dysfunctions of each category of adrenocortical hormones are discussed separately in the following sections:

GLUCOCORTICOIDS

Regulation of Secretion

Glucocorticoid secretion is controlled mainly by feedback mechanisms of ACTH secretion. Angiotensin II and other hormones also contribute.

Role of ACTH

ACTH is the polypeptide hormone containing 39 amino acids secreted from anterior pituitary. This is the major stimulator of glucocorticoid secretion. ACTH is secreted in irregular bursts throughout the day. Accordingly, the concentration of cortisol alters in the plasma.

1. The bursts are more frequent and prominent in the early morning (4–10 AM), which accounts for about 75% of the total ACTH secreted in a day (for details, refer chapter “Anterior Pituitary”).
2. This circadian rhythm (the diurnal variation) of ACTH secretion is an important regulator of cortisol secretion. Therefore, cortisol secretion also has a definite pattern that follows the pattern of ACTH secretion (Fig. 59.5).

Feedback Control

Glucocorticoid secretion is controlled by feedback release of ACTH from the anterior pituitary.

1. ACTH secretion is stimulated by CRH (corticotropin releasing hormone) secreted from the hypothalamus CRH secretion is influenced by various stimuli originating
Chapter 59: Adrenal Cortex

from the limbic system, pain pathways, NTS, reticular formation and suprachiasmatic nucleus (Fig. 59.6).

2. CRH increases ACTH secretion, which in turn increases glucocorticoid secretion from the adrenal cortex.

3. Increased glucocorticoid level in plasma provides negative feedback signal to the hypothalamus and anterior pituitary to inhibit the secretion of CRH and ACTH respectively.

4. Thus, cortisol secretion returns to normal.

5. Conversely, decreased glucocorticoid secretion increases CRH and ACTH release by feedback mechanisms that tend to increase the secretion of cortisol (Clinical Box 59.1).

Clinical Box 59.1

Steroid therapy should not be stopped abruptly: A patient receiving steroid for a long time should not stop the medicine abruptly. This is because, after a prolonged treatment with steroid, the adrenal cortex atrophies and becomes unresponsive to the ACTH for about six months. Also, pituitary secretes less ACTH initially, due to its diminished synthesis. However, pituitary recovers and secretes more ACTH thereafter. Increased level of ACTH slowly stimulates adrenal cortex to secrete glucocorticoids and it takes about 8 to 10 months for cortisol level to return to normal plasma level (Fig. 59.7). ACTH, from its level also returns to normal in about 10 months. Thus, pituitary-adrenocortical axis takes about 10 months to recover from the suppressive effect of prolonged steroid therapy. During this period, an individual fails to cope with stress and may succumb to stressful situations. To prevent such a dangerous complication, steroids should not be stopped abruptly after a prolonged therapy; rather the dose should be decreased gradually over weeks before finally stopping the treatment.

In Stress

In stress, increased cortisol secretion occurs mainly due to increased hypothalamic release of CRH. Fibers projecting from limbic system, especially from amygdala to hypothalamus (amygdalohypothalamic pathway) mediate the responses to emotional stress, fear, and anxiety. Ascending nociceptive fibers give collaterals to hypothalamus and they mediate the stress response to painful stimuli or injury.

Angiotensin II

Normally, angiotensin II is an important stimulator for aldosterone secretion. However, it also induces glucocorticoid secretion.

Other Hormones

ADH, serotonin, and VIP also stimulate glucocorticoid secretion. But their role in the physiologic regulation of glucocorticoid secretion is not clearly known.

Mechanism of Action

Cortisol takes few hours to days to exert its effect.

1. It diffuses into the cell and binds with the glucocorticoid receptors (GR) present in the cytoplasm.

2. Binding of cortisol with the receptor displaces the inhibitory heat shock protein complex from the receptor.

3. This results in alteration in the receptor configuration and causes hyperphosphorylation of the receptor.

4. Then, the hormone-receptor complex enters the nucleus, where it binds with the specific glucocorticoid regulatory elements (GRE) on the target DNA molecule (Fig. 59.8).

5. This leads to transcription of mRNAs that regulate expression of various genes.
Functions of Glucocorticoids

There are receptors for glucocorticoids in almost all tissues of the body and glucocorticoids influence many physiological processes of the body. Cortisol influences metabolisms profoundly, facilitates action of other hormones (permissive actions), influences functions of important organ systems, controls inflammation and immunity, and mediates responses of the body to stress. For its all-around physiological and pharmacological effects, cortisol is used widely in clinical practice.

Effects on Intermediary Metabolisms

On Carbohydrate Metabolism

Glucocorticoid is essential for survival during fasting. In prolonged fasting, the liver glycogen store is depleted and unless there is gluconeogenesis, death occurs due to hypoglycemia. Cortisol increases blood glucose by various mechanisms and, thus, plays an important defensive role in fasting (Clinical Box 59.2), and also against hypoglycemia induced by insulin.

Clinical Box 59.2

Adrenal-deficient patients should not fast: Cortisol increases blood glucose, and therefore is an important defense against hypoglycemia in fasting. In adrenal insufficiency, blood glucose remains normal so long as the food intake is normal. However, fasting induced hypoglycemia becomes fatal in such patients, as cortisol defense of hypoglycemia is lacking. Therefore, patients suffering from adrenocortical insufficiency are advised not to fast.

Cortisol increases plasma glucose by following mechanisms:

1. **Cortisol stimulates hepatic gluconeogenesis**: Cortisol secretion increases in fasting. Cortisol induces gluconeogenic enzymes. Especially, it activates glucose-6-phosphatase, which converts glucose-6-phosphate to glucose and, therefore, increases the release of glucose from liver. Also, by causing proteolysis, it mobilizes amino acids for neoglucogenesis.

2. **Increased secretion of glycogenolytic hormones**: Another defense mechanism of cortisol against hypoglycemia is the increase in secretion of glucagon and epinephrine that cause glycogenolysis. However, cortisol per se facilitates liver glycogen synthesis.

3. **Anti-insulin effect**: Cortisol decreases the utilization of glucose by antagonizing the action of insulin on peripheral tissues. It prevents the mobilization of glucose transporters from cytosol to the cell membrane. Especially, it inhibits the insulin stimulated glucose uptake in skeletal muscle and adipose tissue. This adds to the hyperglycemic effects of cortisol and makes diabetes worse (Clinical Box 59.3). It also reverses insulin suppression of hepatic glucose production.

Clinical Box 59.3

Cortisol complicates diabetes: In normal individuals, rise in blood glucose by cortisol increases insulin secretion, which counteracts ketone bodies and lipids raised by the cortisol. In diabetes, cortisol effects on ketone body and lipid remain unaffected as insulin is lacking. Thus, excess cortisol makes the diabetes worse by promoting ketoacidosis.

On Protein Metabolism

Cortisol facilitates proteolysis, especially in skeletal muscle, and inhibits protein synthesis. It mobilizes muscle protein for gluconeogenesis. The overall action is to facilitate the conversion of protein to glycogen. The chronic administration of cortisol or excess secretion of glucocorticoid causes depletion of protein storage in the body, especially in the muscle, bone, skin, and connective tissue.

On Fat Metabolism

Cortisol causes lipolysis. In fact, the lipolytic effect of epinephrine and growth hormone requires cortisol. During fasting, by promoting lipolysis, cortisol causes rapid release of free fatty acid and glycerol from adipose tissues, which are utilized for gluconeogenesis. Increased free fatty acid formation promotes ketogenesis, especially in diabetes.

On Food Intake and Fat Distribution

Cortisol increases appetite and food intake by stimulating neuropeptide Y secretion from the hypothalamus.

1. It stimulates differentiation of pre-adipocytes to adipocytes in the adipose tissue.

2. It also stimulates lipogenesis by activating lipoprotein lipase and glucose-6-phosphate dehydrogenase activity of the adipocytes in some other parts of the body.
3. Therefore, the action of cortisol varies from tissues to tissues. Thus, cortisol excess causes maldistribution of fat in the body that result in truncal obesity, moon face and buffalo hump with thinning of extremities. The exact cause of peculiar distribution of fat is not known, but it is associated with insulin resistance and/or increase in insulin level.

4. Cortisol also increases leptin synthesis in adipose tissue. Therefore, obesity is restricted by the negative feedback actions of leptin (leptin inhibits feeding).

To summarize the effect of cortisol on metabolisms, it is an important diabetogenic, ketogenic, and anti-insulin hormone (Flowchart 59.7).

**Permissive Actions of Cortisol**

Glucocorticoid is essential (even in small quantity) for some physiological actions of other hormones to take place. This is called permissive action of cortisol (as cortisol allows the specific actions of these hormones to occur, though it does not produce these effects by itself).

Permissive actions of cortisol include the following:

1. **Vasopressor and bronchodilator effects** of catecholamines.
2. **Calorogenic effects** of glucagon and catecholamines.
3. **Lipolytic effects** of catecholamines.
4. Development of **mammary gland** during puberty in females.
5. Development of **hepatic enzyme systems** during fetal life.
6. **Surfactant synthesis** in the fetal lung and maturation of lungs during intrauterine life.
7. Development of **bacterial flora and enzyme** systems in the intestine.

**Effects on Cardiovascular System**

**On Heart**

Cortisol increases myocardial performance by increasing Na⁺–K⁺ ATPase activity and also by increasing expression of β-adrenergic receptors in the heart.

**On Blood Vessels**

Cortisol maintains vascular reactivity. This is an important action of cortisol. It increases the responsiveness of arterioles to catecholamines and angiotensin II.

1. Probably, this action is mediated by inhibition of Na⁺–Ca²⁺ exchanger in the cell membrane so that the Ca²⁺ concentration is maintained in the blood vessel smooth muscle cells. Cortisol also decreases the release of vasodilators like prostaglandins.
2. In adrenal insufficiency, blood vessels become unresponsive to catecholamines (Clinical Box 59.4). This promotes vascular collapse, as already hypovolemia exists in such patients.

**Clinical Box 59.4**

**Injection of cortisol is a must in shock:** Injection of catecholamines in hypovolemic shock is required to restore blood pressure, as they cause vasoconstriction and increase cardiac output. However, it is desirable to inject cortisol along with catecholamines as it maintains vascular reactivity. Also, cortisol mediates responsiveness of catecholamines to vasoconstrictors by its permissive action. Catecholamine injection without administration of cortisol in shock does not ensure adequate vasoconstriction and blood pressure continues to remain low.
Effects on Central Nervous System
Cortisol influences the mood and behavior of individuals. There are abundant glucocorticoid receptors (both type I and type II) in limbic system including prefrontal cortex.

1. Cortisol decreases REM sleep but increases the slow wave sleep. The increased level of cortisol in plasma can cause insomnia.
2. It causes both elevation and depression of mood, and impairs memory.
3. It decreases the responsiveness to gustatory, olfactory, auditory, and visual stimuli.
4. The patients with adrenal insufficiency develop changes in personality, and remain irritable and apprehensive.

Effects on Musculoskeletal System

**On Muscle**
It increases the performance of cardiac and skeletal muscle. The inotropic effect on skeletal muscle is due to increase in acetylcholine synthesis at the muscle-nerve terminals. However, cortisol in excess decreases muscle protein synthesis and promotes proteolysis. Therefore, it decreases the muscle mass and strength.

**On Bone**
Cortisol inhibits bone formation by various mechanisms:
1. It decreases the synthesis of type-I collagen, which is a fundamental component of bone matrix.
2. It inhibits the conversion of osteoprogenitor cells to the osteoblasts.
3. It decreases absorption of Ca**+** from GI tract (by inhibiting the effect of vitamin D on GIT). It also decreases the synthesis of active vitamin D. Thus, it decreases supply of Ca**+** to the bones, which is essential for bone mineralization.
4. Cortisol also facilitates bone resorption. The overall effects are decreased bone mass and mineralization. Therefore, prolonged administration of cortisol may cause osteoporosis (Clinical Box 59.5).

**Clinical Box 59.5**
Bone X-ray should be done to check complications: Cortisol decreases bone mass and promotes osteoporosis. Even, vertebral collapse may occur. Therefore, patients receiving steroid for a longer period should be checked for osteoporotic changes by taking bone X-rays or MRI, especially in elderly patients.

Effects on Connective Tissue
Cortisol inhibits collagen synthesis. Therefore, it decreases skin thickness and causes thinning of capillary walls. The capillaries become fragile (susceptible to rupture). Thus, intracutaneous hemorrhage occurs in cortisol excess.

Effects on Kidney and Water Metabolism
Cortisol increases GFR by increasing glomerular blood flow. It is essential for the rapid clearance of a water load (fast excretion of water from the body) as happens in infusion of saline or glucose solution. Cortisol achieves this partly by inhibiting ADH secretion. Therefore, in the absence of cortisol, free water clearance is impaired and dilution of urine is limited (Clinical Box 59.6). It also increases phosphate excretion by inhibiting reabsorption of it in proximal tubule.

**Clinical Box 59.6**
Be cautious while infusing glucose solution in cortisol deficiency: Patients with adrenocortical insufficiency can not excrete a water load. Sudden infusion of large volume of saline or glucose solution in such patient may result in water intoxication. Following infusion of glucose saline, the glucose is metabolized, but the body can not remove water as cortisol is lacking. Therefore, plasma becomes hypoosmolar due to hemodilution. The cells in the brain swell, that impairs the hypothalamic thermoregulatory centers. Patient develops high fever and collapses. Therefore, such patients should receive cortisol while receiving a water load.

Apparent Mineralocorticoid Excess
In the absence or deficiency of 11-β-OH-steroid dehydrogenase type-2 (that converts cortisol into cortisone), cortisol has marked mineralocorticoid activity (Table 59.4), which causes hyperaldosteronism like situation due to action of cortisol on mineralocorticoid receptors.

1. The patient develops clinical features of hyperaldosteronism, though the plasma aldosterone and plasma renin activity remains low. Hence, the condition is called apparent mineralocorticoid excess.
2. It may occur due to congenital deficiency of the hormone or ingestion of licorice.
3. Licorice contains glycyrrhetinic acid that inhibits 11-β-OH-steroid dehydrogenase type-2. Persons consuming large quantity of licorice may also develop hypertension as sodium absorption through ENaC (epithelial sodium channel) in kidney is high.

Effects on Fetus
Cortisol imparts profound influence on fetal maturation.
1. Cortisol causes maturation of CNS during intrauterine life.
2. It causes growth of retina, GI tract, lungs, and skin of the fetus.

3. The intestinal enzyme system of fetal pattern to the postnatal or adult pattern is altered by cortisol, which is essential for disaccharides to be digested by the infants.
4. Cortisol causes lung development. It promotes growth of alveoli and causes flattening of alveolar epithelial cells. Cortisol also facilitates pulmonary surfactant synthesis. All these actions allow the fetal lung to satisfactorily expand at the first breath.

**Effects on Blood Cells**

Though, cortisol influences all the three formed elements of blood, the impact is more on leucocytes.

**On Leucocytes**

Cortisol causes leucocytosis. Though it causes mild neutrophilia and monocytes, it causes profound lymphocytopenia, eosinopenia and basopenia.

**Causes of Lymphocytopenia**

2. It decreases the size of lymph nodes and thymus.
3. It decreases the ability of lymphocytes and monocytes to secrete cytokines that are essential for proliferation of lymphocytes.

**Causes of Eosinopenia**

1. Cortisol causes eosinopenia by stimulating apoptosis (programmed cell death) of eosinophil.
2. By inhibiting the release of cytokines, it prevents eosinophil growth.
3. It facilitates sequestration of eosinophil in spleen and lungs (thus, decreases the peripheral eosinophil count).

**On RBC**

It causes mild erythrocytosis by stimulating erythropoietin production.

**On Platelets**

It produces mild thrombocytosis.

**Effects on Inflammation**

Cortisol has profound anti-inflammatory and anti-allergic actions. Inflammation is the response of tissue to injury. The inflammatory responses include: dilation of capillaries, increased capillary permeability, migration of granulocytes to the site of injury and killing of the organisms or the insulting agents by the granulocytes, mainly neutrophils (for details, refer Chapter 19). These responses are mediated by various chemicals like prostaglandins, thromboxanes, leukotrienes, kinins, histamine, serotonin, lymphokines, EDRF and PAF (platelet activating factor) (refer to Tables 19.2 and 19.5, Chapte 19). Cortisol interferes in most of the mechanisms of inflammation.

1. Cortisol inhibits synthesis of chemical mediators of inflammation. It stimulates synthesis of lipocortins (a family of phosphoproteins) in the target cells. Lipocortin inhibits the activity of phospholipase A₂; therefore, decreases the release of arachidonic acid, which is the precursor for many mediators of inflammation like prostaglandins, thromboxanes, leukotrienes, etc. Thus, cortisol prevents the formation of these mediators of inflammation.
2. Cortisol stabilizes the lysosomal membrane. Therefore, it decreases release of proteolytic enzymes and hyaluronidase from lysosomes that are required for inflammatory reactions to occur.
3. Cortisol inhibits mast cells. It prevents differentiation and proliferation of mast cells. Consequently, it decreases the release of histamine, an important mediator of inflammation (histamine causes vasodilation and increases capillary permeability).
4. Cortisol inhibits leucocyte functions. It prevents migration of leucocytes to the site of inflammation or infection. It prevents the margination of leucocytes and adherence of leucocytes to the capillary endothelial wall. Cortisol inhibits the expression of receptors in the endothelial cells that normally causes chemotactic peptides to interact with leucocytes to stick to the vessel endothelium.
5. Cortisol inhibits phagocytic and bactericidal activity of neutrophils. Though cortisol causes mild neutrophilia, it actually decreases the activity of leucocytes.
6. Cortisol inhibits proliferation of fibroblasts. Thus, it decreases the synthesis and deposition of fibrils at the site of inflammation. This forms the basis of chronic anti-inflammatory action of cortisol to injury. Cortisol prevents walling off of a chronic infection.
7. Recent evidences suggest that a transcription factor, called nuclear factor-κB (NF-κB), plays an important role in inflammation. Normally, NF-κB is bound to another cytoplasmic protein called IκBα, and this binding keeps NF-κB in an inactive state. Viruses and cytokines that induce inflammation separate NF-κB from IκBα by activating IκB kinase. NF-κB then migrates to nucleus and attaches with the DNA. This induces the transcription of genes for formation of various chemicals that participate in inflammation. Thus, NF-κB stimulates synthesis and secretion of mediators of inflammation. Glucocorticoids increase the production of IκBα in the cell, and, therefore, prevent the activation of NF-κB. This is suggested to be the primary mechanism of anti-inflammatory actions of cortisol (Flowchart 59.8). Nevertheless, the physician has to be cautious for use of cortisol to prevent inflammation (Clinical Box 59.7).
Flowchart 59.8: Mechanism of anti-inflammatory actions of cortisol.

(PG: Prostaglandins, LT: Leukotrienes; I₁B₅: A cytoplasmic protein; NF-κB: Nuclear factor-κB).

Clinical Box 59.7
Cortisol should be given with antibiotics: For its strong anti-inflammatory properties, cortisol is very often prescribed for the treatment of inflammatory diseases. However, it should not be prescribed for treating acute inflammations due to infections. If cortisol is given in infections, the toxic features of infection dramatically disappear due to its anti-inflammatory actions. This may give the wrong impression that the infection has subsided. But, actually infection spreads as cortisol suppresses immunity (discussed below). Thus, cortisol in such conditions masks the actual disease and delays the diagnosis. Moreover, it also aggravates the disease, which may become fatal. Therefore, cortisol should not be prescribed in acute infections like pneumonia, cholecystitis, pancreatitis, active tuberculosis etc. If situation warrants cortisol treatment in such conditions, it should always be prescribed with appropriate and adequate antibiotics.

Effects on Allergy
Cortisol has intense anti-allergic effects. Allergy occurs due to antigen-antibody reaction that stimulates the release of histamine from mast cells. There are two types of allergies: local and systemic.

1. In local allergy, release of histamine locally causes redness, itching and swelling.
2. In systemic allergy (anaphylaxis), histamine released into circulation inhibits heart that decreases cardiac output, and causes vasodilation that decreases blood pressure. Most of the effects of allergy are mediated through histamine.

The antiallergy effects of cortisol include the following:

1. Cortisol inhibits degranulation of mast cells and, therefore, prevents release of histamine.
2. It also prevents the growth of mast cells.

Thus, cortisol strongly prevents allergic reactions. Therefore, cortisol is used frequently for the treatment of allergy both locally and systemically (Clinical Box 59.8).

Effects on the Immune System
Cortisol has profound immunosuppressive effects. The influence is more on cellular immunity. When an antigen enters the body, antigen presenting cells (APCs) take it up and present to the T cells. This causes proliferation and activation of T cells. The activated T cells kill organisms, secrete interleukins and activate type 1 helper T cells that mediate immunological responses. Cortisol suppresses immunity by following mechanisms.

1. Cortisol decreases circulating lymphocytes by inhibiting lymphocyte mitotic activity. It mainly decreases T cell population, especially type-I helper T cells by stimulating their apoptosis.
2. Immature T cells in thymus and immature B and T cells in lymph nodes are destroyed by high level of plasma cortisol, which in turn decreases the size of thymus and lymph nodes.
3. Cortisol inhibits the cytotoxic effects of T cells by inhibiting the transport of lymphocytes to the site of antigenic stimulation and by decreasing the production of cytokines from them. Cortisol inhibits cytokine secretion by inhibiting the NF-κB activity of the cells.
Chapter 59: Adrenal Cortex

4. Cortisol inhibits production of interleukins (IL-1, IL-2, and IL-6) from the helper T cells, and inhibits synthesis of γ interferon from macrophage and lymphocytes. IL-2 and γ interferon are essential for cellular immunity.
5. Cortisol inhibits both resting as well as activated lymphocytes. It inhibits lymphocyte proliferation. It also inhibits differentiation of monocytes to macrophages (Flowchart 59.9).

**Important Note**

**Indications and contraindications of cortisol use:** Cortisol is used in the treatment of many diseases and also contraindicated for other diseases.

1. Cortisol is used for the treatment of inflammatory diseases like rheumatoid arthritis, etc. When an inflammatory process is life-threatening, administration of cortisol provides immediate relief.
2. Cortisol is frequently used for prevention of transplant rejection as it inhibits cellular immunity. However, cortisol given for a long time decreases body immunity and, therefore, increases the susceptibility to various bacterial, fungal, and viral infections. Therefore, cortisol treatment is supplemented with antibiotics.
3. Cortisol is used in the treatment of both local and systemic allergy. For example, in the management of bronchial asthma, to ensure effective bronchodilation, inhalation of both cortisol and salbutamol is advised. In acute exacerbation of asthma, systemic steroid is very helpful.
4. Cortisol prevents fibroblastic growth. Therefore, it is used in the treatment of keloid (the tumor of scar tissue) by local injections.
5. A person suffering from acute infection should not be treated with steroids without antibiotics, though it suppresses inflammation and dramatically improves the condition. This is because cortisol suppresses immunity and spreads infection (person may die due to severe infection).

Thus, cortisol has profound inhibitory effects on cellular immunity, for which it is frequently used for prevention of transplant rejection. However, in large doses, it also suppresses production of antibodies and, therefore, inhibits humoral immunity. Cortisol does not facilitate degradation of antibodies nor does it interfere in the interaction of antigen and antibodies. The decreased production of interleukin-1 by cortisol suppresses the febrile responses to inflammation.

**Clinical Box 59.8**

**Use and misuse of steroids:** Steroids are used in the treatment of various diseases for their anti-inflammatory, immunosuppressive, metabolic, and permissive actions. However, they are also misused by some sportspersons and others. The usual synthetic steroids in use are:

1. **Prednisolone:** It has predominantly glucocorticoid activity and less mineralocorticoid activity. Its glucocorticoid activity is about four times that of cortisol.
2. **Dexamethasone:** It has only glucocorticoid activity. Its glucocorticoid activity is about six times that of prednisolone.
3. **9α-Flurocortisol:** It has predominantly mineralocorticoid activity and less glucocorticoid activity. Its glucocorticoid activity is about two-and-half times that of prednisolone.

**Effects on GI tract**

1. It stimulates HCl secretion from parietal cells of the stomach. Thus, it causes hyperacidity and gastritis. Given for a long period, it produces gastric ulceration.
   Therefore, cortisol is prescribed cautiously in patients already having history of peptic ulcer.
2. Cortisol decreases Ca++ absorption from GI tract.

**Effects on Endocrine Function**

1. Cortisol inhibits growth hormone secretion. Therefore, it inhibits growth.
2. Cortisol inhibits TSH secretion. Therefore, it inhibits thyroid functions.
3. Glucocorticoids inhibit ACTH secretion. In cortisol excess ACTH secretion is less and in cortisol deficiency ACTH secretion is more. This helps in the diagnosis of adrenocortical dysfunction by estimating plasma ACTH concentration.

4. Cortisol induces expression of PNMT (phenylethanolamine-N-methyltransferase), the enzyme that catalyzes the formation of epinephrine from norepinephrine.

Role in Stress
The most important function of cortisol is to protect the body against stress. In absence of glucocorticoids, body cannot cope with stress even in mild intensity.

1. The glucocorticoid secretion increases due to increased ACTH secretion, which exclusively occurs due to increased release of CRH from hypothalamus.

2. In fact, stress is defined as the condition in which plasma ACTH secretion is high. The stimuli that increase ACTH secretion are called stressors.

3. In stress, glucocorticoid is essential for catecholamines to exert their FFA mobilizing action (FFA is an important source of energy supply in emergency situations) and for maintenance of vascular reactivity to catecholamines (Fig. 59.9).

4. Therefore, in absence of cortisol, the individual succumbs to stress.

Rapid Actions of Steroid
As steroids act though transcription of genes in the cells, it takes hours to days for their full actions to manifest. These are called genomic actions. However, recently, it has been observed that some of the steroid actions occur within few minutes. These rapid actions of steroid are due to their direct action on the membrane channels or enzymes. These are called nongenomic action of steroids. They activate various membrane enzymes that lead to formation of second messengers like cAMP in the cells, and second messengers in turn change cell functions.

Dysfunctions of Glucocorticoids

Cushing's syndrome
This is a pathological condition that occurs due to hypersecretion of glucocorticoids. This is called Cushing’s syndrome as it was described by Harvey Cushing.

Etiology
It occurs due to either a tumor of the adrenal cortex that causes cortisol excess or exogenously administered excess steroids (ACTH independent) or due to the tumor of the pituitary that increases secretion of ACTH (ACTH dependent).

Traditionally, Cushing’s disease refers to the disease that occurs only due to the ACTH producing tumor of pituitary, whereas Cushing’s syndrome refers to all the causes of cortisol excess.

Scientist contributed
Harvey William Cushing (1869-1939) was an American Neurosurgeon, developed neurosurgery as a branch of medicine, and he is often called as the ‘Father of modern neurosurgery’. He had pioneered in the study of functions hypothalamus, pituitary and the hypothalamo-pituitary-adrenocortical axis. During his experiments with Kocher, he first encountered the Cushing reflex which describes the relationship between blood pressure and intracranial pressure. He described the cortisol excess is due to increased pituitary activity, which was later named after him as Cushing’s disease and the cortisol excess is due to adrenocortical tumor as Cushing’s syndrome.

The common causes of Cushing’s syndrome are:
1. Adrenal hyperplasia secondary to pituitary ACTH producing tumors, hypothalamo-pituitary dysfunctions, and ectopic ACTH or CRH producing tumors, such as bronchogenic carcinoma.
2. Adrenal tumors (adenoma or carcinoma)
3. Adrenal macronodular hyperplasia
4. Familial adrenal dysplasia (Carney syndrome)
5. Prolonged and excess use of ACTH or cortisol (iatrogenic)

Features
The features of Cushing’s syndrome according to their frequency of occurrences are:
1. Centripetal obesity and overweight: This is due to peculiar distribution of body fat in which fat is deposited more in the abdomen and upper back. Fat pad in lower neck and interscapular region gives the typical appearance of buffalo hump (Fig. 59.10).
2. **Moon face**: The face becomes round with red cheeks due to fat deposition. Salt and water retention contribute to it.

4. **Hypertension**: Patient develops hypertension due to water accumulation as glucocorticoid in excess has significant mineralocorticoid activity. Increased angiotensinogen secretion by cortisol and direct action of cortisol on blood vessel contribute to it.

5. **Hirsutism and amenorrhea**: Occurs due to associated increased adrenal androgens.

6. **Reddish purple striae**: Striae develop on the abdomen. Excess fat deposition in abdomen causes rapid stretching of the skin that results in formation of striae.

7. **Ecchymoses**: The skin and subcutaneous tissue are thin as a result of protein catabolism. Capillaries of the skin become thin and fragile. Therefore, minor injury causes ecchymoses and bruises (subcutaneous and intracutaneous hemorrhages).

8. **Proximal myopathy**: The legs become thin due to proteolysis in the skeletal muscle and reduced bone mass. The muscle development is poor.

9. **Poor wound healing**: Hyperglycemia promotes growth of the organism at the wound site. Also, decreased immunity favors growth of the organism. Cortisol prevents walling off of a chronic infection.

10. Many patients develop **hyperglycemia** and glucose intolerance, and about 20% of patients develop insulin resistant **diabetes mellitus**.

11. **Osteoporosis** develops due to decreased bone mineralization and decreased bone mass. This may cause collapse of vertebral bodies and pathologic fractures of bones.

---

**Fig. 59.10**: Features of Cushing syndrome. Note the presence of centripetal obesity, moon face, buffalo hump, pendulous abdomen with stria over it, poor muscle development and thin limbs, easy bruisability, poor wound healing (infections).

12. Emotional changes may be profound ranging from irritability to frank psychosis.
13. Hyperacidity is common. Some patients may develop peptic ulcer.
14. The hairs are thin and scraggly. Some may have increase in facial hair and acne.

**Diagnosis**

Diagnosis is based on demonstrating increased cortisol production (increased plasma level of cortisol) and failure to suppress cortisol secretion by dexamethasone (dexamethasone suppression test). ACTH in plasma differentiates pituitary (ACTH dependent) causes from adrenal (ACTH independent) causes. In general, in ACTH independent cases, ACTH is less and, in ACTH dependent cases, ACTH is high.

**Treatment**

If the disease is due to tumor of adrenals or pituitary, surgical resection of the tumor is required. Medical adrenalectomy is done in few patients by inhibiting steroidogenesis with administration of high dose of ketokonazole or metyrapone that inhibit cortisol synthesis.

**Adrenocortical Insufficiency**

Hypofunction of adrenal gland may be primary or secondary variety.

**Primary adrenal insufficiency:**
1. Idiopathic atrophy of the gland (usually due to an autoimmune process).
2. Surgical removal of the gland
3. Infection (usually tubercular infection, but fungal and viral infection may also cause)
4. Bilateral hemorrhage into the gland
5. Metastatic invasion of the gland
6. Drugs: ketokonazole, metyrapone, mitotane, etc.

Primary adrenocortical insufficiency is called Addison's disease.

**Secondary adrenal insufficiency:**
1. Pituitary disease that decreases ACTH secretion
2. Hypothalamic disease that decreases CRH secretion

**Addison's Disease**

This is the condition of hyposecretion of glucocorticoid that results from progressive destruction of the adrenals.

**Etiology**

The atrophy of the adrenal cortex is usually idiopathic. An autoimmune mechanism is thought to be responsible. However, tubercular infection of the adrenal gland, secondary metastasis, amyloidosis and cytomegalovirus infection affecting the gland may destroy and produce the disease.

**Clinical Features**

Features, in order of their frequency are as follows:
1. Loss of weight and easy fatigability
2. Pigmentation of skin: The most characteristic feature of the disease is hyperpigmentation of skin, especially marked over the pressure points, sun-exposed areas and on the scar marks. Less plasma cortisol increases ACTH secretion by feedback mechanism. As ACTH has intrinsic MSH activity, pigmentation occurs.
3. Hypotension: Hypotension occurs due to decreased mineralocorticoid activity and decreased vascular reactivity. In sever cases, hypotensive shock occurs.
4. Anorexia, nausea and sometimes abdominal pain.
5. Hyponatremia (depletional), hyperkalemia.
6. Eosinophilia: Cortisol causes eosinopenia. Therefore, deficiency of it produces eosinophilia.
7. Patient develops rapid hypoglycemia on fasting; stress causes collapse.

**Diagnosis**

Decreased plasma level of cortisol with increased ACTH is diagnostic.

**Treatment**

Hormone replacement is mainstay of therapy.

**Adrenogenital Syndrome**

**Etiology**

This occurs due to 21β-hydroxylase deficiency, which decreases the synthesis of glucocorticoids and mineralocorticoids. Decreased plasma level of cortisol increases secretion of ACTH by feedback mechanism that increases the production of pregnenolone. Excess pregnenolone is diverted for the production of androgen. Thus, steroids in this syndrome are converted to excess of androgen that produces virilization.

**Features**

Excess androgen secretion in females causes masculinization and precocious pseudopuberty or female pseudohermaphroditism. The usual features are:
1. Hirsutism
2. Small breast
3. Receding hairline
4. Heavy arms and legs
5. Enlarged clitoris (clitoromegaly)
6. Male escutcheon (male distribution of suprapubic hair)
7. Androgenic flush.

**MINERALOCORTICOIDS**

Aldosterone is the major mineralocorticoid in humans.

### Regulation of Aldosterone Secretion

Aldosterone secretion is regulated mainly by three important stimuli: angiotensin-II, ACTH, and plasma K⁺ concentration. Many conditions alter aldosterone secretion (Table 59.5) by influencing these stimuli.

#### Angiotensin II

Angiotensin II is an important stimulator of aldosterone synthesis and secretion. It is formed from angiotensinogen, an α₂-globulin secreted from liver.

1. Renin, a circulating protease enzyme secreted from JG cells of kidney catalyzes the conversion of angiotensinogen to angiotensin I (A I).
2. A I is converted to angiotensin II (A II) by the action of angiotensin converting enzyme (ACE), present in the endothelial cell of blood vessels, especially in the pulmonary vasculature.
3. A II is further degraded to angiotensin III (A III). A II and A III stimulate the formation of aldosterone (Flowchart 59.10).

Thus, this system of aldosterone formation is called renin-angiotensin-aldosterone system (Details of RAS is described in first chapter of Renal System). A III is as potent as stimulator of aldosterone synthesis and secretion as A II. A I has no such activity. A II also stimulates synthesis of aldosterone. A II causes vasoconstriction and has many other functions (for details, refer to Chapter 75).

### Angiotensin Receptors

There are two types of angiotensin receptors: AT₁ and AT₂. AT₁ receptors are present on the zona glomerulosa cells of adrenal cortex. A II binds with AT₁ receptors and increases intracellular IP₃ and DAG production that in turn increase intracellular calcium. Rise in calcium facilitates aldosterone secretion.

**ACTH**

Cells of zona glomerulosa of adrenal cortex have ACTH receptors.

1. ACTH stimulates aldosterone synthesis and secretion, mediated by cyclic AMP and protein kinase.
2. However, the quantity of ACTH required to stimulate aldosterone secretion is more than the concentration required to stimulate cortisol secretion.
3. Moreover, the effect of ACTH on aldosterone secretion is temporary (Application Box 59.2). Aldosterone secretion declines, even if ACTH secretion is elevated, which is partly due to decreased renin secretion secondary to hypervolemia. Interestingly, deoxycorticosterone (another mineralocorticoid) secretion remains high.

#### Application Box 59.2

**ACTH stimulated aldosterone secretion is not transient in GRA:** Though ACTH-mediated aldosterone secretion is a temporary phenomenon; it is persistent in glucocorticoid-remediable aldosteronism (GRA). This is an autosomal dominant disorder, in which ACTH causes persistent hypersecretion of aldosterone that leads to hypertension. GRA occurs due to fusion of genes coding for 11b-hydroxylase and aldosterone synthase (as they are 95% identical and remain close together on chromosome 8) forming a hybrid gene called ACTH-sensitive aldosterone synthase. Therefore, ACTH effect on aldosterone becomes a prolonged phenomenon. Hypertension in GRA is treated by glucocorticoid, as this decreases the production of ACTH, which in turn decreases the synthesis of aldosterone. Hence, this syndrome is called glucocorticoid-remediable aldosteronism.

### Hyperkalemia

Aldosterone secretion is stimulated by increase in K⁺ in ECF.

1. Rise in ECF K⁺ activates voltage gated calcium channels that increases intracellular calcium.
2. Increased cytosolic calcium increases aldosterone synthesis and secretion.
3. Aldosterone, in turn promotes excretion of K⁺. Thus, aldosterone is a natural regulator of K⁺ level in ECF. Also, acute decrease in plasma Na⁺ or increase in plasma K⁺ stimulates the aldosterone synthesis and secretion.

**Mechanism of Action of Aldosterone**

Aldosterone binds with the cytoplasmic receptor. The HR complex moves to the nucleus where it induces transcription of mRNA. This increases new protein synthesis that alters cell function.

Aldosterone has both genomic and nongenomic actions:

**Genomic Action**

The gene activated by aldosterone is *sgk* gene (serum and glucocorticoid regulated kinase gene).

1. This is an early response gene that increases ENaC (Epithelial Na⁺ Channels) activity.
2. Aldosterone also increases mRNA for synthesis of proteins that form subunits of ENaC.
3. Aldosterone increases insertion of these channels on cell membrane and also increases their activity.

**Nongenomic Action**

Nongenomic action occurs rapidly. This is due to stimulation of the activity of Na⁺-K⁺ exchanger, which increases intracellular accumulation of Na⁺. The second messenger that mediates this action is IP₃.

**Physiological Actions of Aldosterone**

**Electrolyte and Water Balance**

The main function of aldosterone is to increase Na⁺ and water reabsorption and to promote K⁺ and H⁺ excretion from the kidney. Na⁺ reabsorption is the primary function, and other effects are mostly secondary to Na⁺ reabsorption. For Na⁺ reabsorption, aldosterone acts primarily on P cells (principal cells) of collecting duct and distal tubule of kidney. In fact, aldosterone controls only 3% of total Na⁺ reabsorption from the kidney. However, aldosterone deficiency results in significant hyponatremia.

Aldosterone increases Na⁺ and water reabsorption by following mechanisms:

1. It increases the number of Na⁺ channels in the epithelial cells of the kidney tubule.
2. It stimulates Na⁺-K⁺ ATPase activity, therefore, Na⁺ is reabsorbed and K⁺ is excreted.
3. It stimulates enzymes of Krebs cycle that facilitate ATP generation and provide energy for removal of Na⁺ from the interstitial fluid into the capillary.

Thus, aldosterone increases plasma Na⁺ concentration and decreases K⁺ concentration. Therefore, in aldosterone deficiency, hyponatremia is associated with hyperkalemia.

As Na⁺ is reabsorbed, Cl⁻ is transported in the same direction to maintain electroneutrality. The reabsorption of NaCl causes osmotic reabsorption of water. Thus, reabsorption of salt and water leads to ECF expansion.

**Aldosterone Escape Phenomenon**

Increased reabsorption of salt and water by aldosterone causes ECF expansion.

1. Increased ECF volume increases venous return to the heart that causes further distention of atria during their filling.
2. Atrial stretching increases synthesis and secretion of ANP from atrial myocytes.
3. ANP causes profound natriuresis and diuresis.
4. Therefore, ECF volume returns back to normal. This is called aldosterone escape phenomenon as kidney escapes from the effect of aldosterone.

**Dysfunctions of Aldosterone**

**Hypersecretion of Aldosterone**

Hyperaldosteronism can be divided broadly into two categories: primary and secondary.

**Primary Hyperaldosteronism**

The cause of excess aldosterone secretion is due to adrenal disease. The usual causes are aldosterone-producing adrenal adenoma (*Conn’s syndrome*), adrenal hyperplasia and adrenal carcinoma. *Renin secretion is decreased* in primary hyperaldosteronism (Fig. 59.11A).

**Conn's Syndrome**

This is the major cause of primary hyperaldosteronism. It occurs due to the tumor (adenoma) of zona glomerulosa of adrenal cortex.

1. The disease manifests with hypertension (due to sodium retention and ECF expansion), muscle weakness and fatigue (due to potassium depletion), and polyuria (due to impairment of urinary concentrating ability).
2. Edema is usually not a feature of primary hyperaldosteronism.
3. Hypokalemia, hypernatremia and low renin in plasma, and metabolic alkalosis are usual laboratory findings.

**Secondary Hyperaldosteronism**

Increased aldosterone secretion due to activation of renin-angiotensin system is called secondary hyperaldosteronism.

1. It is associated with increased renin in plasma (Fig. 59.11B), as decreased volume is the initiating stimulus for renin secretion. This is a major differentiating feature from primary hyperaldosteronism, in which renin secretion is less.
2. It occurs in congestive heart failure, cirrhosis of liver and nephritic syndrome. Renin secreting tumor (primary reninism) can also cause it.
3. **Edema is a usual feature** in secondary hyperaldosteronism. However, secondary hyperaldosteronism in **Bartter syndrome** and **Gitelman syndrome** occurs without edema.

**Bartter Syndrome**

It is a condition of hyperplasia of JG cells (juxtaglomerular hyperplasia).

1. The disease occurs due to **mutation in the Na⁺-K⁺-2Cl⁻ cotransporter gene**, which results in **high renin activity** and increased aldosterone synthesis.
2. Hyperaldosteronism produces **K⁺ depletion**.
3. Major features are **hypokalemic alkalosis and hypercalciuria**.
4. However, **blood pressure remains normal and there is no edema**.

**Hyposcretion of Aldosterone**

Hyposcretion of mineralocorticoid is usually associated with **adrenal insufficiency**. However, **isolated hypoaldosteronism** with normal cortisol production occurs in following conditions:

1. Inherited defect of biosynthesis of aldosterone.
2. Decreased renin production (**hyporeninemic hypoaldosteronism**).
3. Surgical removal of aldosterone secreting adenoma causing more resection of normal adrenocortical tissue.
4. During protracted heparin administration.
5. Selective unresponsiveness of Zona glomerulosa to angiotensin II (**hyperreninemic hypoaldosteronism**).
6. Pretectal disease of nervous system.
7. Severe postural hypotension.

**SEX STEROIDS**

Sex steroids secreted from adrenal gland are called **adrenal androgens**. The major adrenal androgens are **dehydroepiandrosterone** and **androstenedione**.

---

**Functions of Adrenal Androgens**

Adrenal androgens have less than 20% of activity of testicular androgen.

1. **Adrenarche**: At the onset of puberty in both boys and girls, in the **stage 1** (before the physical development of puberty), secretion of adrenal androgen becomes **high** before the gonadal secretions are significantly elevated. This is called **adrenarche**. It is proposed that adrenarche **initiates the process of puberty** in which adrenal androgen sensitizes the gonads to secrete more sex hormones and **sensitizes the sex organs** to the effects of sex hormones.
2. They exert **masculinizing effect**: However, the masculinizing effect is less in normal concentration of adrenal androgens. These effects are prominent only when the hormones are secreted in excess amount.
3. **Promote protein synthesis**: They are protein anabolic, increase protein synthesis.
4. **Facilitate growth**: They **facilitate growth**. In adult males, they accentuate the already developed sex characteristics. However, in prepubertal boys, in excess, they develop secondary sex characteristics precociously. This is called **precocious pseudopuberty**.
5. **Source of estrogen**: Adrenal androgens are converted to estrogen in the peripheral tissue and serve as the **major source of estrogen in males and postmenopausal females**.
Dysfunctions of Adrenal Androgens

Excess of adrenal androgens results in **virilization**. However, along with increased secretion of adrenal androgens, other adrenocortical hormones are secreted in larger quantity. Therefore, the features are collectively called as **“virilization syndromes”**.

1. One such example is **“Adrenogenital syndrome”** as described earlier in this chapter.
2. In males, they cause **precocious pseudopuberty**.
3. In females they cause **pseudohermaphroditism** and **adrenogenital syndrome**.

**CHAPTER SUMMARY**

**KEY CONCEPTS**

1. Glucocorticoids have many important functions. Permissive action, metabolic action, effects on blood cells and immunity are examples. However, anti-inflammatory and antiallergic properties of cortisol are very useful in the treatment of many acute and life-threatening conditions. The immunosuppressive effect of cortisol helps in prevention of transplant rejection.
2. Mineralocorticoids regulate serum electrolyte (especially K⁺) and water metabolisms of the body. Thus, aldosterone maintains ECF volume and blood volume. Cortisol maintains vascular reactivity to assist in control of blood volume and pressure.
3. Sex hormones, especially adrenal androgens (mainly DHEA) sensitize gonads for secretion of sex hormones at the time of puberty. Therefore, adrenocortical deficiency leads to delayed puberty or dysfunctions of puberty.

**Important to Know (Must Read)**

1. In examination, Describe the functions of glucocorticoids (or cortisol) usually comes as a **Long Question**. Regulation of secretion, mechanism of action, physiological actions and dysfunctions of aldosterone may come as a **Long Question**.
2. Regulation of cortisol synthesis and secretion, Mechanism of action of cortisol, Effects of cortisol on inflammation, Effects of cortisol on allergy, Effects of cortisol on immunity, Effects of cortisol on blood cells, Permissive actions of cortisol, Cushing's syndrome (etiology, features diagnosis and treatment), Addison's disease (etiology, features diagnosis and treatment), Conn's syndrome, Adrenogenital (Virilization) syndrome, Aldosterone (physiological actions, regulation of secretion, mechanism of action), Mechanism of action of glucocorticoids, Aldosterone escape phenomenon, are usual **Short Questions** in exam.
3. In **Viva**, examiner may ask… List the hormones of adrenal cortex and the layer from where they are secreted, Specific enzymes involved in synthesis of adrenocortical steroids and the diseases produced by their deficiencies, Functions of cortisol especially permissive actions of cortisol, effects of cortisol on inflammation, allergy, immunity and blood cells, Why steroid therapy should not be stopped abruptly? Why adrenal deficient patients should not fast? How cortisol excess complicates diabetes mellitus? Why injection of cortisol is a must during treatment of shock? Why bone X-ray should be checked in patients receiving steroid therapy for a prolonged period? Why one should be cautious while infusing glucose solution in cortisol deficiency? What are the indications and contraindications for cortisol use? Name some important synthetic steroids and their glucocorticoid activity, What is rapid action of steroids? What is the role of cortisol in stress? Effects of cortisol on intermediary metabolism (carbohydrate, protein and fat), Effects of cortisol on cardiovascular system and central nervous system, Effects of cortisol on bone, connective tissue and musculoskeletal system, Effects of cortisol on fetus, Effects of cortisol on gastrointestinal tract and endocrine system, What is Cushing’s syndrome and what are its features? Also, how these features develop? What is Addison's disease and what are its features? Physiological actions of aldosterone, What are the conditions that increase or decrease aldosterone secretion? What is aldosterone escape phenomenon? What is Conn's syndrome and what are its features? Functions of adrenal androgens, What is adrenogenital (Virilization) syndrome and what are its features? Regulation of glucocorticoids secretion, Mechanism of action of glucocorticoids, Regulation of aldosterone secretion, Mechanism of action of aldosterone, What is apparent mineralocorticoid excess? Cause and features of hyposecretion of aldosterone, Why ACTH stimulated aldosterone secretion is not transient in GRA (Glucocorticoid-remediable aldosteronism), Steps of synthesis of Cortisol, Steps of synthesis of Corticosterone, Steps of synthesis of Aldosterone, Steps of synthesis of Androstenedione, Steps of synthesis of Estradiol, and effect of deficiency of key enzymes like 21β-hydroxylase, 11β-hydroxylase, 17α-hydroxylase and 3β-hydroxysteroid dehydrogenase and cholesterol desmolase.
The digestion, storage and utilization of nutrients are processes that require higher degree of regulation. Pancreas plays a crucial role in controlling these processes. Pancreas has two parts: the exocrine pancreas, which constitutes about 80% of the pancreatic tissue that controls digestion, and the endocrine pancreas, which constitutes 1–2% of the pancreatic tissue that controls storage and utilization of nutrients. Endocrine pancreas is an important endocrine organ as it secretes insulin, the only antidiabetogenic and antiketogenic hormone in the body.

Importance of insulin-glucagon ratio: Pancreas secretes another three hormones: glucagon, somatostatin and pancreatic polypeptide. Glucagon has metabolic actions that are opposite to that of insulin:
1. **Insulin is anabolic and promotes storage of nutrients** (glucose, fatty acids and amino acids), whereas glucagon is **catabolic and promotes mobilization of nutrients** from their storage depots into the bloodstream.
2. Insulin and glucagon, by their opposing effects, control metabolism of carbohydrate, fat and protein to ensure energy supply during basal and active states. As insulin and glucagon have reciprocal physiological actions, the **ratio of insulin to glucagon** is more important than their individual concentrations in the regulation of intermediary metabolisms.

**Scientists contributed**

FG Banting (1891–1941) and JJ Rickard MacLeod (1876–1936) were awarded the **Nobel Prize in Physiology or Medicine** 1923 for their discovery of insulin. They studied the role of insulin for the control of carbohydrate metabolism. They acknowledged and shared the prize with Charles H Best and James Bertram Collip, who had also worked with them.
Section 6: Endocrine Physiology

3. Usually, the conditions that stimulate secretion of one inhibit the secretion of other, because when one is essential for the body the other is usually not.

4. **Deficiency of insulin produces diabetes mellitus** and its excess results in hypoglycemia. On the contrary, **deficiency of glucagon produces hypoglycemia** and its excess worsens diabetes mellitus.

5. Usually, insulin deficiency is associated with glucagon excess.

### PHYSIOLOGICAL ANATOMY

**Islets of Langerhans**

The endocrine pancreas, which constitutes less than 2% of the total pancreatic tissue, is formed by **islets of Langerhans** (named after the German medical student, Paul Langerhans who first described it in a dog pancreas in 1869). Islets are more abundant in the tail than the head and body of the pancreas. There are about **1 million islets** in the human pancreas. Islets are oval in shape with diameter ranging from 50 to 300 µm (Fig. 60.1). Each islet contains about **2,500 cells**.

**Scientist contributed**

Paul Langerhans Jr (1847–1888), a German pathologist and physiologist was born into a family of physicians and scientists, known for two medical eponyms. He made his first major contribution before he finished his medical school, with the discovery of epidermal nonpigmentary dendritic cells that are derived from the bone marrow and play a role in cell-mediated immunity. These cells are known as **Langerhans cells**. Second, Langerhans made the first detailed description of the pancreas during his studies for his doctorate degree at the Berlin Pathological Institute in 1869. He described different types of cells in the pancreatic islets, that later became known as the **islets of Langerhans**.

**Fig. 60.1:** Histology of pancreas showing islets of Langerhans.

**Fig. 60.2:** Structure of islet of Langerhans. Note, beta cells constitute majority of cell mass of the islet.

**Four type of cells** present in the islets:
1. **β cells** (B cells): Secrete **insulin**.
2. **α cells** (A cells): Secrete **glucagon**.
3. **δ cells** (D cells): Secrete **somatostatin**.
4. **F cells** (PP cells): Secrete **pancreatic polypeptide**.

**β Cells**

They constitute 70–80% of islet cells that **secrete insulin**. The cells are placed centrally in the islet (Fig. 60.2):
1. The diameter of each cell is 10–20 µm.
2. Packets of insulin are present in the form of **secretory granules** in the cell cytoplasm that measure about 0.25 µm.
3. Each packet of insulin is present in a vesicle and a clear space or halo exists between the wall of the vesicle and the packet.
4. A developed system of microtubules and microfilaments are present in the cytoplasm that facilitates the exocytosis of vesicles.

**α Cells**

They constitute 15–20% of islet cells that **secrete glucagon**. They are present in the periphery of the islet.

**δ Cells**

They constitute about 10% of the islet cells that **secrete somatostatin**. The cells are typically located toward the periphery between the β and α cells.

**F Cells**

They constitute 1–2% of islet cells that **secrete pancreatic polypeptide**. The cells are distributed randomly among the D cells.
**Fate of islet hormones:** The hormones secreted from islets are released into the pancreatic vein from where they are transported into the portal vein and from there they enter general circulation:

1. This special arrangement provides liver the first and maximum access to the proper concentrations of islet hormones as they are secreted, and then to other tissues in the body.
2. Thus, liver being the primary site of substrate metabolism avails maximum advantage of actions of islet hormones, especially of insulin and glucagon.

**Islet blood supply:** Islets are highly vascular:

1. They receive about 10% of the total pancreatic blood supply though they constitute only about 1% of the pancreatic tissue.
2. There is a portal arrangement of the blood vessels of pancreas, which allows hormones secreted from a cell group to reach the other islet cells.
3. This arrangement is essential for paracrine regulation of hormone secretion from the islet cells.

**Innervation:** Islet cells are neuroectodermal in development:

1. They receive both parasympathetic and sympathetic innervations.
2. Usually, stimulation of β adrenergic receptor increases insulin secretion and α adrenergic receptor decreases it.
3. Increased vagal (cholinergic) activity increases insulin secretion.

**INSULIN**

**Structure of Insulin**

Insulin is a peptide hormone consisting of two chains, A and B, which are connected by disulfide bridges. The molecular weight of insulin is 6,000:

1. The A chain contains 21 amino acids and B chain 30 amino acids (Fig. 60.3).
2. The final structure of insulin is determined by the N-terminal and C-terminal amino acids of A chain, and the hydrophobic character of the amino acids at the C-terminal of B chain.
3. However, the hydrophobic character of the amino acids at the C-terminal of B chain is important for biological activity of insulin.
4. Insulin is synthesized as monomers that immediately form the crystalline hexamer unit within two zinc atoms (Application Box 60.1).

**Application Box 60.1**

**Synthetic insulin:** Insulin is synthesized in pharmaceuticals usually as crystalline zinc insulin. This preparation is the fast acting insulin. Usually, insulin is injected subcutaneously as it is absorbed slowly to provide a slow rise in insulin concentration that resembles basal insulin secretion from pancreas.

**Scientist contributed**

Christian de Duve (born, 1917) a Belgian cytologist and biochemist, was awarded the Nobel Prize for Physiology or Medicine in 1974, for his research work on lysosomes (the cell’s digestive system) and peroxisomes (cell metabolic system), and shared his Nobel honors with Albert Claude and George E. Palade. He won Nobel Prize for his research in the field of diabetes mellitus and how his revelations led to the discovery of lysosomes. de Duve demonstrated that hepatectomized dogs needed considerably less glucose to be kept normoglycemic after injection of a supramaximal dose of insulin than did an intact animal. He proved that the liver is the major site of insulin action.

**Synthesis, Secretion and Metabolism**

**Synthesis of Insulin**

Like other peptide hormones, insulin is synthesized as preproinsulin, containing 110 amino acids. The insulin gene belongs to the superfamily of genes that encode synthesis of a variety of insulin like growth factors. The insulin gene is located on the short arm of the chromosome 11. Insulin is first formed as preproinsulin in the ribosome of rough endoplasmic reticulum. The preproinsulin contains four sequential peptides:

1. An N-terminal signal peptides
2. The B chain of insulin
3. A connecting peptide (C peptide), and
4. The A chain of insulin.

The N-terminal signal peptide is immediately cleaved from the preproinsulin molecule to form the proinsulin, a 86 amino acid peptide, which then enters the Golgi apparatus.
1. In the Golgi apparatus, the disulfide bridges are established that allows the proinsulin molecule to be folded (Figs. 60.4A and B). The A and B chains of insulin are linked by the connecting peptide (C peptide). The C peptide not only connects, but also facilitates folding of A and B chains.

2. During packaging in the Golgi apparatus into the granules, the proinsulin is cleaved to form insulin molecules, and C peptides are retained in the granules.

3. When insulin is secreted, the C peptide is also released in equimolar concentration with insulin.

4. Insulin is associated with zinc as molecule matures. The zinc insulin crystals form the dense central core of the granule with a clear space around.

5. The C peptide is present in the clear space between the membrane of the granule and the central dense core.

6. Also, during insulin secretion, some amount of proinsulin is secreted from the granules. Thus, β-cell granules secrete the following substances:
   1. **Insulin**: Insulin constitutes about 95% of secretion from β-cell.
   2. **Proinsulin**: Proinsulin is a 86 amino acid peptide. It has about 10% of biological activity of insulin. It is secreted as only about 3% of the amount of secreted insulin. However, as plasma clearance is slower (half life 15-30 min) than insulin, the plasma concentration in fasting state is about 10-15% of insulin concentration.
   3. **C peptide**: It is a 31 amino acid peptide. The amount of C-peptide secreted is about 7% of the insulin secreted from the gland:
      - It has no biological activity of insulin. Its importance lies in the fact that it is secreted in equimolar ratio with insulin.
      - Measurement of C-peptide has advantages over measurement of insulin. Hepatic metabolism of C-peptide is negligible; therefore its concentration in plasma directly reflects the β-cell activity.

   Moreover, C-peptide assay does not measure exogenous insulin and do not cross-react with insulin antibodies, whereas insulin measurements have these fallacies.

   Therefore, C-peptide assay is the better index of β-cell activity (Application Box 60.2).

**Substances Having Insulin Like Activity**

There are few substances present in human plasma having insulin like activity. However, their insulin activity is very poor. Therefore, insulin deficiency or insulin resistance leads to diabetes. Important among them are nonsuppressible insulin like activities (NSILAs) that are mainly somatomedins (IGF I and II). NSILAs are not suppressed by anti-insulin antibodies. Following are the insulin like activities in human plasma:

1. Insulin
2. Proinsulin
3. NSILA (IGF I, IGF II and IGF bound proteins).

**Application Box 60.2**

**C peptide measurement**: As C peptide is secreted in equimolar concentration with insulin, and is least degraded in liver, its concentration in plasma provides a good index of beta cell secretory capacity. It is measured by RIA.

The major regulator of insulin synthesis is the plasma glucose concentration. Glucose stimulates insulin secretion. Therefore, feeding (hyperglycemia) increases and fasting (hypoglycemia) decreases insulin synthesis and secretion. Glucose increases insulin synthesis by increasing translation of insulin mRNA and transcription of insulin gene.

**Secretion of Insulin**

Insulin secretion is greatly influenced by plasma glucose concentration. Elevation of glucose level in plasma is an important stimulator of insulin secretion. Factors that control insulin secretion are listed in Table 60.1.
Regulation of Insulin Secretion

Insulin secretion is mainly regulated by the feedback control signal provided by nutrients level in plasma. When the nutrients are more, insulin secretion increases to facilitate their metabolism and use, and when nutrients are less, insulin secretion is less.

**Plasma Glucose**

Glucose is the most important stimulator of insulin secretion. With the rise in plasma glucose level, there is almost a linear rise in plasma insulin concentration in the range of 50–300 mg% of plasma glucose (Fig. 60.5). Insulin secretion is almost nil below 50 mg% and no extra secretion above 300 mg% of plasma glucose. The secretion of insulin in response to rise in plasma glucose concentration occurs in two phases.

**First Phase Response**

Immediately following the rise in plasma glucose (in response to i.v. glucose infusion), insulin secretion increases rapidly to reach a peak within 1–2 minutes and then decreases to basal level in another 2 to 3 minutes (Fig. 60.6).

1. This is the first and rapid phase of insulin secretion in response to sudden increase plasma glucose concentration.
2. The first phase response is due to release of already synthesized and stored insulin from granules of β cells.

**Second Phase Response**

In the next phase, the rise in plasma insulin concentration occurs slowly that reaches a peak in about 60 minutes and then remains elevated for 3–5 hours. The second and slow phase insulin response is due to stimulation of insulin synthesis and secretion.

**Mechanism of Glucose-induced Insulin Secretion**

Glucose enters β-cells of pancreas via GLUT 2:

1. In the β-cells, glucose is utilized by glycolytic enzymes (see below) to pyruvate that enters TCA cycle to produce ATP.
2. Increased intracellular ATP inhibits ATP-sensitive K⁺ channels, which increases cytosolic K⁺ by decreasing K⁺ efflux (Fig. 60.7).
3. This depolarizes the β cells, which in turn opens the Ca²⁺ channels. Ca²⁺ influx increases cytoplasmic Ca²⁺ that facilitates Ca²⁺-mediated exocytosis of insulin granules.
4. Plasma K⁺ is a natural regulator of insulin secretion. Hypokalemia decreases insulin secretion (Application Box 60.3).

**Response depends on route of administration:** The insulin response to plasma glucose depends on the route of glucose administration:

1. The response of insulin secretion to orally administered glucose is more than the glucose administered intravenously.
2. When given orally, glucose stimulates secretion of hormones from gastrointestinal tracts. Many GI hormones such as gastrin, secretin, enteroglucagon, GLP1, and GIP are insulinogenic.
3. They stimulate insulin secretion in addition to its secretion that occurs due to rise in plasma glucose.
Therefore, insulin response is higher when glucose is given orally than intravenously.

**Application Box 60.3**

**Effects of hypokalemia:** Hypokalemia decreases insulin secretion. Therefore, patients with hypokalemia as seen in primary hyperaldosteronism develop impaired glucose tolerance. Similarly, patients receiving thiazide diuretics develop glucose intolerance as thiazide causes hypokalemia and may also produce damage to pancreatic islets.

**Other Stimuli**

Insulin secretion is also stimulated by **products of protein digestion.** Arginine, leucine, lysine and alanine are potent stimulator of insulin release:
1. **Glucose and amino acids** facilitate the insulinogenic action of each other.
2. **Triglycerides and fatty acids** also stimulate insulin secretion.
3. **Ketoacids** are also insulinogenic.
4. **Cholinergic vagal stimulation** strongly increases insulin secretion, which provides the basis of secretion in the cephalic phase of digestion.
5. **Catecholamines via β receptors stimulate** and via α receptors inhibit insulin secretion.
6. **During exercise,** sympathetic stimulation causes α-adrenergic inhibition of insulin secretion that tries to prevent hypoglycemia during exercise.

Obesity significantly increases insulin secretion and activity of insulin receptors. However, down-regulation of receptor causes insulin resistance (see below). Therefore, obesity contributes to development of type II diabetes mellitus (NIDDM), which can be prevented by regular physical exercises and maintaining normal weight.

**Metabolism of Insulin**

Insulin circulates freely (unbound to carriers) in the plasma, therefore, its **half-life is 5–8 minutes.** The metabolic clearance rate of insulin is about 800 mL/min.

1. The basal insulin release to the circulation is about 0.5 – 1 unit/h (20–40 µg/h).
2. Following food intake, release of insulin increases to about 10 times.
3. The total release of insulin into peripheral circulation in a day is about 30 units.
4. Insulin is metabolized mainly in the liver and kidney.

**C peptide Activity**

**C peptide** is secreted in equimolar concentration to that of insulin. However, the basal plasma concentration of C peptide is 5 times more than insulin (1 ng/mL). This is because the **metabolic clearance of C peptide is slower** than insulin. Therefore, the concentration of C peptide in plasma is a better index of β cell activity than the insulin (Clinical Box 60.1).

**Clinical Box 60.1**

**C Peptide is a better marker of cell activity:** C peptide is secreted in equimolar concentration with insulin. But, as the metabolic clearance of C peptide is slower than insulin, its concentration in plasma provides better knowledge of β cell activity than the insulin. Therefore, C peptide assessment is done in good laboratories to assess β cell functional status.
Mechanism of Action

Insulin acts on insulin receptors present on various cells. The major target tissues of insulin are liver, skeletal muscle and adipose tissues.

Insulin Receptor

Insulin receptor (IR) is a glycoprotein tetramer consisting of two α and two β subunits. The α subunits are present on the membrane extracellularly, whereas the β subunits traverse the membrane. Thus, β subunits have extracellular domain, membrane domain, and intracellular domain (Fig. 60.8). The α and β subunits are glycosylated.

They are bound to each other by disulfide bridges. The insulin receptor gene is located on the chromosome 19, which belongs to the superfamily of genes that code for other growth factors also.

Down regulation of IR: Insulin binds with α subunits of the insulin receptor, which results in conformational change of the receptor. The HR complex is then internalized by endocytosis:

1. The hormone is degraded in the cytoplasm, whereas the receptor is either degraded, or stored or recycled back to the membrane.
2. Therefore, excess insulin activity down-regulates the insulin receptors.

Fig. 60.8: A: Mechanism of action of insulin. Binding of insulin with α-subunit causes autophosphorylation of intracellular part of β-subunit of the insulin receptor. This causes phosphorylation of intracellular proteins like IRS and Shc that in turn activate phosphorylation cascades and generate other signals. Phosphorylation of Grb 2 proteins activates a series of signals that finally activate mitogen activated protein (MAP) kinase, which induces gene transcription. Phosphorylation of IRS activates intracellular enzymes that alter cell metabolisms, and transfers GLUT from cell to the cell surface. Increased GLUT on cell surface increases glucose uptake of the cell.
3. This is one of the mechanisms by which insulin resistance (decreased sensitivity to insulin) develops in obesity.

**Hormone Mechanisms**

Insulin binding to its receptors trigger following events:

1. The binding of insulin to α subunits brings about conformational change in the β subunits.
2. The intracellular domain of β subunits possesses tyrosine kinase activity. Conformational change of the β subunits activates its tyrosine kinase activity. This produces autophosphorylation of β subunits on tyrosine residues.
3. Autophosphorylation triggers phosphorylation of many intracellular proteins that alter cell functions. Also, dephosphorylation of proteins occurs.
4. The active tyrosine kinase phosphorylates tyrosines on insulin receptor substrates (IRS 1 and IRS 2):
   - IRS proteins are docking proteins to which a variety of downstream proteins bind. Thus IRS phosphotyrosines serve as docking site and activating site for different protein kinases and protein phosphatases (see Fig. 60.8).
   - The IRS also serves as facilitatory proteins that link to membrane G proteins, phospholipases, and ion channels.
5. Phosphorylation of IRS causes activation or deactivation of many target enzymes, translocation of GLUTs (glucose transport proteins) to the cell membranes and induction or suppression of genes in the nucleus. This results in synthesis of different intracellular proteins.
6. The GLUTs that move to the cell membrane facilitates glucose entry into the cell. The insertion of different protein channels on the plasma membrane increases entry of amino acids, potassium, magnesium, and phosphates into the cell.
7. Activation of mitogenic proteins increases transcription of various factors that are essential for stimulation of gene expression, especially concerned with cell growth.
8. IRS also activates growth receptor binding protein-2 (GRB 2), which stimulates binding of GTP to ras oncogene (a proto-oncogene present in plasma membrane). This activates the enzyme glycogen synthase, a key enzyme that modulate the metabolic effects of insulin.

**Action through GLUT 4**

Binding of insulin with receptors rapidly mobilizes glucose transport into the muscle and adipose tissue cells. This process of glucose entry in to the cell is increased by about 20 times by the activation of a glucose carrier system in the plasma membrane:

1. Insulin rapidly recruits the glucose transporter 4 (GLUT-4), which is specifically meant for insulin-stimulated glucose uptake in skeletal and cardiac muscle, adipose tissue and other tissues.

2. In the basal state, GLUT 4 is internalized from cell membrane into the endosomes of the cell and maintained in the cytoplasm in vesicles.
3. On activation by insulin, the vesicles containing GLUT 4 are swiftly transported to the cell membrane.
4. Membrane of the vesicles fuses with the membrane of the cell during which GLUT 4 is inserted into the cell membrane (Fig. 60.9).
5. Insulin facilitates this process of recruitment of GLUT 4 from its intracellular pool to the membrane pool by activating the enzyme phosphoinositole-3-kinase, and perhaps this is the most important function of insulin (Application Box 60.4).

**Application Box 60.4**

Regular exercise prevents diabetes: Exercise facilitates the recruitment of GLUT 4 from its cytoplasmic pool into the cell membrane in all tissues of the body, especially in the skeletal muscle and adipose tissues. This, exercise promotes glucose uptake by the cells and decreases blood glucose level. The increased glucose entry into the cell persists for many hours after exercise. Moreover, exercise-induced glucose entry does not depend on insulin. It is likely that S-AMP-activated kinase facilitates GLUT 4 insertion from endosomes into membrane in exercise. Thus, to check the rise in plasma glucose, one should perform regular exercise. Also, regular exercise can cause prolonged increase in insulin sensitivity. However, diabetic patients should be careful during exercise. As acute exercise significantly decreases blood glucose level by facilitating glucose uptake by skeletal muscles, and during exercise absorption of injected insulin is more rapid, hypoglycemia may be precipitated in diabetic patients during exercise. Therefore, diabetic patients should decrease their insulin dose when they exercise or they should take extra calorie just prior to exercise.
Chapter 60: Endocrine Pancreas

Physiological Actions of Insulin

Insulin is secreted in fed state, i.e. at the time of nutrient abundance. Therefore, insulin is known as the hormone of abundance. Insulin facilitates storage of nutrients when nutrients are present in excess of the energy need. It also suppresses mobilization of endogenous substrates. The stored nutrients are made available at the time of need like exercise, fasting, etc. Insulin produces its target effects by acting mainly on the liver, adipose tissue, and skeletal muscle.

On Carbohydrate Metabolism

Insulin increases glucose entry into the cell, stimulates its oxidation and promotes also its storage. At the same time insulin inhibits glucose production. Therefore, the primary function of insulin is to lower the plasma glucose concentration. It is the only hormone that decreases plasma glucose level (decreases basal glucose level and also prevents rise in plasma glucose following feeding). Insulin is the only effective anti-diabetogenic hormone. The antidiabetogenic functions of insulin are mediated by its action on liver, adipose tissue and muscle.

In general, insulin increases glucose entry into cells of almost all tissues of the body except brain (excluding ventromedial hypothalamus), RBCs, epithelium of GI tract, and renal tubules.

In Liver

In liver, insulin promotes glucose storage and prevents its production by following mechanisms (Flowchart 60.1):

1. Insulin facilitates glucose entry into the hepatic cell by inducing the action of the enzyme glucokinase. Glucokinase catalyzes phosphorylation of glucose to glucose-6-phosphate. Thus, by facilitating glucose entry into the cells and also simultaneously converting glucose into glucose-6 phosphates, insulin keeps cytoplasmic glucose concentration at lower level. Therefore, facilitated diffusion of glucose into the cell continues.

2. It stimulates glycolysis by activating the enzymes phosphofructokinase and pyruvate kinase. These actions convert glucose into pyruvic and lactic acids. Pyruvate and lactate are also oxidized by insulin as it stimulates pyruvate dehydrogenase activity. Thus, insulin decreases the cellular concentration of glucose and consequently helps in its facilitated diffusion into the cell.

3. It promotes glycogen synthesis in liver. In the liver cells, it activates the enzyme glycogen synthase complex that promotes formation of glycogen. Thus, it promotes storage of glucose in the form of hepatic glycogen.

4. It inhibits hepatic glycogenolysis, and therefore it decreases hepatic glucose output. Insulin achieves it by inhibiting the activity of the enzymes glycogen phosphorylase and glucose-6-phosphatase.

6. Once insulin action is over, again they are internalized into the vesicles. In liver, insulin facilitates glucose uptake by activating the enzyme glucokinase not by GLUT 4.

Glucose Transporters

Glucose enters the cell by means of facilitated diffusion or by secondary active transport with sodium in intestine and kidney. In skeletal and cardiac muscle, adipose tissue and other tissues, entry of glucose into the cell is facilitated by insulin by increasing the number of glucose transporters (GLUTs) in the cell membrane. GLUTs promote the facilitated diffusion of glucose into the cell:

1. Glucose transporters are different from sodium dependent glucose transporters (SGLT 1 and SGLT 2) that mediate secondary active transport of glucose in the kidney and GIT.
2. GLUTs are expressed in different tissues. GLUTs are membrane proteins that span membrane 12 times.
3. About 14 different types of glucose transporters have been described (GLUT 1 – GLUT 14). However, the first 7 types have been extensively studied.
4. GLUT 1 and GLUT 3 are meant for basal glucose uptake by the cells.
5. GLUT 4 is primarily meant for insulin stimulated glucose uptake especially in the skeletal and cardiac muscle and adipose tissues (Table 60.2).
6. GLUT 2 acts as the β cell glucose sensor.
7. GLUT 5 facilitates fructose transport in jejunum and sperm.
8. GLUT 7 acts as glucose-6-phosphate transporter in the endoplasmic reticulum of liver and other tissues.
9. GLUT 6 is a pseudogene.
5. It also **inhibits gluconeogenesis**. This is achieved by two mechanisms: (i) insulin inhibits gluconeogenic enzymes (pyruvate carboxylase, phosphoenolpyruvate carboxykinase, and fructose-1, 6-diphosphatase), and (ii) insulin decreases hepatic uptake of gluconeogenic amino acids.

**In Adipose Tissue**
Insulin **stimulates entry of glucose** into the adipose tissue cells by **activating GLUT 4 and hexokinase activity**:
1. In fat cells, glucose is then **converted into α-glycerophosphate** (α-GP). The α-GP is used for the **esterification of fatty acids**.
2. It also promotes storage of fatty acids as triglycerides.

**In Skeletal Muscle**
Insulin **facilitates transport of glucose** into the muscle cells by **activating GLUT 4 and hexokinase activity**:
1. In muscle cell, **glucose is oxidized** by activation of the enzyme *pyruvate dehydrogenase*.
2. Glucose is also **stored as muscle glycogen**, which is stimulated by insulin.

**On Fat Metabolism**
Actions of insulin on fat metabolism are as profound as its influences on carbohydrate metabolism. Insulin **increases storage of fat** and inhibits mobilization and oxidation of fatty acids from fat depots. It decreases the level of free fatty acids and ketoacids in the plasma. Insulin is the **only anti-ketogenic hormone** in the body. The functions of insulin on fat metabolism are achieved by its actions on adipose tissue and liver.

**In Adipose Tissue**
Insulin **promotes storage of fat** in the adipose tissues in various ways:

1. **By inhibiting lipolysis**: It inhibits the activity of hormone sensitive lipase (HSL) in adipose tissues:
   - HSL causes breakdown of triglycerides into free fatty acids (FFA) and glycerol. Thus, insulin inhibits lipolysis and **decreases release of stored FFA**.
   - Decreased plasma FFA decreases the formation of ketoacids. Insulin also facilitates the use of ketoacids by peripheral tissues. Thus, insulin **profoundly decreases ketoacid level** in the plasma (see below).
2. **By promoting lipogenesis**: Lipids absorbed from intestine circulate in plasma in the form of triglycerides. Triglycerides cannot enter adipose tissue as such. They must be split by lipoprotein lipase, which is present in the vascular endothelium to FFA and glycerol. Then, FFA can enter adipose tissue and form TG there:
   - Insulin **promotes the enzyme lipoprotein lipase**, therefore makes FFA available from blood stream for formation of triglyceride in the adipose tissue cell (Fig. 60.10).
   - FFA is immediately **esterified to α-glycerophosphate** in adipose tissue, which is also induced by insulin.

**In Liver**
Insulin is **anti-ketogenic and lipogenic** in liver:
1. The anti-ketogenic function of insulin is achieved by **its stimulation of malonyl-CoA formation**. Normally, acetyl-CoA is converted to malonyl-CoA by the enzyme *acetyl-CoA carboxylase*. Insulin stimulates the activity of acetyl-CoA carboxylase and thus increases malonyl-CoA formation. Malonyl-CoA inhibits the enzyme *carbamoyl transferase* (CAT). CAT transfers FFA from cytoplasm into mitochondria for oxidation and then conversion into ketoacids. Thus, insulin by inhibiting CAT through malonyl-CoA prevents ketoacid formation (Fig. 60.11).
Chapter 60: Endocrine Pancreas

2. Fatty acid is also synthesized from glucose by insulin. Insulin achieves this by three mechanisms:
   i. The rate-limiting step in fatty acids synthesis is the conversion of acetyl-CoA to malonyl-CoA by the action of acetyl-CoA carboxylase, which is activated by insulin. Malonyl-CoA is used as substrate for FFA synthesis.
   ii. Insulin also induces fatty acids synthase, the final step in fatty acid synthesis.
   iii. Insulin activates the HMP shunt by activating the enzyme glucose-6-phosphate dehydrogenase. HMP shunt increases the supply of reduced triphosphopyridine nucleotide, which is required for fatty acid synthesis. Thus, from circulation, FFA is shunted away from oxidation and ketogenesis to be stored in the liver.

3. Insulin facilitates synthesis of cholesterol in the liver from acetyl-CoA by activating the enzyme HMG-CoA reductase, the rate-limiting step in the process.

On Protein Metabolism
Insulin is an anabolic hormone. It facilitates protein synthesis in the muscles and liver by following mechanisms:
1. It facilitates amino acid entry into the muscle cells. Therefore, it decreases plasma amino acid concentration. Thus, supply of amino acids for gluconeogenesis is also decreased.
2. It promotes protein synthesis in ribosomes. This is achieved by induction of gene transcription for various proteins by insulin (Fig. 60.12).
3. Insulin also decreases degradation of RNA.
4. Insulin inhibits proteolysis by decreasing lysosomal activity. Thus, it decreases release of amino acid from muscle and inhibits their oxidation.

On Plasma K+ Concentration
Insulin facilitates the rapid entry of K+ into the cell by stimulating Na+-K+ ATPase activity in the membrane. Thus, it decreases plasma K+ level:
1. Insulin is considered as a physiological regulator of plasma K+ concentration.
2. Infusion of insulin and glucose markedly decreases plasma $K^+$ level; and therefore is very useful in the management of acute renal failure (Clinical Box 60.2).

3. This is the reason why diabetic patients receiving insulin sometimes develop hypokalemia.

**Clinical Box 60.2**

Insulin is given with glucose in the treatment of hyperkalemia: Hyperkalemia is a feature of acute renal failure (ARF) and it is dangerous if remains untreated for a longer time. Insulin for its rapid and profound hypokalemic effect may be prescribed in the treatment of hyperkalemia as seen in acute renal failure, for prompt relief. Glucose is administered simultaneously, as insulin induces hypoglycemia.

**Other Actions of Insulin**

1. Insulin increases entry of phosphate and magnesium into the cell.
2. It also increases reabsorption of $K^+$, $Na^+$, and phosphate from the kidney.
3. Insulin decreases food intake. This action is partly mediated by its inhibitory effect on neuropeptide Y release from hypothalamus.
4. Chronic insulin excess increases body weight and adipose tissue mass. The leptin level in plasma increases that promotes satiety (decreases food intake).
5. Growth promoting actions: Insulin stimulates synthesis of macromolecules in cartilage and bone that promotes their growth. Insulin stimulates transcription of genes for growth factors such as IGF-I and II. Thus, insulin facilitates growth of the individual, in addition to its stimulation of protein synthesis. Therefore, deficiency of insulin in childhood (as in diabetic children) decreases their height, growth, and maturation.

In summary, insulin by acting on liver, adipose tissue and muscle increases glucose uptake and its storage, decreases lipolysis, promotes lipogenesis and stimulates protein synthesis (Flowchart 60.2).

**Applied Physiology**

**Insulin Deficiency (Diabetes Mellitus)**

Deficiency of insulin results in diabetes mellitus (DM). Diabetes mellitus is the most common endocrine disorder in both developing and developed worlds. Recently, the incidence of DM in India is increasing like an epidemic. Every one in three in urban and every one in five in rural population are found to have latent (glucose intolerance) or frank DM. Change of lifestyle, easy access to food (increased calorie intake), junk foods, sedentary life, environmental factors and stressful life are among the causes for such a spurt in diabetes in India.

Insulin only matters: Though there are few more chemicals (insulin like substances) in the body having insulin activity, they are not adequate to fulfill metabolic actions of insulin in states of insulin deficiency. These substances are proinsulin and somatomedins (IGF I and IGF II). These chemicals have only about 10% of insulin activity. Therefore, insulin deficiency leads to DM.

Type of DM: Etiologically diabetes has been traditionally classified into two:
1. Type I DM or insulin-dependent DM (IDDM) as it is associated with profound insulin deficiency and requires insulin replacement therapy.
2. Type II DM or non-insulin-dependent DM (NIDDM) as it is associated with normal insulin level in plasma and patient is usually treated without insulin replacement therapy.

However, recently it has been observed that more than 25% of type 2 DM ultimately develop insulin deficiency requiring insulin replacement therapy. Therefore, the classification of IDDM and NIDDM has become obsolete. Etiological classification of diabetes is depicted in Table 60.3.

Major Types of DM

Diabetes is primarily classified into two types: type-1 and type-2.

Type-1 Diabetes Mellitus
Type 1 DM is characterized by insulin deficiency, which is usually caused by selective autoimmune destruction of β-cells of pancreas. Therefore, the disease has traditionally been called insulin dependant diabetes mellitus (IDDM):
1. The disease starts with insulitis. Many patients demonstrate antibodies against β-cell surface antigens.
2. If one of the twins develops the disease the other twin has more chance of developing the disease than people in the general population (the concordance rate is < 50%).
3. The disease usually starts early in childhood, and ketoacidosis is common (Table 60.4).
4. The disease is treated by insulin replacement.
5. Sometimes it occurs due to mutation of proinsulin gene that decreases insulin synthesis.

Type-2 Diabetes Mellitus
Type 2 DM is characterized by impaired ability of the target cells to respond to insulin. This is usually caused by insulin receptor resistance. The insulin secretion may be normal or even more. Therefore, the disease has traditionally been called non-insulin dependant diabetes mellitus (NIDDM):
1. The chance of identical twin developing the disease (concordance rate) is 100%.
2. The disease usually starts late, in third or fourth decade of life.
3. The patients are usually overweight and sedentary in their habit.
4. Feeding habit and environment also contribute.
5. Chronic stress is usually associated with it.
6. Usual complication is hyperosmolal coma.
7. Oral antidiabetic drugs are usually preferred for treatment. However, insulin may also be prescribed.
Mechanism of insulin resistance: The exact mechanism of insulin resistance in type II DM is not known. However, insulin resistance has been highly correlated with body weight gain and few other factors. The following factors contribute to insulin resistance:

1. **Obesity:** In obesity, insulin fails to transport glucose into the tissues. Obesity eventually leads to hyperinsulinemia, hyperlipidemia and accelerated atherosclerosis that are part of metabolic syndrome (Clinical Box 60.3). These are combinely called as metabolic syndrome of obesity. With reduction in body weight, insulin resistance and dyslipidemia decrease.

2. **Adipokines:** The chemical signals originating from adipose tissue are recently proposed to be contributing factors for insulin resistance. Fat cells secrete a group of hormones called adipokines that influence insulin resistance. The known adipokines are:
   - Leptin
   - Adiponectin
   - Resistin
   - Tumor necrosis factor (TNFα) Usually, leptin and adiponectin decrease, and resistin and TNFα increase insulin resistance. Resistin and TNFα are increased significantly in NIDDM.

3. **Decreased second messengers:** Knockout of intracellular second messengers that are usually formed following autophosphorylation of tyrosine kinase has been recently reported to be the major factor in insulin resistance.

4. **Decreased GLUT:** Knock out of glucose transporters in skeletal muscles and adipose tissue has been suggested as a contributing factors.

5. **Free fatty acids:** Increased FFA contributes to insulin resistance.

Secondary Diabetes Mellitus

Diabetes also occurs due to the diseases of pancreas like pancreatitis, or following pancreatectomy. Diabetes can also occur in Cushing’s syndrome (cortisol increases plasma glucose) and acromegaly (growth hormone increases plasma glucose). These forms of diabetes are included under the category of secondary diabetes mellitus. This category constitutes about 5% of the total diabetes.

Maturity Onset Diabetes of the Young (MODY)

MODY constitutes about 5% of all cases of diabetes. This is a form of Type II (maturity-onset) DM in younger individuals:

1. Six types of MODY have recently been described, MODY 1 to MODY 6. Commonest among them is MODY 3 that accounts for 20–75% of all MODYs.
2. It occurs due to mutation of HNF1-α gene (gene for hepatic nuclear factor 1 alpha).
3. Patients with MODY 3 are mostly in their adolescence, diabetic complications are frequent, but they have a greater hypoglycemic response to sulphonylureas than the patients with type II DM.
4. MODY 2 is the next common (10–65%) group that occurs due to mutation of glukokinase gene. They present with mild hyperglycemia from birth, but they are stable and managed by diet alone. Other forms of MODYs are rare.

Gestational DM

This refers to the hyperglycemia occurring for the first time during pregnancy. 80% of women with gestational diabetes develop diabetes permanently.

Features of DM

Diabetes mellitus is characterized by polyphagia, polyuria, polydipsia, weight loss in spite of increased food intake,
hyperglycemia, and glycosuria. If not treated, the disease leads to ketosis, acidosis, and coma. In chronic cases, there may be diabetic retinopathy, neuropathy and nephropathy.

**Polyphagia**

Glucose entry into cells of brain except in ventromedial hypothalamus (VMH) is independent of insulin. Thus, VMH depends on insulin for its glucose uptake:

1. VMH is the *satiety center* that normally inhibits the lateral hypothalamus (LH), the *feeding center*.
2. As VMH depends on insulin for glucose uptake and utilization, *insulin deficiency in diabetes decreases the activity of VMH*.
3. Decreased VMH activity removes its inhibitory effect on LH (Fig. 60.13).
4. Therefore, LH activity increases due to *disinhibition* (abolition of inhibition from VMH).
5. **Facilitation of feeding center** (increased LH activity) increases feeding (polyphagia).

**Polyuria**

In diabetes, when plasma glucose concentration increases above renal threshold (above 180 mg%), glucose appears in urine. Filtration of more glucose increases its tubular load. Increased concentration of glucose in the tubular fluid causes *osmotic diuresis* that result in polyuria.

**Polydipsia**

In diabetes, because of polyuria water is lost in excess from the body. This decreases plasma and ECF volumes. *Dehydration stimulates thirst center* that causes polydipsia.

**Weight Loss**

In diabetes, food intake is more due to stimulation of feeding center. However, in spite of more food intake, *glucose is not utilized by the cells* due to deficiency of insulin. Insulin is essential for entry and utilization of glucose in the tissue. Insulin also facilitates growth. Therefore, insulin deficiency causes weight loss and growth retardation.

**Hyperglycemia and Glycosuria**

Insulin is the only hormone that decreases plasma glucose concentration. Therefore, deficiency of insulin results in hyperglycemia. When plasma glucose concentration exceeds renal threshold (180 mg%) glucose appears in urine (glycosuria).

**Ketosis**

Insulin prevents lipolysis, and therefore, decreases release of free fatty acids into the circulation. Insulin also facilitates utilization of ketone bodies (acetoacetate, acetone, and β-hydroxybutyrate) by the tissue. Therefore, ketosis occurs in insulin deficiency diabetes (IDDM). Presence of *excess acetyl-CoA* also facilitates conversion of aceto-acetyl-CoA to acetoacetate in the liver.

**Acidosis**

The *hydrogen ions liberated from ketone bodies* (acetoacetate and β-hydroxybutyrate) are usually buffered:

1. When ketosis becomes severe, the *buffering capacity decreases*. This causes plasma acidic.
2. Decreased pH of plasma stimulates respiration (*Kussmaul breathing*).
3. Urine also becomes highly acidic.
4. Normally, insulin increases Na+, K+ and phosphate reabsorption from kidney. Therefore, in diabetes, there is *loss of electrolyte and water*.
5. This causes dehydration, hypovolemia, and hypotension.
6. Diabetic acidosis is a *medical emergency* that requires immediate and appropriate replacement of electrolyte and fluid.

**Coma**

Coma in diabetes is of two types: *Acidotic coma* (due to acidosis) and *hyperosmolar coma* (due to hyperosmolality of plasma):

1. In acidosis, loss of water and electrolyte causes dehydration that results in coma (Flowchart 60.3). Accumulation of lactate (lactic acidosis) also causes coma.
2. *Increased glucose concentration* in plasma to a very high level increases its osmolality to the extent that it causes dehydration of brain cells that results in coma without affecting pH.

**Diagnosis**

Diagnosis of diabetes is done by demonstrating persistent hyperglycemia and glycosuria. Estimation of fasting and post-prandial blood glucose is performed to demonstrate hyperglycemia, and estimation of glucose in urine is carried out to demonstrate glycosuria. This is done by GTT, estimation of fasting blood glucose (FBG), and estimation of glycated hemoglobin (HbA1c).

**GTT:** In the past, glucose tolerance test was usually performed for the diagnosis of diabetes:

1. The *oral GTT* was preferred to intravenous GTT. The **GTT curve in diabetes** typically exhibits persistent rise in blood glucose above the normal value (Fig. 60.14).
2. Abnormal GTT also occurs in few other conditions like renal disease, intestinal problems, etc.

**FBG:** Recently, estimation of fasting blood glucose (FBG) has been recommended to be the main criterion to diagnose DM. FBS more than 126 mg% in more than
two occasions confirms DM. The blood glucose levels are classified into 3 types (Table 60.5).

**HbA1c:** This is the **glycated hemoglobin.** HbA1c indicates the state of **persistent hyperglycemia** at least more than three months. The normal range is 4 to 5.6%. The values between 5.7 and 6.4% indicate prediabetes, and 6.5% or above indicates diabetes.

**Treatment**

Diabetes is usually treated by insulin and oral hypoglycemic agents. However, change in life style improves the condition to a greater extent as recently diabetes has been found to be closely associated with chronic stress.

**Insulin Therapy**

Insulin replacement is the cornerstone of treatment of type 1 DM. The maximum decline in plasma glucose occurs following 30 minutes after IV injection of crystalline insulin. Insulin is also injected subcutaneously, but decrease in plasma glucose concentration occurs in 2–3 hours.

Different types of insulin preparations are commercially available. Generally, **insulin preparations** are divided into three categories depending on their duration of action:

1. Rapid acting insulin,
2. Intermediate acting insulin, and
3. Long acting insulin.

**Pork insulin** differs from human insulin only by one amino acid and therefore, has low antigenicity. Therefore, pork insulin is preferred to beef and other insulins. However, **human insulin** is produced nowadays from bacteria by recombinant DNA technology.

**Oral Hypoglycemic Agents**

These are usually used for the treatment of type II diabetes mellitus. The usually administered drugs are:

1. **Sulphonylurea derivatives,** like tolazamide, glipizide, glyburide, etc. These drugs are usually prescribed for
the treatment of type-2 (NIDDM) diabetes. They act by binding to the ATP-inhibited K⁺ channels in the membrane of B cells of pancreas. This increases Ca²⁺ influx and increases insulin secretion.

2. Other oral hypoglycemic agents are biguanides (phenformin and metformin). Metformin acts mainly by decreasing gluconeogenesis; therefore, it decreases hepatic glucose output.

3. Other group of drugs like thiazolidine-diones (troglitazone is an example of this group) are also used. They increase insulin mediated peripheral glucose disposal. Hence, they decrease insulin resistance (used in NIDDM). Troglitazone also binds with peroxisomes proliferator-activated receptor γ (PPAR γ) in the nucleus of the cell. It activates PPAR γ, which induces nuclear transcription that in turn regulate metabolic functions of the cell.

**Change in Lifestyle**

In addition to drugs, it is important to assure lifestyle modification and proper calorie intake in the long-term management of DM:

1. **Calorie intake**: Food intake should be adjusted to ensure appropriate nutritional requirements. Excess intake should be avoided. Diet should have less carbohydrate and fat, more fibers and adequate proteins and vitamins.

2. **Regular exercise**: Morning walk and freehand exercises improve insulin release and decreases insulin resistance.

3. **Relaxation of body and mind**: Healthy body and mind without stress will not only cure diabetes, but also prevent other diseases.

4. **Practice of yoga**: Yoga is very helpful in reducing the intensity of diabetes, and reducing the complications.

**Complications**

Improperly treated or untreated chronic diabetes results in various complications. The disease affects small and larger vessels:

1. The microangiopathy causes retinal edema and scarring, which is often associated with hard exudates in retina, the condition known as diabetic retinopathy, which also occurs due to neovascularization of retina, especially in the advanced stages (Fig. 60.15).

2. The microangiopathy in kidney is known as diabetic nephropathy.

3. The macrovascular complications are primarily due to increased atherosclerosis. Atherosclerosis is accelerated is due to increased plasma LDL. This increases the incidence of heart attack (myocardial infarction) and stroke.

4. Autonomic nervous system and peripheral nerves are also involved in the disease process. This results in autonomic neuropathy (diabetic neuropathy).

5. Hyperglycemia and neuropathy decrease the resistance to infection. This results in chronic ulcer and gangrene formation especially in the foot, called as diabetic foot.

**Insulin Excess**

Insulin excess occurs in insulin secreting tumor of pancreas (insulinoma). This causes hypoglycemia:

1. Chronic hypoglycemia causes incoordination of movement and slurring of speech. This is usually misdiagnosed as drunkenness. It is typically most common in the morning, as toward the early morning blood glucose concentration decreases and hepatic glycogen store is depleted.

2. Hypoglycemia also occurs in excess administration of insulin in the treatment of diabetes. But in this condition hypoglycemia is acute and manifest in the form of sweating, palpitation, anxiety, and other autonomic functions.

**OTHER PANCREATIC HORMONES**

**Glucagon**

Glucagon has opposite metabolic action to that of insulin. It is a prodiabetogenic and ketogenic hormone.
Source and Structure
Glucagon is secreted from α-cells of pancreas which constitutes about 20–25% of the islet cell mass. Glucagon is also secreted in the intestine (enteroglucagon) as local hormone and found in some parts of the brain as neurotransmitter. It is a polypeptide hormone containing 29 amino acids. The molecular weight is 3,485.

Synthesis
Like other peptide hormones, it is synthesized as preproglucagon that has 179 amino acids. Preproglucagon is found in α-cells of pancreas, L cells in terminal part of intestine and in the brain. Preproglucagon molecule in α-cells contains glucagon, major proglucagon fragment (MPGF) and glicentin related polypeptide (GRPP), whereas preproglucagon molecule in L-cells of intestine contains glicentin, glucagon like polypeptides (GLP 1 and 2), oxyntomodulin and MPGF. Accordingly, preproglucagon molecule forms different hormones in α-cells and L cells. In α-cells, it forms proglucagon that finally forms glucagon.

Both glucose and insulin inhibit glucagon synthesis by suppressing transcription of preproglucagon gene.

Functions of products of preproglucagon molecule are as follows:
1. Glicentin has some glucagon activity.
2. GLP-1 and GLP-2 are found in the brain and intestine. GLP1 stimulates insulin secretion and facilitates glucose utilization. GLP 1 is a neurotransmitter in nerve terminals projecting from NTS in the medulla to the dorsomedial hypothalamus.
3. GLP 2 inhibits food intake.
4. Oxyntomodulin inhibits HCl secretion from stomach.
5. Function of GRPP is not clearly known.

Secretion
Glucagon secretion is regulated by following factors:
Factors that increase secretion: Amino acids (especially gluconeogenic amino acids), cortisol, CCK, gastrin, stress, exercise, infection, β receptor agonist and theophylline.
Factors that decrease secretion: Glucose, somatostatin, insulin, secretin, ketone bodies, FFA and α receptor agonist.

Metabolism and Mechanism of Action
It is mainly degraded in the liver. It circulates freely in blood. Its half-life in circulation is about 5–10 minutes. Glucagon acts by increasing cyclic AMP in the cell. It also increases IP₃ in the cell.

Physiological Actions
Physiological actions of glucagon are almost opposite to that of insulin. It facilitates mobilization of nutrients by decreasing their storage. It especially facilitates hepatic glucose output and ketogenesis.

On Carbohydrate Metabolism
Glucagon increases blood glucose by following mechanisms:
1. Stimulates glycogenolysis: It causes immediate and profound glycogenolysis in the liver by activating glycogen phosphorylase. This causes release of glucose 6-phosphate:
   - Glucagon increases cAMP in the cell. cAMP stimulates protein kinase A that in turn activates phosphorylase and other enzymes.
   - Activated protein kinase A also inhibits conversion of fructose-6-phosphate to fructose 1,6-biphosphate, which helps in increasing glucose 6-phosphate in the cell.
   - Accumulated glucose 6-phosphate is converted to glucose.
   - Thus, more glucose is released from liver. It does not cause glycogenolysis in muscle.
2. Gluconeogenesis: It also stimulates gluconeogenesis by activating gluconeogenic enzymes, especially phosphoenolpyruvate carboxykinase. It also promotes hepatic proteolysis and supplies more amino acids for gluconeogenesis.
3. Inhibition of glycogenesis: Glucagon inhibits glycogen synthase. Therefore, conversion of glucose to glycogen is inhibited.

All these actions result in increased output of glucose from the liver. Normally, the metabolic actions of glucagon on muscle and adipose tissue are not significant.

On Fat Metabolism
Glucagon promotes lipolysis and ketogenesis in liver:
1. Lipolysis: In hepatic cells, glucagon facilitates lipolysis. Thus, it increases release of FFA from liver. However, the fat store of liver is not more unlike in adipose tissue. Therefore, the degree of lipolysis is moderate.
2. Ketogenesis: Glucagon increases ketone body formation in liver cells by decreasing the level of malonyl-CoA. Increased FFA also promotes ketogenesis. Glucagon facilitates entry of FFA into mitochondria for their β-oxidation and production of ketone bodies.

On Calorigenesis
Glucagon increases calorigenesis. Calorigenic action of glucagon is not due to increased blood glucose, rather to the hepatic deamination of amino acids.

On Heart
Glucagon in supraphysiological concentration increases myocardial contractility by increasing cyclic AMP level in myocardial cells. Therefore, glucagon is advocated for the treatment of heart disease.

On Other Hormones
Glucagon stimulates secretion of growth hormone, insulin, and pancreatic polypeptide.
Insulin-Glucagon Ratio

Insulin is glucopenic, glycogenic, anti-gluconeogenic, antilipolytic, and anti-ketotic (anti-diabetogenic and anti-ketogenic). Therefore, insulin is the hormone of energy storage. Glucagon is prodiabetogenic and proketogenic. Therefore, glucagon is the hormone of energy release. Because of their opposing effects, a balance should be maintained between the secretion of insulin and glucagons for maintaining normal metabolic functions. Therefore, insulin-glucagon molar ratio (I/G ratio) in plasma is more important than their individual concentration. Normally, the I/G ratio following a balance diet is approximately 3. Following overnight fasting, it decreases to 1, and after prolonged fasting the ratio may be as low as 0.4. Following glucose infusion, the ratio may rise up to 30.

Physiological Significance:
1. During starvation, the low I/G ratio favors glycogen break down and gluconeogenesis that increases nutrient supply. Conversely, during high-fed state, the ratio is high favoring deposition of nutrients in the form glycogen, protein and fat.
2. During neonatal period (immediately after birth), a low I/G ratio is critical for the survival of the neonate. In first few hours to days, the abrupt cessation of maternal fuel supply during which neonate does not receive required amount of fuel from its own GI tract, a low I/G ration maintains internal supply of nutrients.
3. In diabetes, inappropriate I/G ratio influences metabolic status. Secretion of glucagon is inappropriately elevated in insulin deficiency. The metabolic derangements are affected by this abnormal ratio.

Applied Physiology
Glucagon excess is produced by tumor of α-cells of pancreas. This is called glucagonoma. It causes hyperglycemia, ketosis and other metabolic derangements that mimic diabetes mellitus. In fact, insulin deficiency in diabetes is associated with glucagons excess. Glucagon deficiency occurs rarely.

Somatostatin

Source and Structure
Somatostatin is secreted from D cells of pancreas. It is also secreted in hypothalamus and gastrointestinal tract. Somatostatin is a peptide hormone. It has two forms. One contains 14 amino acids and the other 28 amino acids. The 14 amino acid somatostatin is mostly synthesized in pancreas and 28 amino acid peptide in GI tract.

Synthesis and Secretion
Like other pancreatic hormones it is synthesized as preprosomatostatin, which becomes prosomatostatin. Prosomatostatin is converted to somatostatin. Somatostatin secretion is stimulated by glucose, amino acids, free fatty acids, GI hormones, glucagon, vagal stimulation and sympathetic stimulation via β receptors.

Functions
1. Somatostatin profoundly inhibits the secretion of insulin and glucagon from pancreas, by neurocrine and paracrine fashions.
2. It decreases the rate of assimilation of all nutrients from GI tract.
3. It inhibits gastric, duodenal and gallbladder motility.
4. It inhibits HCl and pepsin secretions from stomach, and intestinal secretions.
5. It inhibits secretion of secretin and gastrin.
6. It inhibits pancreatic exocrine secretion.
7. It inhibits absorption of glucose, and triglycerides from the mucosal epithelial cells of intestine.
8. It regulates feedback control of gastric emptying (entry of food from stomach into the intestine). When food enters intestine, somatostatin inhibits gastric emptying. Therefore, it prevents rapid overload of intestine by gastric content.

Clinical Significance
Treatment of Diarrhea: Somatostatin preparations are used in medical practice for the treatment of diarrhea as somatostatin inhibits GI motility.

Somatostatinoma: In tumor of D cells of pancreas (somatostatinoma), excess somatostatin secretion decreases nutrient absorption from GI tract. Therefore, excess of undigested food appear in the stool. This causes weight loss. Moderate hyperglycemia is observed due to low insulin level in the plasma. These patients also develop dyspepsia due to decreased gastric emptying and decreased gastric secretion. They also develop gallstone, which is precipitated by decreased gallbladder contraction as somatostatin inhibits CCK secretion.

Pancreatic Polypeptide

Source and Structure
Pancreatic polypeptide is secreted from F cells of pancreas. It is a polypeptide containing 36 amino acids. It has a characteristic C terminal tyrosine-amide residue. Structurally, it is similar to the neuropeptide Y (NPY) secreted from hypothalamus and polypeptide YY, a GI hormone. However, in functions, it is not very similar to them.

Synthesis and Secretion
It is synthesized like other peptide hormones. It is secreted primarily in response to food intake. When food is ingested and food passes through the GI tract, the GI hormones and vagal stimulation stimulate the secretion of pancreatic...
polypeptide. It is also **stimulated by hypoglycemia and inhibited by hyperglycemia**. Its secretion is also inhibited by **somatostatin**. As pancreatic polypeptide secretion is under the influence of cholinergic control, its secretion decreases after atropine administration. Its secretion is stimulated by protein rich food, fasting and exercise.

**Functions**
1. **It inhibits exocrine pancreatic secretion**. This is partly due to its inhibition of uptake of precursor amino acids by the acinar cells.

**Clinical Significance**
1. Increased secretion of pancreatic polypeptide is invariably **associated with islet cell tumors**. Therefore, its increased level in plasma serves a **tumor marker** for the tumors of endocrine pancreas.
2. Failure of pancreatic polypeptide concentration in plasma to rise in response to hypoglycemia suggests loss of cholinergic innervation of pancreatic islets.

### CHAPTER SUMMARY

#### Key Concepts
1. Insulin has prominent effects on fat metabolism, as it has effects on carbohydrate metabolism. Therefore, in diabetes, in addition to hyperglycemia, there are hyperlipidemia and ketonemia. Diabetic complications are considerably linked to hyperlipidemia.
2. HbA1c reflects the chronicity of hyperglycemia. Therefore, HbA1c should be assessed in all diabetic patients to assess their level of hyperglycemia for last few months, rather than to check FBG or PPBG, which indicates the current blood glucose level.
3. For assessing insulin sensitivity, C peptide estimation should be done, which is a more reliable marker of β cell activity.

#### Important to Know (Must Read)
1. In examination, 'Describe the functions of insulin' usually comes as a **Long Question**.
2. Mechanism of insulin secretion in response to plasma glucose, Mechanism of action of Insulin, Physiological actions of Insulin on fat metabolism, Physiological actions of Insulin on carbohydrate metabolism, Glucose transporters (GLUT), Explain the physiological basis of features of DM, Differences between type I and type II DM, Glucagon, Effect of life style changes including exercise on DM, Insulin-glucagon ratio (I/G ratio), Somatostatin, Pancreatic polypeptide are usual **Short Questions** in exam.
3. In **Viva**, examiner may ask... List the hormones secreted from pancreas and the cell type from which they are secreted, Physiological actions of insulin especially on carbohydrate, fat and protein metabolism, List the factors that increase or decrease insulin secretion, What are the types of GLUTs and what are their functions, What is the mechanism of insertion of GLUT into cell membrane by insulin in insulin- sensitive cells, How is insulin secreted from beta cells in response to glucose, What is the relationship between increase in plasma glucose and rate of insulin secretion, What is first phase response and what is second phase response, Why the secretion of insulin is greater in response to orally administered glucose compared to intravenously administered glucose, Why is insulin given with glucose in the treatment of hyperkalemia, What is the effect of insulin on growth, Classify diabetes mellitus based on etiology, What are IDDM and NIDDM? List the differences between type I and type II DM, What is metabolic syndrome and what are its components, What is secondary DM, What is gestational DM, What is Maturity onset Diabetes of the Young (MODY), Explain the physiological basis of polyphagia in DM, Explain the physiological basis of polydipsia in DM, Explain the physiological basis of polyuria in DM, Explain the physiological basis of hyperglycemia and glycosuria in DM, Explain the physiological basis of weight loss in DM, Explain the physiological basis of ketosis, acidosis and coma in DM, What is the normal blood glucose level, in fasting and post prandial, What do you mean by impaired fasting glucose or impaired glucose tolerance, What is the fasting and post prandial blood glucos level in DM, List some oral hypoglycemic agents and give their mechanism of action, What are the types of insulin preparation used in the treatment of DM, What is the plasma glucose response to oral glucose tolerance test (OGTT), Explain how does regular exercise prevent diabetes, What is the effect of healthy life style on DM, What are the complications of DM, What are the physiological actions of glucagon, What is insulin-glucagon ratio, What are the physiological significances of I/G ratio, What are the functions of somatostatin, What are the functions of pancreatic polypeptide, What is the structure of insulin, How insulin is synthesized, What is C-peptide, What is the importance/ functions of C-peptide, List the substances having insulin like activity, What is the structure of insulin receptor, What is the physiological and clinical significance of Somatostatin, What is the physiological and clinical significance of pancreatic polypeptide.
Learning Objectives

On completion of study of this chapter, the student MUST be able to:
1. Learn the basics of calcium and phosphate metabolism.
2. Understand the importance of learning calcium and phosphate metabolism to learn bone physiology.
3. List the functions of calcium and phosphate.
4. Appreciate various aspects of bone physiology.
5. Understand the mechanism of bone formation and bone resorption.
6. Describe the hormonal regulation of calcium metabolism.
7. Learn the physiological basis of osteoporosis and osteomalacia.

The student MAY also be able to:
1. Describe the role of calcium and phosphate in bone physiology.
2. Describe the mechanism and regulation of bone formation and resorption.

The major hormones involved in the regulation of plasma calcium and phosphorous metabolisms are parathormone (PTH) secreted from parathyroid gland, calcitonin secreted from parafollicular cells of thyroid gland, and vitamin D. Other hormones like glucocorticoids, growth factors, insulin, etc. also influence calcium metabolism. These hormones control calcium metabolism by primarily acting on three structures: GI tract, kidney, and bones. While regulating calcium concentration, many of these factors also influence phosphate level in the plasma. A balance between calcium and phosphate is always maintained in our body and abnormalities in this balance result in severe dysfunctions. To understand the regulation of plasma calcium, it is important to understand the basics of calcium and phosphate metabolisms and also the physiology of bone dynamics.

Calcium and Phosphate Metabolism

Calcium Metabolism

The normal plasma calcium concentration is 9–11 mg% (average 10 mg%). This is among the most tightly regulated physiological parameters of the body. The regulation of plasma calcium concentration within a narrow range of 1–2% indicates the importance of this ion in controlling critical body functions.

Functions of Calcium

Calcium ions are involved in many key physiological processes of the body. These are:
1. Genesis and maintenance of action potentials, especially in cardiac and smooth muscles.
2. Genesis of pacemaker potential in various pacemaking tissues.
3. Excitation-contraction coupling during muscle contractions.
4. Excitability of nerve and muscle: Calcium influences sodium permeability; therefore, influences the ease with which action potentials are triggered. Especially in nerves, low calcium can cause generation of spontaneous action potentials. This causes the characteristic muscle spasm in hypocalcemic tetany.
5. Cell division.
7. Secretion of endocrine and exocrine glands (calcium-mediated exocytosis causes release of hormones and enzymes from the gland cells).
8. **Neurotransmitter release** from nerve terminals.
9. **Blood coagulation**: Calcium is coagulation factor IV and is highly essential for clotting of blood. Many anticoagulants chelate calcium to prevent clotting.
10. Modulation of various enzyme activities (enzymes use calcium as cofactor).
11. Calcium acts as a second or third messenger in various intracellular signaling pathways for hormone actions.
12. GI motility and motility of many other structures.

Therefore, it is essential to maintain calcium concentration within its normal range. A minor deviation in calcium level results in alteration in many physiological functions of the body.

**Distribution of Calcium in the Body**

In the cell, calcium is stored in mitochondria and endoplasmic reticulum. A transient alteration in plasma calcium is balanced by entry or extrusion of calcium from the intracellular or extracellular reservoirs. The total intracellular free calcium is about 0.2 mg, whereas about 9 g is present in the bound form or in the storage sites such as in mitochondria and endoplasmic reticulum. This intracellular calcium provides an immediate source of calcium for cell functions.

</tr>
</tbody>
</table>

**Metabolism**

Daily dietary intake of calcium ranges from 200 mg to 2 g. In an adult, the **recommended daily intake** is about 800 mg.
1. Calcium absorption from the intestine is inversely proportional to its intake. This prevents calcium overload when intake is high or maintains calcium concentration even with low intake.
2. With a daily intake of 1 g of calcium, generally 30% (300 mg) of it is absorbed in the intestine and about 70% (700 mg) is excreted in the stool.
3. About 150 mg of calcium is secreted into the intestine, which makes a total of about 850 mg excreted daily in the stool.
4. About 150 mg is excreted in the urine.
5. Thus, about 1 g of calcium is excreted daily from the body to maintain the balance between input and output (Fig. 61.1).
6. Calcium absorption from the intestine is diminished with advancement of age, which contributes to the development of osteoporosis. Calcium absorbed from intestine enters the ECF pool of calcium which is about 1000 mg. This is in equilibrium with the rapidly exchangeable pool (4000 mg) of the body. From the rapidly exchangeable pool of plasma, 500 mg of calcium enters bones for normal bone remodeling and from bone about 500 mg of calcium extrudes back into the plasma.

Phosphate Metabolism

The normal plasma phosphate concentration is 2.5 to 4.5 mg%. Functions of Phosphorus

Phosphorus (usually as phosphate) is important as calcium for biological activities.
1. Phosphate is present in the ATP, creatine phosphate, various co-factors like NAD, NADP, and thiamine pyrophosphate.
2. It is an integral part of second messengers in the cells like cyclic AMP and inositol triphosphate.
3. It is also found in DNA and RNA.

4. It is required for phosphorylation of many intracellular proteins, for formation of phosphoproteins. Phosphoproteins mediate many intracellular metabolic activities.
5. Phosphate acts as covalent modifier of many enzymes.
6. It is a major constituent of the bone and teeth like that of calcium.
7. It serves as an important component of intracellular pH buffering system.

Like calcium metabolism, phosphate metabolism is also closely regulated in the body.

Distribution of Phosphate in the Body

Total body phosphate content is roughly half of the calcium content. Out of 600 g of total phosphate in the body, about 86% is present in the bones, 14% in intracellular fluid and 0.08% in extracellular fluid (Table 61.2). About 6% is present in the muscle and 8% in other cells.

Metabolism

The daily phosphate intake is about 1400 mg, of which 75% is absorbed from the intestine and 25% is excreted in the stool.
1. The phosphate pool in the ECF is about 700 mg, from where about 200 mg is exchanged with the bones for bone remodeling.
2. Normally, about 1000 mg is excreted in urine.
3. Regulation of renal excretion of phosphate mainly controls the concentration of plasma phosphate.
4. Renal (1 g) and fecal (0.4 g) excretion balances the daily intake with daily output of phosphate (Fig. 61.2).
5. Phosphate deficiency results in muscle weakness, cardiac and respiratory dysfunction, abnormal bone formation, and loss of red cell membrane integrity.

Fig. 61.2: Summary of phosphorus metabolism.
Magnesium: Magnesium is closely related with the calcium and phosphate metabolisms.
1. It is essential for neuromuscular transmission and it serves as cofactor for many enzymatic activities.
2. The normal plasma concentration of magnesium is 1.5–2.5 mg%.
3. About 35% of it is bound to protein.
4. There is about 25 g of magnesium in our body of which about 50% is present in the bones and rest 50% in the intracellular fluid.
5. The magnesium depletion causes neuromuscular dysfunction and ventricular arrhythmias.

Regulation of Calcium and Phosphate Homeostasis
Homeostasis of calcium and phosphate is influenced mainly by exchange of these ions between plasma and bone. Also, absorption of calcium and phosphate from intestine and kidney that determines their fecal and urinary excretion respectively greatly contributes to their homeostasis. In general, calcium is excreted more in the stool (850 mg/day) and less in urine (150 mg/day), whereas phosphate is excreted more in urine (1000 mg/day) and less in stool (400 mg/day).

Intestinal Control of Calcium and Phosphate
Absorption of calcium and phosphate from intestine significantly contributes to their plasma concentration.

Absorption of Calcium
About one third of ingested calcium is absorbed from GI tract and remaining two-third is excreted. The percentage absorption is more in growing children, pregnant women and nursing mother.
1. About 150 mg of calcium enters intestine in the form of various GI secretions, and from sloughing of mucosal cells. Intestinal absorption plays an important role in calcium homeostasis.
2. Calcium absorption occurs by active transport in duodenum and jejunum, and passive diffusion in ileum. Active transport is facilitated by 1,25-dihydroxycholecalciferol (metabolite of vitamin D), which increases the expression of calcium binding proteins in the intestinal epithelial cells increasing their capacity to transport more calcium.
3. Calcium is transported across the brush border of intestinal epithelial cells via TRPV6 (transient receptor potential vanilloid type 6) channels.
4. Calbindin sequesters the absorbed calcium, which is then delivered to the basolateral membrane of the epithelial cells and from there enters the blood stream via sodium-calcium exchanger or calcium-dependent ATPase.
5. However, some degree of intestinal calcium uptake persists in the absence of TRPV6 and calbindin. Cholecalciferol and calcitonin influence calcium absorption either directly or indirectly through vitamin D.

Absorption of Phosphate
In contrast to calcium, most of the ingested phosphorous (about 75–85%) is absorbed from intestine as inorganic phosphate (Pi).
1. Pi absorption occurs by a transporter called NaPi-IIb, which is related to the transporter in kidney.
2. Though absorption occurs by both active and passive processes, active transport is the primary mechanism of absorption.
3. However, the regulatory mechanism for phosphate absorption is not well developed. To some extent, it is coupled to calcium absorption.

Renal Control of Calcium and Phosphate
Reabsorption of calcium and phosphate from kidney contributes significantly to their plasma concentration.

Reabsorption of Calcium
About 60% of plasma calcium is filtered in the glomeruli and 40% is bound to plasma proteins.
1. Of the filtered calcium, 1–5% is excreted in urine and about 95% is reabsorbed back into the plasma. Therefore, the total urinary excretion is less.
2. Of the filtered load of calcium, about 65% is reabsorbed in proximal tubule, 25% in loop of Henle and 8% in distal tubule.
3. In proximal tubule, the transport process is active that involves two sodium-dependent Pi co-transporters such as NaPi-IIa and NaPi-IIc.
4. Parathyroid hormone (PTH) inhibits NaPi-IIa. PTH regulates plasma calcium by also acting on the distal tubule.

Reabsorption of Phosphate
Phosphate is mainly excreted in urine. Therefore, kidney plays important role in phosphate homeostasis.
1. Usually, 75–85% of filtered phosphate is reabsorbed.
2. The major site of reabsorption is proximal tubule, where about 70% of the filtered load of phosphate is reabsorbed.
3. Parathyroid hormone controls phosphate excretion by mainly inhibiting its reabsorption in the proximal tubule.

Bone Physiology
Bone is a compact living connective tissue, which is well vascularized. It plays a vital role in calcium and phosphate homeostasis in addition to its other important functions.
Chapter 61: Calcium and Phosphate Metabolism and Physiology of Bone

The major functions of bones are as follows:
1. They form the skeletal framework of the body, which is crucial for changing and maintaining various body postures.
2. By providing stable postural background, bones allow movements to occur.
3. They play important role in metabolism of various minerals, especially, contribute to calcium, phosphate and magnesium homeostasis.
4. Bones protect important structures and viscera in the thoracic and pelvic cavities and in the skull.
5. Bone (bone marrow) is the primary site of hemopoiesis. They produce and supply formed elements of blood.

**Composition of Bone**

Bone is simply a collagen framework in which inorganic minerals are deposited on an organic matrix.

**Inorganic Components**

Inorganic component consists of various minerals such as calcium, phosphate, carbonate, magnesium and sodium. Minerals constitute about 25% of the bone volume, but they comprise half the bone weight because of their high density.
1. Bone is the major reservoir of these minerals in the body.
2. About 99% of calcium, 86% of phosphate, 80% of carbonate and 50% of magnesium of their total body content are present in bones (Table 61.3).

**Organic Matrix**

Organic matrix of the bone is called osteoid.
1. It is formed mainly by the Type I Collagen, which forms 95% of the matrix.
2. The remaining 5% noncollagen part is called the ground substance, which is a mixture of various proteoglycans and high molecular weight compounds, consisting mainly of polysaccharides.

**Parts of Bone**

Long bones consist of epiphysis, the both ends, and diaphysis, the shaft which is separated from epiphyses by epiphyseal plates (Fig. 61.5).
1. The linear growth of the bones occurs at the end of long bones by replacement of cartilage at the epiphyseal plates.
2. Closure of epiphyseal plates occurs towards the end of puberty. This causes cessation of further increase in height of the individual.
3. However, width of the bone continues to increase due to addition of cells to the periosteum, the outer surface of the bone. The nutrients from ECF diffuse into the trabecular bone via canaliculi (see below). In compact bone, nutrients are supplied by Haversian canal that contains blood vessels.

**Remodeling of Bone**
Bone is continuously remodeled throughout the life, which is synchronized by bone formation and resorption (bone destruction).
1. During the growth period, bone formation exceeds bone resorption so that the bone mass increases.
2. During the adulthood, rate of formation and resorption is almost balanced so that the bone mass remains unchanged.
3. After the age of 40 to 50, bone resorption exceeds formation so that bone mass slowly decreases.

**Cell Types in Bone**
There are three types of cells in the bone: these are osteoblasts, osteoclasts, and osteocytes (Figs. 61.6A to C). Osteoblasts and osteocytes are called osteoprogenitor cells as they develop from primitive cells. Osteoclasts develop from the precursors such as monocytes and tissue macrophages.

**Osteoblasts and Osteocytes**
Osteoblasts are bone forming cells. They are modified fibroblasts.
1. Osteoblasts synthesize osteoid, the organic matrix of the bone. They have numerous endoplasmic reticulum and Golgi apparatus. They are present towards the periphery of the bone and their cytoplasmic processes connect osteocytes that are present deeper in the bone.
2. Osteoid produced by osteoblasts is secreted towards the interior of the bone. Slowly the osteoblasts are surrounded by osteoid and osteoid is mineralized.
3. Osteoblasts surrounded by mineralized osteoid gradually lose their ability to form bones and they become osteocytes.
4. The cytoplasmic connection between osteoblasts and osteocytes become canaliculi (Fig. 61.7).
5. The canaliculi are the anatomical link for transfer of nutrients, chemicals and waste products between the surface and interior of the bone.

**Osteoclasts**
Osteoclasts are cells of mononuclear phagocyte system in the bone. Therefore, they are large, multinucleated cells located towards the periphery of the bone.
Mechanism of Bone Formation

Chapter 61: Calcium and Phosphate Metabolism and Physiology of Bone

1. They cause bone resorption by secreting proteolytic enzymes into the surroundings.
2. The chemicals secreted by osteoclasts make the environment acidic that enhances the solubility of bone minerals and the enzymes secreted cause degradation of the organic matrix.

Mechanism of Bone Formation

Formation of bone is the function of osteoblasts (Figs. 61.8A to E).

1. Osteoblasts synthesize collagen and extrude it into the adjacent extracellular space (Fig. 61.8A). The collagen fibrils form the organic matrix of the bone, which is called as osteoid (Fig. 61.8B).
2. In the osteoid, calcium-phosphate is deposited which is called as mineralization of bone. Thereafter, to the organic matrix, hydroxides and bicarbonates are added to form the hydroxyapatite crystals (the complete mineralization). Osteoid converted into lamella of the bone (Fig. 61.8C).
3. The mineralized matrix slowly accumulates and surrounds the osteoblasts. As this process of mineralization of matrix continues, the osteoblasts decrease their synthetic activity and become osteocytes (Fig. 61.8D).
4. Osteoblastic activity is seen along the surface of the bones. Lamellae of the bones are formed with osteocytes remaining inside the lamellae (Fig. 61.8E).
5. Vitamin D is essential for bone mineralization. It profoundly influences the availability of calcium and phosphate to the bone matrix.
6. The canaliculi that connect osteocytes from bone interior to the surface transfer calcium from the interior to the exterior bone units and then from there to the ECF.
7. This process of transfer of calcium carried out by osteocytes is known as osteocytic osteolysis.
8. Normally, this process does not decrease the bone mass rather removes calcium from the recently formed bone crystals.

Role of Chondrocytes and Endochondral Ossification

Before epiphyseal closure, the leading edge of the epiphyseal plate contains chondrocytes.

1. The active chondrocytes synthesize cartilage that gradually embeds the chondrocytes.
2. The embedded chondrocytes die and are replaced by new chondrocytes and the formation of cartilage continues.
3. The cartilage is slowly calcified and osteoblasts migrate into it.
4. Osteoblasts secrete osteoid that ultimately mineralize and the new bone is formed.
5. Thus, the bone increases in length as the epiphyseal plate lays down new bone on the end of the shaft. This is called endochondral ossification (Fig. 61.9).
6. IGF I, insulin and thyroid hormones stimulate chondrocyte activity.
7. Within few years from the onset of puberty, the chondrocytes become unresponsive to hormonal stimuli and lose their activity. Finally the epiphyses unite with the shaft and this process is called 

**closure of epiphysis** (Clinical Box 61.1). This is also called ossification. This stops the linear growth of the bone.

Clinical Box 61.1

Epiphyseal closure determines age: The epiphyses of various bones close in an orderly fashion in sequence and the age at which they close is known. Therefore, the age of an individual especially in adolescents and young adults can be determined easily by taking x-rays of bones by determining whether the epiphysis is closed or still open.

**Bone Resorption**

This is process of destruction of the bone matrix. Therefore, resorption of bone decreases bone mass. It also removes calcium from the bone. But, it differs from osteocytic osteolysis in which the calcium is removed without bone destruction. Bone resorption is carried out by osteoclasts.

1. Osteoclasts contain many mitochondria and lysosomes.
2. The phosphatases, type 4-collagenase and lysosomal enzymes cause dissolution of bone matrix.
3. During the process of resorption, the calcium, phosphate, hydroxyproline, and hydroxylysine are released into ECF.
4. Therefore, the rate of excretion of these organic compounds, especially hydroxyproline indicates the rate of bone resorption.

**Phases of Bone Resorption**

Bone resorption occurs in two phases.

**First Phase**

In the first phase, H⁺ is secreted by osteoclasts. There are proton pumps (H⁺—dependent ATPases) in the endosomes present in the cytosol of the osteoclasts.

1. When osteoclasts are activated, proton pumps migrate to the cell surface and are inserted into the osteoclast membrane.
2. Secretion of H⁺ makes the environment acidic; pH decreases to about 4. The acidic pH dissolves the hydroxyapatite and favors action of acidic enzymes.

**Second Phase**

In the second phase, the acid protease enzyme secreted by osteoclasts destroys the collagen, the organic matrix.

1. The collagen breakdown products have pyridinoline structures. One such important product is hydroxyproline.
2. Therefore, hydroxyprolinuria is an index of bone resorption.

**Balance Between Bone Formation and Resorption**

Normally, balance is maintained between the bone resorption and formation within its bone modeling units so that bone mass is maintained within the normal range.

1. Possibly, the balance is due to release of chemicals (some paracrine signals) from the osteoblasts or osteoclasts. For example, when osteoclasts cause destruction of bone matrix, the chemicals released from the osteoclasts attract osteoblasts to the site.
2. Osteoblasts then form bone matrix and fill the resorption cavity.
3. The flux of calcium into and out of bone reflects the remodeling, i.e. the turnover and formation of bone tissue.

**Factors that Control Bone Formation and Resorption**

Factors that stimulate bone formation: Growth hormone, growth factors, insulin, estrogen, testosterone, vitamin D, PDGF, transforming growth factors (TGF-β) and calcitonin.

Factors that inhibit bone formation: Cortisol.

Factors that stimulate bone resorption: Parathormone, cortisol, thyroxine, prostaglandins, interleukin 1 and 6, and TNF.

Factors that inhibit resorption: Estrogen, androgen, calcitonin, γ interferon, and TGF-β.

**Osteoporosis**

Osteoporosis is decrease in bone mass and density. All human beings gain bone early in life. The peak of total bone mass is attained between 25–35 years of age.

1. Usually, after the age of 40, bone mass gradually decreases. This is called involutional osteoporosis.
2. In females, the process of bone resorption is facilitated at the time of menopause due to cessation of estrogen secretion (postmenopausal osteoporosis).
3. In fact, the rate of bone remodeling increases with age. However, with increased osteoclastic activity, bone matrix is lost and more cavities are formed, which is not refilled by the osteoblastic activity. Also, the mineralization decreases. This causes reduction in bone density and bone mass. The process is known as osteoporosis.

**Causes**

Osteoporosis is commonly seen in following conditions:
1. Hyperparathyroidism,
2. Hyperthyroidism,
3. Cushing’s syndrome
4. Ovarian diseases reducing estrogen secretion,
5. Cigarette smoking
6. Alcoholism reducing calcium absorption
7. Deficiency of vitamin C (vitamin C causes collagen synthesis)
8. Inadequate dietary calcium.

**Features**

Osteoporosis increases the susceptibility of bones to fractures, especially in elderly. Osteoporosis is more common in vertebra, hip bones and in distal forearms, because these bones have more trabecular component. As trabecular bones are metabolically more active, they are lost rapidly.

**Treatment**

The treatment is by administration of calcium or vitamin D tablets, or in worst case estrogen therapy.

**Osteopetrosis**

Defective increase in bone formation is called osteopetrosis.
1. The bone resorption is defective due to decreased osteoclastic activity. Therefore, osteoblastic activity is unopposed. This results in unusual increase in bone formation.
2. Bone density is increased and bones are deformed.
3. Neurologic deficits occur due to bones compressing on nerves and hematologic abnormalities occur due to decreased marrow cavity.

**CHAPTER SUMMARY**

**Key Concepts**

1. Calcium, phosphate and magnesium are essential for bone formation and mineralization.
2. Calcium absorption from the intestine is inversely proportional to its intake, which prevents calcium overload when intake is high or maintains calcium concentration in low calcium intake.
3. Osteoblasts are meant for bone formation ad osteoclasts are for bone resorption. A balance between the two cells is essential for maintenance of bone mass.

**Important to Know (Must Read)**

1. In examination, Long Questions may not be asked from this chapter.
2. Osteoporosis, Functions of calcium and calcium metabolism, Mechanism of bone formation and bone resorption, Regulation of calcium and phosphate homeostasis, & Osteoblasts and osteoclasts, may be asked as Short Questions in exam.
3. In Viva, examiner may ask… List the functions of calcium, List the functions of phosphorous, How calcium and phosphorous are distributed in the body, How ECF calcium pool is exchanged with GIT, bone, kidneys and tissues, How ECF calcium pool is exchanged with GIT, bone, kidneys and tissues, How ECF phosphorous pool is exchanged with GIT, bone, kidneys and tissues, What are the types of bones, What is the composition of bone, What is the structure of bone, Functions of osteoblasts and osteocytes, Mechanism of bone formation, Mechanism of bone resorption, What are the factors that control bone formation and bone resorption, What are the cells in the bone, What are the functions of osteoblasts and osteoclasts, What are the stages of bone formation, Name the hormones that influence bone functions, Cause, features and treatment of osteoporosis, What is osteopetrosis and what are its symptoms, How epiphyseal closure determines age.
Parathyroid Gland, Calcitonin and Vitamin D

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:

1. Name the cell types in parathyroid gland and give their functions.
2. Describe the mechanism of action and functions of parathyroid hormone.
3. Describe the mechanism of action and functions of calcitonin.
4. Describe functions of vitamin D.
5. Understand the physiological basis of dysfunctions of PTH.

The student **MAY** also be able to:

1. Explain the role of calcitonin and vitamin D in calcium metabolism.
2. Describe the hormonal regulation of calcium metabolism.

Parathormone (PTH) secreted from parathyroid gland, calcitonin secreted from parafollicular cells of thyroid gland, and cholecalciferol (vitamin D₃) are the major hormones involved in the regulation of plasma calcium and phosphorous metabolisms and bone physiology. Therefore, usually functions of these three hormones are discussed together.

**Parathyroid Gland**

Parathyroid gland secretes hormone called **parathyroid hormone** or **parathormone** (PTH). PTH is the major regulator of calcium and phosphate metabolism. PTH **increases plasma calcium and decreases plasma phosphate level.**

**Scientist contributed**

Marcel Eugène Émile Gley (1857–1930) was a French physiologist and endocrinologist. Gley was the first to show the importance of the parathyroid glands for the maintenance of life in mammals. He had demonstrated tetany in animal models after removal of parathyroids. Because of his discovery, parathyroid glands have sometimes been referred to as ‘Gley’s glands’.

**Fig. 62.1:** Location parathyroid glands. Note that these are 4 small glands (2 superior parathyroids and 2 inferior parathyroids) located behind the thyroid gland. They receive blood supply from thyroid arteries.

**Physiological Anatomy**

In human beings, there are four parathyroid glands present in the anterior aspect of the neck embedded posteriorly at four poles in the thyroid tissue (Fig. 62.1). The glands develop at about 10th week of pregnancy from the 3rd and 4th branchial pouches. The total weight of the four glands is about 200 mg, each gland weighing approximately 50 mg. Parathyroid glands derive blood supply from the thyroid arteries.
Cell Types
Parathyroid glands contain two types of cells: chief cells and oxyphil cells (Figs. 62.2A and B).

Chief Cells
The chief cells are the predominant cells in the parathyroid gland that are present throughout life.
1. They have bigger Golgi apparatus in their cytoplasm.
2. They also contain numerous vesicles and endoplasmic reticulum.
3. Chief cells secrete PTH.

Oxyphil Cells
Oxyphil cells are less plentiful in parathyroid gland. They appear in the glands during puberty and then the number increases with the advancement of age.
1. They contain numerous oxyphil granules.
2. Normally, they do not secrete PTH. However, sometimes they secrete PTH and contribute to parathormone excess.

Parathyroid Hormone (PTH)

Structure
PTH is a single chain polypeptide containing 84 amino acids. The molecular weight is 9,500. The biological activity, especially the calcium regulating ability of PTH resides in the N-terminal portion of the molecule (within amino acids 1–27). The C-terminal portion is not related to its action on calcium metabolism.

Synthesis, Secretion and Metabolism
Like other peptide hormones, PTH is synthesized from the larger precursor molecule called prepro-PTH that contains 115 amino acids. The leader sequence containing 25 amino acids is removed from amino terminal in endoplasmic reticulum to form pro-PTH, which contains 90 amino acids. In the Golgi apparatus, another six amino acids are removed from the amino terminal to form PTH containing 86 amino acids. PTH is then packaged and stored in the granules of chief cells.

Regulation of Secretion
PTH secretion is regulated mainly by plasma calcium and vitamin D. Other factors also influence PTH secretion.

Plasma Calcium Level
The major regulator of PTH secretion is the plasma calcium level and they have inverse relationship.
1. With increased plasma concentration of ionized calcium, PTH secretion decreases. The relationship is linear between 3–6 mg% of the ionized plasma calcium (Fig. 62.3). It may be remembered that about 50% of the total plasma calcium is present in the ionized form. Conversely, with decreased plasma calcium, PTH secretion increases.
2. Recently, the receptors for sensing plasma calcium, the calcium sensing receptors (CaSR) have been identified on the membrane of chief cells. The CaSR is a G-protein coupled receptor attached to phospholipase C and on binding with calcium generates IP$_3$ and DAG.
3. IP$_3$ and DAG release calcium from cytosolic stores and activate protein kinase C that inhibits PTH secretion.
4. Another example of increase in calcium inhibiting hormone secretion is decreased renin release from JG cells of kidney.

Vitamin D
Vitamin D inhibits PTH secretion by decreasing the formation of preproPTH mRNA.

Other Factors
1. Plasma phosphate: Usually phosphate does not affect parathormone secretion. However, a rise in plasma...
phosphate stimulates PTH secretion by lowering plasma calcium and inhibiting formation of 1,25-dihydroxycholecalciferol.

2. **Cyclic AMP, β receptor agonists, dopamine, magnesium and histamine (H₂ receptor) stimulate PTH secretion.** Prostaglandins and α receptor agonists inhibit PTH secretion by decreasing cyclic AMP.

### Metabolism of PTH

The normal plasma PTH level is 10–60 pg/mL.

1. As PTH is rapidly degraded by Kupffer cells in liver to carboxy terminal and mid-region fragments, the half life of PTH is about 10 minutes.
2. The fragments are cleared by kidneys.
3. However, the synthetic PTH which has only 34 amino acid sequence of amino terminal of the natural PTH, possesses all the biological effects of the hormone.

### Mechanism of Action

**PTH Receptors**

There are three types of PTH receptors.

**Type 1 Receptor (PTH 1R)**

It binds to PTH and PTH related proteins (PTHrP). The action of PTH to regulate plasma calcium is mediated via PTH 1R.

**Type 2 Receptors (PTH 2R)**

It binds to PTH, but not to PTHrP. It is found in brain, pancreas and placenta.

**Type 3 Receptor (CPTH)**

It reacts only with carboxy terminal of PTH (therefore called CPTH) and not with the amino terminal of the hormone.

**G Proteins for PTH**

PTH 1R and 2R are coupled to two types of G proteins Gs and Gq. Therefore, the binding of PTH with the receptors activates both adenylate cyclase and phospholipase C in the membrane. This results in activation of two signaling systems (Fig. 62.4):

1. Activation of adenylate cyclase-cyclic AMP system that increases cAMP. cAMP activates protein kinase A that causes phosphorylation of intracellular proteins. Formation of phosphoproteins increases transport of calcium and other ions.
2. Activation of phospholipase C that increases IP₃ and DAG in the cell. IP₃ causes intracellular calcium mobilization and DAG causes activation of protein kinase C.

### Physiological Actions

The primary action of PTH is to increase the level of calcium and decrease the level of phosphate in the plasma. This is achieved by the action of PTH on three major target organs: kidney, bone, and GIT (Flowchart 62.1). PTH increases the influx of calcium into the plasma. By acting on bone and intestine, it increases phosphate influx but this is counter balanced by its action on kidney where it increases phosphate efflux. Therefore, finally plasma phosphate concentration decreases.

**Actions on Kidney**

PTH receptors are present on basolateral membrane of the epithelial cells of proximal and distal tubules. PTH has three major effects on kidney:

1. Increased reabsorption of calcium
2. Decreased reabsorption of phosphate
3. Stimulation of 1, 25-dihydroxycholecalciferol formation.
**Chapter 62: Parathyroid Gland, Calcitonin and Vitamin D**

**Increased reabsorption of calcium**

Normally, 65% of filtered calcium is reabsorbed in proximal tubule, 25% in thick ascending limb of loop of Henle and 5–10% in distal tubule. About 1–2% of filtered load is excreted in urine.

1. PTH increases calcium reabsorption from kidney by mainly acting on distal tubule and thick ascending limb of loop of Henle. Thus, PTH action on kidney decreases the calcium excretion to a very minimal quantity.
2. PTH action on kidney is relatively rapid that plasma calcium increases within minutes following its injections.
3. PTH also increases the formation of 1,25-dihydroxycholecalciferol, which in turn increases calcium absorption from distal tubule of kidney.

**Decreased reabsorption of phosphate**

PTH decreases reabsorption of phosphate by mainly acting on proximal tubule.

1. This causes phosphaturia.
2. By decreasing plasma phosphate concentration, PTH prevents calcium-phosphate salts to precipitate.

**Stimulation of 1, 25-dihydroxycholecalciferol formation**

In kidney, in the mitochondria of proximal tubule, PTH facilitates the hydroxylation of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, the active form of vitamin D. 1,25-dihydroxycholecalciferol increases calcium reabsorption from kidney, calcium absorption from intestine and calcium mobilization from bone.

**Actions on Bone**

PTH acts on the receptors present in osteoblasts and osteoclasts. Thus, it activates both bone synthesis and resorption. However, the net effect is increased bone resorption and excess mobilization of calcium and phosphates from bones into plasma.

1. **Stimulation of osteoclastic activity**: This is a slower effect of PTH in which it stimulates osteoclasts to resorb mineralized bones. In this process both calcium and phosphate are transferred into the ECF. The bone matrix is hydrolyzed by the collagenase and lysosomal enzymes.
   - PTH increases the number and size of osteoclasts and also the synthesis of RNA in the osteoclast.
   - PTH also stimulates the differentiation of precursor cells (monocytes, macrophages, etc.) into the osteoclasts. Under the influence of PTH giant osteoclasts (osteoclasts of bigger size) are formed that cause resorption of the larger areas of bone (creates large resorption cavity).
   - The products of bone resorption are released into the plasma. These include calcium, phosphate, hydroxyproline and hydroxylysine.
   - Excretion of these substances in the urine especially that of hydroxyproline is an index of osteoclastic activity.
   - PTH acts on the osteoblasts: PTH inhibits the synthesis of collagen by osteoblasts at higher concentration.
   - This anabolic effect is mediated by increased secretion of insulin like growth factors and transforming growth factors.
   - Therefore, the net effect of PTH on bone is increase in the bone mass in lower concentration and decrease in bone mass in higher concentration.

**Applied Physiology**

**Hyperparathyroidism**

Hyperparathyroidism or PTH excess is divided into two main categories:

1. Primary hyperparathyroidism
2. Secondary hyperparathyroidism.

**Primary Hyperparathyroidism**

Primary hyperparathyroidism occurs due to the tumor of parathyroid gland such as parathyroid adenoma that secretes excess PTH. It may be part of multiple endocrine neoplasia (MEN) syndrome. It is common in MEN type 1.

1. The disease is characterized by hypercalcemia, hypophosphatemia, demineralization of bone, hypercalciuria, and renal stone formation.
2. The chronic effect of parathyroid excess results in the bone disease called osteitis fibrosa. There will be features of osteopenia and fracture.
3. In this disease, the bone marrow is fibrosed and bone resorption exceeds the bone formation.

**Secondary Hyperparathyroidism**

Secondary hyperparathyroidism occurs in chronic renal disease and rickets.

1. In these diseases, the chronic hypocalcemia causes increased secretion of PTH.
2. This results in secondary hypertrophy of parathyroid glands.
3. Neonatal primary hyperparathyroidism has also been described that occurs due to a genetic defect.

**In malignancy:** Hypercalcemia occurs in malignancies.

- This is mainly due to the bone metastases by the cancer cells that cause local osteolysis which results in hypercalcemia.
- Hypercalcemia also occurs in malignancy due to ectopic secretion of PTH or PTH related proteins (PTH rP).
- Usually, it is seen in the cancers of breast, kidney, lungs, ovary, and skin.

**Hypoparathyroidism**

Hypoparathyroidism is rarely seen as a disease of parathyroid gland. Rather, the common entity is pseudohypoparathyroidism in which symptoms of PTH deficiency are observed in the presence of normal PTH level in plasma.

There are two types of pseudohypoparathyroidism:

1. A congenital variety, in which the PTH does not increase the cyclic AMP and IP₃ formation in the target cells due to a receptor defect.
2. Another variety in which cyclic AMP synthesis by PTH remains normal but PTH fails to produce phosphaturic effect.

In hypoparathyroidism, hypocalcemia and increased bone density are main feature.

**Hypocalcemic Tetany**

Hyposecretion of parathyroid is rather common following thyroid surgery in which parathyroid glands are usually removed by mistake along with thyroid tissue. This causes severe hypoparathyroidism that leads to acute hypocalcemic tetany.

**Effects of Parathyroidectomy**

PTH is essential for maintenance of plasma calcium concentration. Acute deficiency of PTH results in neuromuscular defects that endanger life. Therefore, PTH is essential for survival. The symptoms of tetany following thyroid surgery develop in 24 to 48 hours postoperatively.

The features of tetany are:

1. **Chvostek’s sign:** This is the quick contraction of facial muscles of the same side by tapping over the facial nerve at the angle of jaw.
2. **Trousseau’s sign:** The spasm of the muscles of the upper extremity that causes flexion of the wrist and thumb (i.e. flexion at metacarpophalangeal joints) with extension of fingers (i.e. extension of interphalangeal joints).
3. **Carpopedal spasm:** There is also spasm of muscles at the wrist joints (carpal spasm) (Fig. 62.5). The changes at wrist and ankle joints together called as carpopedal spasm.
4. **Laryngospasm:** In hypocalcemic tetany, usually patients die due to hypoxia that occurs due to laryngospasm. The muscles of larynx contract and occlude the laryngeal passage.
5. **Hypocalcemia:** Significant hypocalcemia occurs.
6. Hyperphosphatemia.
The treatment of hypocalcemic tetany includes immediate administration of ionized calcium and parathormone.

Parathyroid Hormone-related Protein

The protein with PTH activity has been described recently. This is called parathyroid hormone related protein (PTHrP). This is produced by many tissues in the body. It is a polypeptide containing 140 amino acids. The gene that encodes the formation of PTHrP is present on the human chromosome 12 (it should be noted that the gene for PTH is present on chromosome 11). PTHrP has marked homology with the PTH.

Functions of PTHrP

1. PTHrP stimulates proliferation of chondrocytes in developing cartilage and inhibits their mineralization.
2. It also acts as a growth factor for the development of skin, hair follicle, and breast.
3. PTHrP is produced in large quantities in the lactating breast tissue and secreted in the milk. However, the plasma concentration of PTHrP does not increase during lactation.
4. PTHrP has also been described in kidney (renal glomeruli) and in the brain (cortex, hippocampus and cerebellum). But, functions of PTHrP in these organs are not clearly known.
5. It also causes calcium transport in placenta.
6. PTHrP is elevated in hypercalcemia of malignancy (Clinical Box 62.1)

Calcitonin

Source and Structure

Calcitonin is secreted from parafollicular cells (C cells) of the thyroid gland. The parafollicular cells develop from ultimobranchial bodies, a pair of glands that develop from 5th branchial pouch.

1. Calcitonin is a polypeptide hormone containing 32 amino acids. The molecular weight is 3,500.
2. The calcitonin gene that transcribes mRNA to form calcitonin is processed to form a different mRNA in the nervous system where it forms calcitonin gene-related peptides (CGRP).
3. CGRP is a potent vasodilator.

Synthesis, Secretion and Metabolism

Synthesis and Secretion

The major stimulus for calcitonin secretion is the rise in plasma calcium level. Above the concentration of 9 mg% of plasma calcium, the secretion of calcium becomes directly proportional to the calcium concentration. Other stimuli: The β receptor agonists, dopamine, GI hormones (CCK, glucagons, gastrin, secretin), and estrogen stimulate calcitonin secretion. Gastrin is a strong stimulus for calcitonin release (Clinical Box 62.2).

Metabolism

The concentration of calcitonin in plasma is 10–20 pg/mL. The concentration increases to almost 10 fold in hypercalcemia. The hormone is degraded in the liver. The half life of calcitonin is 5–10 minutes.

Mechanism of Action

Calcitonin acts on calcitonin receptors present on the target cells. The receptors are coupled to G proteins and therefore, stimulate the adenylate cyclase–cyclic AMP system.

Physiological Actions

Calcitonin decreases the plasma calcium level by acting mainly on bones and kidney (Flowchart 62.2).

Effects on Bone

Calcitonin mainly acts on the osteoclasts.

1. It decreases osteoclastic activity. Thus, it inhibits the bone resorption. The number and size of osteoclasts decrease.
2. The action of calcitonin on bone is just opposite to that of PTH with respect to the calcium turnover in the bone.
3. However, the effect on phosphate turnover is same as that of PTH. It decreases plasma phosphate level. This is due to inhibition of bone resorption, facilitation of phosphate entry into the bone, and also mild increase in urinary phosphate excretion.

4. Thus, the hypophosphatemic effect of calcitonin is independent of hypocalcemic effect.

**Effects on Kidney**

It decreases calcium reabsorption from kidney. Therefore, it produces calciuria. It also causes mild phosphaturia by acting on proximal tubule.

**Calcitonin Escape**

Injection of calcitonin produces hypocalcemia mainly by antiosteoclastic activity. However, this antiresorptive action of calcitonin begins to wane within hours.

1. The body escapes from hypocalcemic effects of calcitonin. This is called calcitonin escape, the exact mechanism of which is not known.

2. It is probably due to rapid down regulation of calcium receptors. Therefore, calcitonin is effective in decreasing plasma calcium only for a short duration.

3. This limits the use of calcitonin in long-term management of hypercalcemia.

**Physiological Significance**

1. Due to calcitonin escape phenomenon, the bones remain essentially normal in conditions of hypersecretion of calcitonin like medullary carcinoma of thyroid.

2. Calcitonin is secreted more in young individuals, which is believed to play some role in skeletal development.

3. **Feeding** increases calcitonin secretion by releasing GI hormones. Calcitonin escape protects against postprandial hypercalcemia.

4. During and after pregnancy, calcitonin protects bone loss in pregnant and lactating mother.

   – During pregnancy maternal calcium is used for bone formation in fetus and after pregnancy calcium is utilized for lactogenesis.

   – To maintain maternal plasma calcium, 1,25-dihydroxycholecalciferol level is increased, which causes bone resorption.

   – Therefore, increased calcitonin level in pregnancy prevents bone loss by opposing osteoclastic activity.

5. Calcitonin and CGRP are found together in some brain regions like pituitary, hypothalamus, limbic system etc, where they act as co-transmitters. They inhibit transmission of pain impulses in CNS independent of opioid system.

**Applied Aspects**

**Clinical Use of Calcitonin**

Calcitonin is used in the treatment of hypercalcemia, and in the diseases in which osteoclastic activity needs to be reduced, for example in Paget’s disease. Calcitonin is sometimes used as a central analgesic as it blocks the transmission of pain impulses in CNS.

**Paget’s Disease**

In this disease, increased osteoclastic activity of unknown etiology results in localized regions of bone resorption followed by a compensatory osteoblastic activity causing patchy new bone formations.

1. Thus, pagetic bones are structurally disorganized and susceptible to deformities.

2. X-ray pictures show areas of increased density and resorptive cavities.

3. Though most of the patients are initially asymptomatic, bone deformities resulting in compressive neuropathy and subsequent neuromuscular dysfunctions are not uncommon.

4. The disease is treated by daily injections of calcitonin.

5. Bisphosphonates like etidronate and pamidronate are more useful in preventing bone resorption.

**Vitamin D**

Vitamin D increases plasma calcium level by increasing calcium absorption from GI tract, calcium reabsorption from kidney and mobilization of calcium from bone. It has similar effects on phosphate.

**Synthesis of Vitamin D**

Vitamin D is acquired from two sources in human being.

1. Skin (ultraviolet irradiation of skin produces vitamin D), and
2. Diet.
**From Skin**

Vitamin D₃ is synthesized in keratinocytes present in the epidermis.

1. When the skin is exposed to sunlight (ultraviolet radiation at 290–315 nm), 7-dehydrocholesterol in the skin is converted to previtamin-D₃. For this conversion to occur, *minimum 20 mJ radiation energy* per sq-cm of skin is required.
2. Previtamin-D₃ is then automatically converted to vitamin D₃ in another 3 days.
3. However, continuous exposure to sunlight prevents this conversion.
4. Thus, mild to moderate exposure to sunlight induces, whereas excessive exposure prevents vitamin D synthesis.

**From Diet**

In food, minimum of 2.5 µg vitamin D should be ingested daily (*daily dietary recommendation* is 10 µg or 400 units). The important sources of vitamin D are liver, fish, cod liver oil and milk. Vitamin D ingested in the diet has very little biological activity.

1. It undergoes activation in the body to be converted into the active vitamin D. This requires successive hydroxylations in the liver and kidney.
2. In the liver, it is hydroxylated at position 25 by microsomal and mitochondrial enzyme, to form 25-hydroxycholecalciferol which undergoes further hydroxylation in the kidney at 1 position to form 1, 25-dihydroxycholecalciferol (Flowchart 62.3).
3. This occurs mainly in the mitochondria in epithelial cells of proximal and straight tubules.
4. The 1, 25-dihydroxycholecalciferol is the active metabolite of vitamin D.

**Mechanism of Action**

There are vitamin D receptors in the GIT, bone, and kidney. Mechanism of Vitamin D action is like that of steroid hormones.

1. It binds with the nuclear receptors and induces receptor phosphorylation, which targets DNA molecules.
2. The major product of vitamin D action is the increase in intracellular calcium binding protein called calbindin.

**Physiological Actions**

Vitamin D increases plasma calcium level by acting on intestine, kidney and bone (Flowchart 62.4).

On small intestine: Vitamin D mainly acts on the intestine to facilitate calcium absorption against the concentration gradient.

1. It combines with the receptors on the brush border of the intestinal epithelial cells and increases number of calcium pumps (Ca²⁺-H⁺ ATPase molecules) and calcium channels in the basolateral membrane and
calcibindin in the cytosol of the epithelial cells of the intestine.
2. Thus, calcium is actively pumped from the cell into the ECF.
3. It also facilitates the absorption of phosphate and magnesium across the intestinal epithelium.
4. PTH stimulates intestinal calcium absorption by promoting formation of 1,25-dihydroxycholecalciferol in kidney.

On kidney: It acts synergistically with PTH to increase calcium reabsorption from kidney.
1. It increases number of calcium pumps in the epithelial cells of proximal and distal tubules.
2. Unlike PTH that causes phosphate excretion, vitamin D increases phosphate reabsorption from kidney.
3. On bone: It acts on osteoblasts that have receptors for vitamin D.
   1. It increases synthetic activity of osteoblasts.
   2. It is also necessary for normal mineralization of bone. Mineralization of newly formed osteoid depends on vitamin D.
   3. It also stimulates bone resorption, not by directly increasing the osteoclastic activity, but by stimulating various paracrine signals that originate from the osteoblasts. Activated osteoclasts produce a number of proteins including phosphatase and collagenase that lyse bone matrix.
4. It promotes development of osteoclasts from their precursor cells.
5. It also increases osteocytic osteolysis.
6. Thus, the direct effect of vitamin D on bone is to mobilize calcium, which is contrary to its overall effect of promoting mineralization.

In summary, vitamin D increases calcium and phosphate absorption from intestine, and their reabsorption from kidney. Thus, vitamin D increases plasma level of calcium and phosphate (Flowchart 62.4), that increases bone mineralization. This overshadows the direct action of vitamin to mobilize these minerals from bone.

Other actions: Receptors for vitamin D are also found in skeletal and cardiac muscles, breast, anterior pituitary, skin, lymphocytes and monocytes.
1. It stimulates transport of calcium into skeletal and cardiac muscle. It has been observed that deficiency of vitamin D results in muscle weakness and cardiac dysfunction.
2. It promotes differentiation of immunological cells and keratinocytes in the skin. Therefore, skin infection is high in vitamin D deficiency.
3. It regulates growth of many tissues. It also stimulates production of tissue growth factors.
4. Anti-aging protein exerts effects partly via 1,25-dihydroxycholecalciferol (Application Box 62.1).

---

**Vitamin D Excess**
Vitamin D excess usually occurs due to excess intake of the vitamin.

---

**Vitamin D Deficiency**
(Rickets and Osteomalacia)
Deficiency of vitamin D causes rickets in children and osteomalacia in adults.

**Causes**
1. Inadequate intake
2. Lack of exposure to sunlight
3. Chronic liver disease (inadequate 25 hydroxylation)
4. Chronic renal disease (inadequate 1 hydroxylation)
5. Hypoparathyroidism
6. Anticonvulsant drugs like phenobarbital
7. Vit. D receptor deficiency
8. Vit. D dependent rickets (Hereditary deficiency of 1(alpha)-hydroxylase, an autosomal recessive disorder).

**Features**
The disease is characterized by inadequate mineralization of bone matrix. Both trabecular and cortical bones are involved. In both adult and children, excess unmineralized osteoid accumulates in the bone. The concentration of calcium and phosphate is significantly low. Bone strength is reduced, and therefore, they distort in response to mechanical load.

**In Children**
Decreased mineralization diminishes bone rigidity that results in bowing of the long bones of lower limbs and rickety chest. The epiphyseal growth centers are affected by defective mineralization of bone.

**In Adults**
As longitudinal growth of long bone is already completed in adults, bowing of bones does not occur. However, due to increased unmineralized osteoid content, bone pain, vertebral collapse, and fractures are common.

**Treatment**
Vitamin D supplement should start at the earliest.

---

**Application Box 62.1**
\(\alpha\)-Klotho partly acts through Vit. D: The anti-aging protein \(\alpha\)-Klotho that plays a major role in calcium and phosphate metabolism has been observed to act partly through 1,25-dihydroxycholecalciferol.

- \(\alpha\)-Klotho facilitates membrane localization of proteins that are involved in calcium and phosphate reabsorption, such as TRPV5 and Na\(^{+}\)-K\(^{+}\) ATPase.
- It enhances the activity of FGF-23 (fibroblast growth factor) by acting at the receptor level.
- FGF-23 decreases the renal NaPi-IIc activity and inhibits synthesis of 1(alpha)-hydroxylase that reduces the level of 1,25-dihydroxycholecalciferol.
1. It causes hypercalcemia, hypercalciuria, and kidney stones.
2. Increased bone resorption is not uncommon.
3. Hyperphosphatemia is also present.

**Other Hormones Affecting Calcium and Bone Metabolism**

**Glucocorticoids**

Glucocorticoid decrease plasma calcium level by inhibiting osteoclastic activity and decreasing calcium absorption from intestine. Therefore, cortisol excess causes osteoporosis.

**Growth Hormone**

It increases calcium absorption from intestine, though it also promotes calcium excretion in urine. The net effect is mild increase in plasma calcium. Stimulates osteoblastic activity and bone formation.

**CHAPTER SUMMARY**

**Key Concepts**

1. The primary action of PTH is to increase the level of calcium and decrease the level of phosphate in the plasma. Though PTH acts on both osteoblasts and osteoclasts and activates both bone synthesis and resorption, the net effect is increased bone resorption and excess mobilization of calcium into plasma.
2. Calcitonin decreases the plasma calcium level by acting mainly on bones and kidney. It decreases osteoclastic activity and inhibits the bone resorption. The number and size of osteoclasts decrease.
3. Therefore, for normal bone health (balance between osteoblastic and osteoclastic activity), the normal concentration of PTH and calcitonin should be maintained.
4. Vit. D is also necessary for normal mineralization of bone. Mineralization of newly formed osteoid depends on vitamin D. It also increases synthetic activity of osteoblasts.

**Important to Know (Must Read)**

1. In examination, “Describe the hormones regulating calcium and bone metabolism,” “Describe the regulation of secretion and physiological actions of parathyroid hormone (PTH)” may be asked as Long Questions.
2. Hypoparathyroidism, Effects of Parathyroidectomy, Hypocalcemic tetany, Calcitonin, Physiological actions of vitamin D, Causes, features and treatment of rickets and osteomalacia are usual Short Questions in exam.
3. In Viva, examiner may ask— Name the three main hormones regulating calcium and bone metabolism, List the other hormones regulating calcium and bone metabolism, List the physiological actions of parathyroid hormone, List the physiological actions of calcitonin, List the physiological actions of vitamin D, Name the features of hypocalcemic tetany, What is treatment of hypocalcemic tetany, What are types and features of hyperparathyroidism, What is osteitis fibrosa, Why hypercalcemia occurs in malignancies, What is pseudohypoparathyroidism and what are the types, What are the causes, features and treatment of rickets and osteomalacia, How is the secretion of PTH regulated, Physiological anatomy and cell types of parathyroid gland, Name the PTH receptors, What is parathyroid hormone related protein (PTHrP) and what are its functions, What is the mechanism of action of PTH, What are the factors that stimulate calcitonin secretion, What is calcitonin escape, What are the physiological significances of calcitonin escape, What are the clinical uses of calcitonin, What are the causes, features and treatment of Paget’s disease, What are the sources of vitamin D, What are the steps of synthesis of vitamin D, What is the mechanism of action of vitamin D, What are the functions of Vit D, What is α-Klotho and what are its functions, What are the features of vitamin D excess, What is the difference between osteoporosis and osteomalacia, What is Gley’s glands.
Pineal gland is also known as epiphysis was initially described as the main controlling center in the brain that influences many CNS functions. In fact, for centuries, it has attracted attention of many researchers in physiology and medicine for its role in integral control of the being. However, till date functions of pineal gland are not clearly understood except its role in melatonin secretion and control of light-dark cycle. It is known to act as photoreceptor in fish, amphibian and reptiles, a biological clock in birds, and has become an endocrine gland in mammals. However, more research needs to be done in human beings to reveal the role of pineal in the evolutionary progression of the mankind.

**PHYSIOLOGICAL ANATOMY**

Pineal is embryologically derived from an evagination of the roof of third ventricle between the habenular and posterior commissures. Along with habenular and posterior commissures it makes up the epithalamus.
1. It is connected by a stalk to the posterior and habenular commissures (Fig. 63.1).
2. The stroma of the pineal gland consists of neuroglial cells, pinealocytes, and parenchymal tissue. Pinealocytes possess secretory function (Fig. 63.2).
3. It is larger in size during infancy and childhood. It regresses at the time of puberty and is small in size in adults.

4. The plasma level of melatonin, which is secreted from pineal gland, in children is about 250 pg/ml, which is much higher than the level in adults, i.e. about 70 pg/ml.

**Hormones of the Pineal Gland**

Pineal gland secretes the hormone melatonin. Recently, it has been detected that pineal gland secretes many other
peptides} that influence hypothalamic and other endocrine secretions. Peptides that have been identified in pineal gland in mammals are arginine vasotocin, arginine vasopressin, oxytocin, pro-opiomelanocortin derived peptides like ACTH, α-MSH and β-endorphin, angiotensin II, renin like activity, and TRH and GnRH like peptides. Thus, pineal gland might be involved in control of many endocrinal functions of the body.

**Melatonin**

Melatonin is N-acetyl-5-methoxytryptamine, which is synthesized from the amino acid tryptamine (Flowchart 63.1). It is synthesized by the parenchymal cells of the pineal gland and then released into circulation and CSF.

Melatonin secretion exhibits a remarkable diurnal variation. The secretion is maximum in the night, especially between 11 pm and 7 am (Fig. 63.3).

1. It is proposed that this diurnal variation is due to the alteration in sympathetic discharge to the pineal gland, mediated by norepinephrine via β receptors.
2. The pineal sympathetic output synchronized with light dark cycle is controlled by inputs from retinohypothalamic pathway that projects to suprachiasmatic nucleus.
3. Fibers from suprachiasmatic nucleus terminate in intermediolateral gray column of the thoracic spinal cord that in turn projects to superior cervical ganglion from where fibers originate to end in the pineal gland (Flowchart 63.2).
Melatonin Receptors

Two types of melatonin receptors have been described: ML 1 and ML 2.
1. Melatonin at ML 1 receptor subtype acts by increasing cAMP. ML 1 receptor has two subtypes: Mel 1a, and Mel 1b (For role of melatonin in sleep-wake cycle, refer, “Theories of sleep”).
2. ML 2 receptor subtype acts by increasing IP3 and DAG in the target cells.

Functions of Pineal Gland

Melatonin secreted from pineal has following functions:

1. Melatonin secreted from pineal has a definite diurnal pattern. This diurnal change in melatonin level is believed to coordinate the endocrinal responses of the body with the light-dark cycle in the environment.
2. Melatonin secreted from pineal inhibits gonadal function. It is believed that pineal secretion inhibits the onset of puberty. Therefore, regression of pineal stimulates the beginning of pubertal changes. It has been observed that precocious puberty and sexual precocity are associated with pineal abnormalities.
3. In lower animals, melatonin influences the activity of melanophores and thereby controls skin color. However, such function in human appears to be uncertain.

CHAPTER SUMMARY

Key Concepts

1. Though pineal gland is known to secrete melatonin, and control circadian rhythm, it might have many more functions.
2. The size of pineal gland decreases with the maturation of sex organs. May be melatonin is meant of inhibition for basic instincts, especially functions related to mating.

Important to Know (Must Read)

1. In examination, Long Questions are not asked from this chapter.
2. The Short Questions may be ‘Pineal gland’ and ‘Melatonin’.
3. In Viva, examiner may ask… List the functions of pineal gland, List the hormones of pineal gland, How the pathway from retina stimulates melatonin secretion, When the peak secretion of melatonin occurs.
Local Hormones

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:
1. Name the local hormones.
2. Name the receptors and describe the functions of histamine and serotonin
3. Classify prostaglandins and describe their functions.
4. Give the functions of other local hormones.

The student **MAY** also be able to:
1. Describe the function of all local hormones.
2. Explain the role of local hormones in various functions and dysfunctions of the body.

**Definition and Types**

**Definition:** Local hormones are chemicals that are secreted locally from an endocrine tissue that are primarily involved in control of local tissue functions where they are secreted.

**Types:** The known local hormones are: renin, erythropoietin, ANP, melatonin, thymosin, histamine, serotonin, bradykinin, and prostaglandins.

**Histamine**

**Source, Synthesis and Metabolism**

Histamine is secreted from **mast cells and basophils**:
1. It is widely distributed in mammalian tissues.
2. It has highest concentration in the skin, gastric mucosa, pituitary and lungs.
3. Histamine is synthesized from the amino acid **histidine** by the action of enzyme **histidine decarboxylase**.
4. Histamine is converted to **methylhistamine** by **histamine-N-methyltransferase**, which is further converted to **methyl-imidazole-acetic acid** (Flowchart 64.1).

**Histamine Receptors**

Three types of histamine receptors have been described so far. They are: **H₁**, **H₂** and **H₃** receptors. All are found in brain and peripheral tissues.

**H₁** receptors: They are attached to phospholipase C. On activation, they produce **IP₃** and **DAG** in the cell. These receptors mediate inflammation and allergy.

**H₂** receptors: Histamine at **H₂** receptors acts by **increasing intracellular cAMP**. They are found in gastric mucosa and mediate gastric acid secretion.

**H₃** receptors: They are found in CNS, especially in presynaptic membrane and are coupled to G proteins. They inhibit release of histamine and other neurotransmitters from presynaptic nerve terminals.
Physiological Actions
Histamine acts mainly on the cardiovascular system, smooth muscles, and exocrine secretions. It mediates inflammation and allergy.

On CVS
Histamine is a potent vasodilator. It decreases blood pressure (causes hypotension). It also decreases the cardiac output.

On Smooth Muscles
Histamine increases tone of most of the smooth muscles. It increases intestinal motility and causes bronchoconstriction.

On Exocrine Secretions
Histamine is a powerful stimulator of HCl secretion from parietal cells stomach. It also potentiates salivary, pancreatic, and intestinal secretions.

Role in Inflammation
It is an important mediator of inflammation. Histamine, by causing local vasodilatation increases blood flow at the site of inflammation and by increasing capillary permeability causes local swelling. It mediates responses (triple response) to local injury.

Role in Allergy
Allergic reactions are mostly mediated by histamine:
1. In acute systemic allergy (anaphylaxis), hypotension occurs due to release of histamine from mast cell that produces acute vasodilatation.
2. Local allergic reactions like urticaria, allergic rhinitis, hay fever, etc. are also due to the release of histamine at the local sites.
3. Bronchial asthma is precipitated or induced by histamine.
4. Histamine is released from mast cells in response to the antibody IgE (the reagin antibody). The antigen-antibody complex causes degranulation of mast cells and release histamine.
5. Histamine is released from mast cell along with slow reacting substance for anaphylaxis (SRS-A).
6. Histamine and SRS-A mediate allergic reactions. Hence, antihistaminics are mainstay of treatment for allergies.

Relation with Itch
Histamine acts as a neurotransmitter for itch sensation. Experimentally, when histamine is injected into the skin, it produces sever itch. Itching associated with skin allergy (urticaria) is cured by antihistaminics.

On CNS
Histamine is a neurotransmitter in many areas of the CNS. Histaminergic neurons project from tuberomamillary nucleus to all parts of the brain. These histaminergic fibers are involved in the control of blood pressure, sexual and ingestive behaviors, arousal and alertness, pain and secretion of anterior pituitary hormones.

Clinical Correlation
Antihistaminic Drugs
Antihistaminics are used frequently in clinical practice for the treatment of allergy and inflammations.

H1 receptor antagonists: H1 antagonists like mepyramine and promethazine are used to prevent histamine induced contractions of smooth muscles of intestine and bronchi. They are also used frequently in the treatment of allergies.

H2 receptor antagonists: H2 antagonists like cimetidine, ranitidine, and famotidine are used to inhibit histamine induced HCl secretion in the stomach. These drugs are frequently used in the treatment of peptic ulcer.

Serotonin

Source
Serotonin is 5-hydroxytryptamine (5-HT). It is distributed in various tissues. It is present in high concentration in GI tract, CNS, especially in the hypothalamus and brainstem, and skin. Due to its higher concentration in the intestine, it is also known as enteramine. It is also present in platelets and basophils.

Synthesis and Metabolism

Synthesis
Serotonin is synthesized from the amino acid tryptophan. Tryptophan is converted to 5-hydroxytryptophan by the action of enzyme tryptophan hydroxylase. 5-hydroxytryptophan is then decarboxylated to form 5-hydroxytryptamine (serotonin) catalyzed by the enzyme 5-hydroxytryptophan decarboxylase (Flowchart 64.2).

Metabolism
Serotonin is metabolized by the enzyme monoamine oxidase to form 5-hydroxyindole acetic acid (5-HIAA), which is excreted in urine. 5-HIAA is physiologically inactive. However, the level of it in urine is an index of serotonin secretion in the body.

Serotonin Receptors
Till date, seven types of serotonin receptors have been identified. They are 5-HT1, 5-HT2, 5-HT3, 5-HT4, 5-HT5, 5-HT6, 5-HT7. The 5-HT1 is further subdivided into 5-HT1A, 5-HT1B, 5-HT1D, 5-HT1F, and 5-HT1E. Also, 5-HT2 is further subdivided into 5-HT2A, 5-HT2B, and 5-HT2C. The 5-HT5 has two subtypes: 5-HT5A and 5-HT5B.
Physiological Actions
Serotonin mainly acts on cardiovascular system, respiratory system, kidney, smooth muscle, and nervous system.

Cardiovascular System
Serotonin, acting locally produces vasoconstriction. It facilitates platelet aggregation. These two functions of platelets are mediated via 5-HT_2A receptors, and are essential for temporary hemostasis. Serotonin also produces tachycardia.

Respiratory System
Serotonin increases bronchial tone (causes bronchoconstriction), which is mediated via 5-HT_2A receptors. In asthmatic patients, it induces the acute attack of asthma. It also stimulates rate of respiration.

Kidney
Serotonin has mild antidiuretic effect. It prevents diuresis by decreasing GFR, which occurs due to afferent glomerular arteriolar constriction. It also causes ureteric spasm and temporarily stops urination.

GI Tract
Serotonin stimulates GI secretions and motility. It promotes peristalsis and produce diarrhea. These effects are mediated by 5-HT_4 receptors.

Central Nervous System
It is released as a neurotransmitter in different parts of the brain. The most important serotonergic pathway in the brain is the raphespinal system that on stimulation produces analgesia. 5-HT_3 receptors are present in area postrema that on activation induces vomiting. 5-HT_6 and 5-HT_7 receptors are distributed throughout the limbic system, neocortex, cerebellum and spinal cord. It has following central functions:
1. Inhibits transmission of pain impulses in dorsal horn of spinal cord, and thus, it is an important component of endogenous analgesia system.
2. Stimulates prolactin secretion from anterior pituitary.
3. Regulates circadian rhythm (suprachiasmatic nucleus receives heavy serotonergic innervation). Serotonin is a strong antidepressant. Hallucinogens produce euphoria by releasing serotonin in the brain. Antidepressant drugs such as fluoxetine act by inhibiting serotonin reuptake in the brain.
4. Serotonin is a strong anorectic agent. It inhibits feeding by acting on hypothalamic and other feeding areas in the brain.
5. Serotonin suppresses sleep and serotonin antagonists enhance slow wave sleep.

Clinical Correlation
Increased serotonin activity is seen in some endocrine tumors, which is detected by estimation of urinary 5-HIAA. This is usually observed in carcinoid syndrome.

Bradykinin
Bradykinin is a peptide containing 9 amino acids (nonapeptide). It is synthesized in tissue and plasma.

Synthesis
Bradykinin is synthesized from high molecular weight kininogen (HMWK) by the action of plasma kallikrein in plasma and tissue kallikrein in tissue. Plasma kallikrein is formed from prekallikrein by activated clotting factor XII.

Physiological Actions
Bradykinin resembles histamine in its physiological functions:
1. It produces vasodilation and increases local blood flow.
2. It causes contraction of visceral smooth muscle.
3. It increases capillary permeability, attracts leucocytes to the site of injury and produces pain when injected into the skin.
4. It increases secretion from exocrine pancreas and salivary gland.
5. It also increases sweat secretion.

Clinical Importance
Bradykinin is secreted from abnormal endocrine tumors as seen in carcinoid syndrome.
Prostaglandins

Prostaglandin was first described by Von Euler in 1937. It was named prostaglandin for its enumeration in the secretion from prostate gland. Afterwards, prostaglandins were found to be synthesized in various tissues of the body. They are 20-carbon unsaturated fatty acids containing a cyclopentane ring. They act as local hormone in kidney, lungs, GI tract, uterus, skin and other tissues.

Scientist contributed

Ulf Svante von Euler (1905-1983) was a Swedish physiologist and pharmacologist. He shared the Nobel Prize in Physiology or Medicine in 1970 for his work on neurotransmitters. His short stay as a postdoctoral student in Dale’s laboratory was very fruitful, where in 1931 he worked with John H Gaddum and discovered substance P. After returning to Stockholm, he pursued his research, and discovered four other important endogenous active substances, prostaglandins, vesiglandin (1935), piperidine (1942) and noradrenaline (1946).

Types

There are different types of prostaglandins. The commonest prostaglandins are PGE, PGF, PGI, PFH and PGA. Further, each has subcategories like are PGA₁, PGA₂, PGE₁, PGE₂, PGF₁α and PGF₂α, etc.

Synthesis

Prostaglandins are synthesized from arachidonic acid, which is formed from membrane phospholipid by the enzyme phospholipase A₂:

1. Arachidonic acid is then converted to cyclic endoperoxides (PGH₂) by the action of enzyme cyclooxygenase (prostaglandin synthase).
2. PGH₂ is then converted to prostacyclin by the enzyme prostacyclin synthase or thromboxane A₂ by the enzyme thromboxane synthase (Flowchart 64.3).
3. PGH₂ is also converted to PGE₂, PGF₂α, etc. by various isomerases.

Physiological Actions

Prostaglandins are present in almost all the tissues of the body. They are mainly involved in the control of functions of various organ systems, hemostasis, and metabolisms and play an important role in inflammation.

Cardiovascular System

PGA₁ and PGA₂ cause peripheral arteriolar dilation. Prostacyclin produces vasodilation and thromboxane A₂ causes vasoconstriction.

Reproductive System

1. PGF₂α produces contraction of gravid uterus. The concentration of this chemical increases in the maternal blood during parturition. It is suggested that the increase in PGF₂α initiates labor in the presence of high concentration of oxytocin.
2. Prostaglandins facilitate luteolysis (regression of corpus luteum).
3. They decrease the secretion of progesterone.
4. Prostaglandins increase in uterine fluid and cause necrosis of blood vessels of the uterus just before the bleeding starts during menstrual cycle. It is proposed that prostaglandins initiate the process of bleeding.
5. It increases secretion of GnRH from hypothalamus.

Hemostasis

Prostacyclin inhibits platelet aggregation and produces vasodilation whereas thromboxane A₂ and endoperoxides promote platelet aggregation and cause vasoconstriction:

1. The balance between the prostacyclin and thromboxane A₂ determines the degree of platelet plug formation (refer to Fig. 20.9, Chapter 20).
2. Thus, prostaglandins greatly influence temporary hemostasis.

Respiratory System

Prostaglandin E causes bronchodilation whereas PGF₁α produces bronchoconstriction. PGF₂α is implicated in the genesis of bronchial asthma.

GI System

Prostaglandins E and F₂α inhibit absorption of sodium and water:
1. The **watery diarrhea** produced in cholera is mediated by prostaglandins.
2. They also stimulate **intestinal motility**.

### Central Nervous System
Prostaglandins act as neurotransmitters in various parts of the brain. PGE inhibits release of norepinephrine from the nerve endings.

### Inflammation
Prostaglandin E and A increase capillary permeability during inflammation. PGE sensitizes the nerve endings to bradykinin and produces pain.

### Metabolism
PGE inhibits lipolysis, induced by ACTH, GH, glucagons, and epinephrine.

### Clinical Correlation
Prostaglandin preparations are used in the treatment of different diseases.
1. **Steroidal anti-inflammatory drugs** such as cortisol inhibit prostaglandin production by inhibiting the enzyme phospholipase A$_2$.
2. **Nonsteroidal anti-inflammatory drugs** (NSAID) such as ibuprofen inhibit prostaglandin synthesis by inhibiting the enzyme cyclooxygenase (see Flowchart 64.3).

### Carcinoid Syndrome
These are tumors of enterochromaffin cells of the GI tract or bronchus or pancreas:
1. A characteristic feature of carcinoid syndrome is the episodic flushing of the skin, associated with hypertension, abdominal pain, diarrhea, and bronchoconstriction.
2. These episodic attacks occur due to secretion of various chemicals from the tumor enterochromaffin cells.
3. Usually, these tumors secrete excess of serotonin and histamine.
4. Therefore, the disease is diagnosed by the excretion of increased amount of 5-HIAA in the urine.

### Other Local Hormones

#### Renin
Renin is the hormone secreted from JG cells of kidney in response to hypovolemia and hypotension. It converts angiotensinogen to angiotensin I, which is further converted to angiotensin II by ACE (for details, refer renin-angiotensin system in Kidney).

#### Erythropoietin
Erythropoietin is the glycoprotein hormone containing 165 amino acids secreted mainly from interstitial cells in the peritubular capillary bed of kidney. It is the major regulator of erythropoiesis (for details, refer erythropoiesis in Section II "Blood").

### ANP
Atrial natriuretic peptide (ANP) is a peptide hormone synthesized by the atrial myocytes. It has profound natriuretic and diuretic effect. Therefore, it is known as a natriuretic peptide. ANP contains 28 amino acids. A similar peptide is isolated in the brain, called as brain natriuretic peptide (BNP), which contains 32 amino acids. A third natriuretic peptide is also described, the C type natriuretic peptide (CNP), which contains 22 amino acids. The CNP is present in the brain, kidney, and vascular endothelial cells. Actions of natriuretic peptides are almost similar (for details, see ANP in ‘cardiovascular system’).

The major functions of ANP are:
1. ANP increases sodium excretion (natriuresis). This is occurs due to increased GFR, which is produced by dilation of afferent arteriole and relaxation of mesangial cells in the glomerulus of kidney. Also, ANP acts on kidney tubule to inhibit sodium reabsorption.
2. It increases water excretion (diuresis). This occurs, secondary to natriuresis.
3. It causes vasodilation, leading to decrease in blood pressure.
4. It also increases capillary permeability that causes extravasation of fluid into interstitial tissue space. This decreases blood volume and pressure.
5. **It decreases the sensitivity of blood vessels to constrictors** like catecholamines and angiotensin II.
6. It decreases heart rate and cardiac output.

### Melatonin
Melatonin is secreted from the pineal gland. The secretion is more in children and less in adults. It inhibits gonadal function (for details, refer previous chapter).

### Thymosin
Thymosin is the hormone secreted from thymus. Thymus is present in the mediastinum posterior to sternum. At birth it weighs about 10 g, which increases in size to about 30 g during adolescence. Thereafter, it decreases to about 5 g in adults and 2 g in elderly:
1. Thymosin controls the development of lymphocytes and plays an important role in immunity. It is secreted by the reticular epithelial cells of thymus (for details, refer Chapter 18).
2. **Development of the T cells** occurs in thymus during childhood and thymosin plays a crucial role in this process.
3. Hence, thymus has the central position in the development of cellular immunity. For details of T cell development, refer ‘Immunity’.
CHAPTER SUMMARY

**Key Concepts**
1. Though local hormones act locally in the tissue where they are produced, some of them have systemic effects.
2. Many local hormones play an important role in many physiological functions such as platelet aggregation, hemostasis, GI secretion and motility, menstrual bleeding, CV functions, neurotransmission in brain, glomerular filtration, bronchial activity, respiratory functions. Therefore, they play a key role in many dysfunctions and diseases.

**Important to Know (Must Read)**
1. In examination, Long Questions are not asked from this chapter.
2. Physiological actions of histamine, Physiological actions of serotonin, Physiological actions of prostaglandins, Bradykinin, ANP, Carcinoid syndrome may be asked as Short Questions in exam.
3. In Viva, examiner may ask... List the physiological actions of histamine, List the physiological actions of serotonin, List the physiological actions of prostaglandins, List the physiological actions of bradykinin, List the physiological actions of ANP, What are the histamine receptors and where are they found, List some antihistaminic drugs and mention their uses, What is carcinoid syndrome and what are its features, What is the mechanism of action of anti-inflammatory drugs (both steroidal and nonsteroidal), List the local hormones, What is ANP and from where is it secreted, List the steps of synthesis and metabolism of histamine, List the steps of synthesis and metabolism of ANP, List the steps of synthesis and metabolism of prostaglandins, List the serotonin receptors and their subtypes, What is thymosin and what are its functions.
SECTION–7
Reproductive System

**Part A: General Reproductive Physiology**
65. Sex Differentiation and Development, Puberty and Menopause
66. Physiology of Puberty and Menopause

**Part B: Male Reproductive Physiology**
67. Male Reproductive System

**Part C: Female Reproductive Physiology**
68. Female Reproductive System: Functional Anatomy, Oogenesis and Follicular Development
69. Menstrual Cycle and Ovulation
70. Ovarian Hormones and Control of Ovarian Functions

**Part D: Physiology of Conception, Pregnancy, Lactation and Contraception**
71. Physiology of Copulation
72. Pregnancy and Parturition
73. Physiology of Breast Development and Lactation
74. Physiology of Contraception
“To live, to love are signs of infinite things,
Love is glory from eternity’s spheres.
Abased, disfigured, mocked by baser mights
That steal his name and shape and ecstasy,
He is still the Godhead by which all can change.”

Sri Aurobindo (in ‘SAVITRI’
Chapter 65
Sex Differentiation and Development, Puberty and Menopause

**Learning Objectives**

On completion of study of this chapter, the student **MUST** be able to:

1. Understand the physiology of sex determination and differentiation.
2. Describe the mechanism of sex differentiation and development in males and females.
3. List the abnormalities of sex differentiation and understand the physiological basis of their causation.
4. Apply the knowledge of sex determination and differentiation in understanding the physiology of reproductive system.

The student **MAY** also be able to:

1. Describe the mechanisms of dysfunctions of sex differentiation.

Reproduction serves a primary goal of the nature in preservation and perpetuation of the species. The creation of two sexually complete and different individuals in same species, known as **sexual dimorphism** is the central scheme of the nature to achieve its principal intention of continuation of species through reproduction. The complete sexual dimorphism is obtained through the attainment of **puberty**. The sexually matured adults then reproduce to maintain their progeny. Therefore, to appreciate the physiology of reproduction one should study the process of sex differentiation, development of gonads, gonadal functions, physiology of puberty and sexual maturation, the principles of functioning of the female and male reproductive systems, and the physiology of pregnancy, parturition and lactation.

**SEX DIFFERENTIATION**

**Sex Determination**

**Normal Chromosomal Pattern**

In a normal human being, there are 46 (23 pairs) chromosomes: 22 pairs are autosomes and one pair is sex chromosome (Fig. 65.1).

**In Males**

The pattern is 22 pairs of autosomes, and one X and one Y sex chromosomes (44 XY).

**In Females**

The pattern is 22 pairs of autosomes and two X chromosomes (44 XX).

**Sex Chromosomes**

Gender is determined by the genetic inheritance of two chromosomes, called sex chromosomes. The two sex chromosomes are the **X chromosome**, the larger one, and the **Y chromosome**, the smaller one.

1. Females possess two X chromosomes and males have one X and one Y chromosome. Thus, ovum always contributes only one X chromosome, whereas half of the sperms contribute X and another half Y.

---

**Fig. 65.1:** Chromosomal pattern in males (44 XY) and females (44 XX).
2. Therefore, union of sperm and ovum (fertilization) usually results in half XX and half XY. Hence, ideally, births of male and female children should have been in equal proportion.

3. However, generally the male births are slightly more than the female births. This difference in sex ratio could be due to the fact that the sperms that contain Y chromosomes are lighter than the sperm that contain X chromosome as Y chromosome is smaller in size than X chromosome. Therefore, sperms with Y chromosomes swim faster in female genital tract and reach ovum earlier. Thus, the opportunity for these chromosomes to fertilize ovum is more than the sperm with X chromosomes.

**Genetic Male**

When a sperm containing Y chromosome fertilizes an ovum, the resultant zygote develops into a genetic male having XY pattern of sex chromosomes. The karyotype is 44 XY.

**Genetic Female**

When a sperm containing X chromosome fertilizes an ovum, the resultant zygote develops into a genetic female having XX pattern of sex chromosomes. The karyotype is 44 XX.

**Sex Determination**

**Karyotyping**

Sex determination is usually done by karyotyping, a technique used for determining sex chromosome composition by employing tissue culture visualization of all chromosomes. The differences in shape and size of chromosomes in males and females help in concrete determination of sex (Figs. 65.2A and B).

**Demonstration of Sex Chromatin**

This is a relatively easy method to demonstrate sex chromatin (Barr body) in leucocytes or mucosal cells of the oral cavity (refer to Fig. 5.7, Chapter 5).

1. Barr bodies are usually formed in females as they have two X chromosomes.
2. When two X chromosomes are present, one X chromosome is functional and other X chromosome which is nonfunctional condenses to form sex chromatin.
3. Thus, presence of Barr body generally indicates female sex.

**Sex Differentiation**

The process of sex differentiation includes the pattern of development of the gonads, genital ducts, and the external genitalia.

1. During pregnancy, no differences in the gonads of male and female fetuses occur during the first five weeks of gestation. This is called the stage of indifferent gonads.
2. The differentiation of gender starts from sixth week of intrauterine life and continues even after birth till the complete maturation of the gonad of either gender is achieved.
3. The process of development from the indifferent gonad to complete mature gonad of either gender is called the sex differentiation.

**Cell Lines of Development:** Following fertilization, two different cell lines develop in the indifferent gonad.

1. The one cell line forms the granulosa cells of the ovarian follicle and the Sertoli cells of the testicular seminiferous tubules. The cells of this cell line nurse the germ cells and promote their maturation, and finally guide their development into the genital duct system. These cells in females produce estrogen.
2. The other cell line of the indifferent gonad (the interstitial cells) forms theca cells in the ovary and Leydig cells in the testis. These cells mainly secrete androgen, which is essential for the development of male sexual characteristics and spermatogenesis. In females, they form the precursors for estrogen synthesis.

**Differentiation of the Genetic Sex, Gonadal Sex and Phenotypic Sex**

**Genetic Sex**

**Male Genetic Sex**

The male chromosomal pattern is 44 autosomes and a pair of sex chromosomes. The sex chromosomes in a normal male is X and Y. The presence of Y chromosomes determines the maleness of the individual, without which neither testis nor the male genital pattern develop.

1. The Y chromosome contains the SRY gene (sex-determining region of the Y) which is located on the distal part of its short arm (Fig. 65.3).
2. This gene encodes the testis determining factor (TDF). The TDF is a transcription factor that binds to DNA molecules.
3. A gene identical to SRY gene encodes a histocompatibility antigen known as H-Y antigen. These are glycoprotein antigens present on the surface of all male cells. Both these antigens are involved in rejection of male tissue by the female recipients. This H-Y antigen helps in development of male gonads, and masculinization.
4. Though SRY gene is essential for masculinization, it is not adequate for the complete maleness.
5. Virilization of the genital duct and external genitalia requires the presence of an androgen hormone receptor. This receptor is encoded by the gene present on the X chromosomes. Therefore, X chromosomal gene also contributes to the development of maleness.

**Female Genetic Sex**

The normal female chromosomal pattern consists of 44 autosomes and a pair of X chromosomes (XX).

1. In the absence of a Y chromosome, SRY gene is absent.
2. Therefore, TDF and H-Y antigen do not develop.
3. Hence, instead of male gonads ovaries develop when both the sex chromosomes are X.

**Gonadal Sex**

**Male Gonadal Sex**

In a normal genetic male, the seminiferous tubule starts to form at 6–7 weeks of gestation.

1. The Sertoli cells enclose the germ cells.
2. The Leydig cells appear at 8–9 weeks. The testis starts secreting testosterone during this period. This helps in development of male sex.
3. The SRY gene prevents the synthesis of estrogen and inhibits the enzyme aromatase, which inhibits the development of female systems.

**Female Gonadal Sex**

In a normal genetic female, the differentiation of indifferent gonad into the female gonads (ovaries) starts after nine weeks of gestation.

1. Both the X chromosomes in the germ cells are activated.
2. The germ cells then undergo divisions to form oogonia that continue to proliferate.
3. Immediately after the start of meiosis, oogonia are surrounded by granulosa cells.
4. Stroma appears inside it, which gives rise to interstitial cells. Now the germ cells are known as primary oocytes.
5. The female gonad remains in this stage (primary oocyte stage), i.e. in the stage of diplotene or late prophase of meiosis for many years until ovulation occurs.
6. Estrogen secreted from the granulosa cells help in the female development.

**Phenotypic (Genital) Sex**

The differentiation of genital duct and external genitalia requires hormones. The basic principle is that under the direction of a positive hormonal influence, the male gonadal system develops, and in the absence of any hormonal control, female genitals develop (Figs. 65.4 and 65.5). The development of brain is also linked to the phenotypic sex (Application Box 65.1).

**In Males**

In males, at about 9–10 weeks Wolffian or mesonephric ducts develop which gives rise to epididymis, vas deferens, seminal vesicles, and ejaculatory ducts.

1. Development of this system is presided by the appearance of Leydig cells in the testis that secrete testosterone.
2. Testosterone stimulates growth and differentiation of Wolffian duct into the male genital system (Flowchart 65.1).
Section 7: Reproductive System

Figs. 65.4A to C: Differentiation of the male and female internal genitalia. (A) Indifferent stage; (B) Male internal genitalia; (C) Female internal genitalia. Note, in male, Müllerian duct degenerates, and in female, Wolffian duct degenerates.

Figs. 65.5A to E: Differentiation of the male and female external genitalia. (A) Indifferent stage; (B) Male genitalia (7th to 8th week); (C) Male genitalia (at about 12th week); (D) Female genitalia (7th to 8th week); (E) Female genitalia (at about 12th week).
In Females
In females, the Wolffian duct degenerates at about 10–11 weeks as ovary does not secrete testosterone. From Wolffian ducts on each side, the Müllerian ducts arise, which develops into fallopian tubes and uterus.

Role of MIS:
In males, müllerian ducts regress at about 8 weeks of gestation, the time during which Sertoli cells appear in the testis. The Sertoli cells produce a hormone called müllerian inhibiting substance (MIS). This is also known as antimüllerian hormone or müllerian regression factor.

1. MIS causes degeneration of müllerian duct by facilitating its apoptosis.
2. The SRY gene promotes the synthesis of MIS.
3. In females who lack MIS, müllerian duct continues to grow and form fallopian tubes, uterus, cervix, and vagina (Flowchart 65.2). This differentiation is completed by 18–20 weeks of gestation.

Müllerian Inhibiting Substance (MIS)
Also known as antimüllerian hormone or müllerian regression factor, MIS is a polypeptide hormone containing 536 amino acids secreted by the Sertoli cells of testis. It belongs to the TGF β superfamily of growth factors that includes activin and inhibin.

1. In males, though the secretion of MIS starts at 8–10 weeks of gestation, the level in plasma reaches its peak, i.e., about 50 ng/mL at 1 to 2 years of age. The concentration then declines gradually to a low level during puberty and a lower concentration of about 2–5 ng/mL is maintained through rest of life.

Functions of MIS
1. During early embryonic life, MIS inhibits development of female gonads by promoting regression of müllerian duct. Therefore, it helps in male gonadal development.
2. Later during fetal life in males, it helps in testicular descent.
3. In both sexes, it helps in maturation of germ cells.

Abnormalities of Sex Differentiation
The abnormalities of sex differentiation can be broadly divided into two categories: chromosomal and developmental abnormalities.

Chromosomal Abnormalities
The common chromosomal abnormalities are Turner’s syndrome, Klinefelter’s syndrome, testicular feminization syndrome, superfemales and true hermaphroditism.
Section 7: Reproductive System

Turner’s Syndrome
This is otherwise known as gonadal or ovarian dysgenesis.
1. It is characterized by diminished sexual development, dwarfism, and webbing of the neck in patients with no gonadal tissue or rudimentary gonads (Fig. 65.6 A).
2. The chromosomal pattern of sex chromosomes is XO, which means there are 44 autosomes and one X chromosome (total 45 chromosomes).
3. It results from nondisjunction of one of the X chromosomes during oogenesis.
4. Usually, it presents with primary amenorrhea. No sexual maturation occurs at puberty.

Klinefelter’s Syndrome
This is the most common sex chromosome abnormality. The syndrome is otherwise called seminiferous tubule dysgenesis.
1. Typically, it is characterized by presence of feminine features in an apparent male with small testes (Figs. 65.6B).
2. The patient is genetically female, but the presence of an extra Y chromosome causes development of the testis. Therefore, the karyotype is 47 XXY (44 autosomes + XX sex chromosomes + one extra Y chromosome).
3. They have male genitalia and at puberty male characteristics develop due to adequate testosterone.
4. But, seminiferous tubules are not properly developed and therefore, infertility results.
5. Thus, the syndrome usually presents with primary hypogonadism and infertility in male. Mental retardation is common.

Superfemales
This is a common aberration of sexual differentiation. Usually, it is not associated with any characteristic abnormalities and therefore remains undetected. The abnormality is commonly diagnosed while performing chromosomal analysis for some other causes. The karyotype is XXX.

Testicular Feminization Syndrome
The patients appear normal females externally. At puberty though breasts develop normally, the growth of pubic and axillary hairs is scanty. It causes primary amenorrhea.
1. Though the external genitalia are of female type, there is no development of uterus. The vagina ends in a blind pouch.
2. The gonads are testis, with immature seminiferous tubules.
3. Therefore, it is called testicular feminization syndrome. Though testes are present, spermatogenesis does not occur. The patients are genetic males (XY karyotype).

True Hermaphroditism
This is a rare condition in which both testes and ovaries are present. Sometimes, ovary is present on one side and the testis on the opposite side. Both male and female sex differentiations occur with the development of combined

Figs. 65.6A and B: (A) Turner syndrome. Note the small breast, webbed neck and short stature in a female with this syndrome; (B) Klinefelter syndrome. Note the gynecomastia and small testis in a male with this syndrome.
female and male external and internal genitalia. Usually, the karyotype pattern is 46 XX-XY.

**Other Chromosomal Abnormalities**

Though other chromosomal abnormalities are not common, they do occur.

**Transposition of Chromosome**

Transposition of a part of one chromosome to another chromosome is possible. For example, genetic males may have XX chromosome pattern due to transposition of short arm of their father’s Y chromosome into the father’s X chromosome during meiosis. They receive X chromosome from their mother and transpositioned X chromosome from father.

**Deletion of a part of Chromosome**

Deletion of small portion of Y chromosome containing SRY gene occurs during meiosis. This results in females with XY karyotype.

**Nondisjunction of Chromosome**

Nondisjunction of chromosome 21 (an autosome) is not uncommon. This is called **trisomy 21**, which is associated with **Down’s syndrome or mongolism**. It is not an aberration of sex chromosome, rather an autosomal abnormality.

**Developmental Abnormalities**

The developmental abnormalities are mainly hormonal disorders. However, nonhormonal abnormalities are also encountered. The hormonal abnormalities are broadly divided into **pseudohermaphroditism** (both female and male patterns) and **enzyme deficiencies**.

**Pseudohermaphroditism**

A pseudohermaphrodite is an individual with genetic constitution and gonad of one sex, but the external genitalia of the other sex. There are male and female pseudohermaphroditism. In these conditions, the patients have normal gonadal development in accordance with their chromosomal sex, but afterward they develop heterosexual characteristics due to opposite hormonal excess.

**Female Pseudohermaphroditism**

Male external genital development occurs in **genetic females** exposed to androgen during 8th to 13th week of gestation.

1. Source of androgen is usually **congenital virilizing adrenal hyperplasia** of fetus or **virilizing ovarian tumor** of the mother.
2. Sometimes it may be **iatrogenically-induced** following treatment of mother with androgens or prophylactic drugs.
3. In a typical female pseudohermaphrodite, the individual possesses ovaries, oviducts, but there is varying degrees of **masculine differentiation of external genitalia**.
4. The chromosomal sex is female.

**Male Pseudohermaphroditism**

Development of female external genitalia in a **genetic male** is called male pseudohermaphroditism.

1. It is usually due to **defective testicular development**.
2. As MIS secreted from testis during early embryonic life prevents development of female gonads, in defective testicular development the internal genitalia are also of female pattern.
3. Male pseudohermaphroditism could also be due to **androgen resistance** that usually occurs in deficiency of 5α-reductase, the enzyme that forms dehydroandrosterone or due to defects in androgen receptors.
4. In **complete androgen resistance syndrome** (testicular feminizing syndrome), MIS is secreted as testes are normal; therefore, vagina ends blindly due to absence of internal genitalia.

**Enzyme Deficiencies**

Congenital **17α-hydroxylase deficiency** causes male pseudohermaphroditism. This also occurs in congenital adrenal hyperplasia in which enzyme defects block the formation of pregnenolone (for details, refer to Chapter 59, ‘The Adrenal Cortex’)

**CHAPTER SUMMARY**

**Key Concepts**

1. In males, the Y chromosome contains the **SRY gene** (sex-determining region of the Y), which encodes the **testis determining factor** (TDF). Another gene identical to SRY gene encodes a histocompatibility antigen known as **H-Y antigen**. Both these antigens are **involved in rejection of male tissue** by the female recipients. This H-Y antigen helps in **development of male gonads**, and masculinization.
2. Virilization of the genital duct and external genitalia requires the presence of an **androgen hormone receptor**. This receptor is encoded by the gene present on the X chromosomes. Therefore, X chromosomal gene also contributes to the development of maleness.
3. In the absence of a Y chromosome, SRY gene is absent. Therefore, TDF and H-Y antigen do not develop. Hence, instead of male gonads ovaries develop when both the sex chromosomes are X.

**Important to Know (Must Read)**

1. In examination, **Long Questions** are usually not asked from this chapter.
2. Mullerian inhibiting substance (MIS), Turner’s syndrome, Klinefelter’s syndrome, Pseudohermaphroditism, Testicular feminizing syndrome, Mechanism of sex differentiation in male, Mechanism of sex differentiation in female may be asked as **Short Questions** in exam.
3. In **Viva**, examiner may ask… How the genetic sex is determined in males and females, How the gonadal sex is determined in males and females, How the phenotypic (genital) sex is determined in males and females, What is called a genetic male and a genetic female? What are the methods for sex determination, What is MIS and what are its functions, What is the role of MIS in sex differentiation, What is SRY gene and what is its role, What is H-Y antigen and what is its role, List the chromosomal abnormalities, What are the features of Turner’s syndrome, What are the features of Klinefelter’s syndrome, What are the features of testicular feminizing syndrome, What is true hermaphroditism, What is pseudohermaphroditism and what are the types and features, What is superfemale, How the phenotypic sex development influences brain development.
Learning Objectives

On completion of study of this chapter, the student **MUST** be able to:
1. Understand the physiology of puberty in boys and girls.
2. Name the stages of puberty and the special features in each stage.
3. Understand the mechanism of onset of puberty.
4. Appreciate the physiological basis of causation of precocious puberty and delayed puberty.
5. Understand the mechanism of onset of menopause.

The student **MAY** also be able to:
1. Describe the mechanism of onset of puberty, and physiological basis of changes at puberty.
2. Explain the physiological basis of puberty abnormalities.

Puberty is the physiological phenomenon of attainment of sexual maturity. The ability to reproduce is attained with puberty and ceased with menopause. In females, reproducibility totally stops at menopause, whereas in males reproducibility continues.

**Puberty**

**Definition**

The period of transition from the non-reproductive state to the state of reproductive functions that allows procreation is defined as puberty. During this period, the hypothalamic-pituitary-gonadal axis is activated to bring the gametogenic functions of the gonads to their threshold of reproductive maturation.

1. Normally, gonads of both genders remain quiescent until the onset of puberty. Under the influence of gonadotropins secreted from pituitary, maturation of gonads occurs that in turn helps in maturation of the reproductive system.
2. This period of maturation is known as puberty or adolescence. During this period, the endocrine and gametogenic functions of the gonads first develop to the point where the reproduction becomes possible.

**Age and Initiating Stimulus**

**Age of Onset of Puberty**

The age of onset of puberty varies depending on various factors like socioeconomic and environmental conditions and genetic constitutions. In general, in developed countries, puberty occurs earlier than in the developing countries. In advanced nations, it occurs between the age of 8–13 in girls and 9–14 in boys. In developing nations, the age of onset of puberty is **11–16 years in girls** and **13–18 years in boys**.

**Initiating Stimulus**

The increased secretion of adrenal androgen, called adrenarche, occurs about 1 to 2 years before the onset of puberty.

1. This **increased adrenal androgen** is believed to stimulate the production of gonadal hormones that cause maturation of reproductive organs. As increase in adrenal androgen at this stage occurs without any alteration in ACTH or cortisol secretion, it is proposed that this is the primary and sole stimulus that heralds puberty.
2. One hypothesis suggests that increased secretion of adrenal androgen before puberty occurs due to secretion of **adrenal androgen stimulating hormone** (AASH) from pituitary. But actual nature and mechanism of it are not known.
**Stages of Puberty**

**In Boys**
The pubertal development in males occurs in five stages (by **Tanner method**, modified). Usually it is completed within 2 to 4 years from its onset.

**Stage 1**
This is the preadolescent stage. There is no enlargement of external genitalia (penis, scrotum and testes). No pubic hair is present. However, secretion of adrenal androgen is increased (**adrenarche**).

**Stage 2**
Testes enlarge to more than 2.5 cm, which occurs due to growth of seminiferous tubules.
1. Though this occurs due to the secretion of adrenal androgen (**adrenarche**), testicular androgen also contributes.
2. Testicular testosterone secretion increases significantly.
3. Pubic hairs appear in scanty at the root of the penis.

**Stage 3**
Penis enlarges in length. Scrotum and testes are further enlarged. **Pubic hairs become darker and coarser** above the pubis. **Sperm first appears** in the morning sample urine (**spermarchy**).

**Stage 4**
Penis enlarges in width and further in length. Scrotal and testicular enlargement continues. Pubic hair becomes adult type. **Ejaculation of sperm** occurs either in dreams, or on masturbation or by sexual act.

**Stage 5**
Full adult pattern of sexual features develops.

**In Girls**
The pubertal development in females also described in five stages (by **Tanner method**, modified). Usually, it is completed within 2 to 5 years from its onset.

**Stage 1**
This is the preadolescent stage. There is no breast development. No pubic hair is present. However, secretion of adrenal androgen is increased (**adrenarche**).

**Stage 2**
Breast development starts (**thelarche**). **Breast paillae is elevated** and the diameter of areola is increased. Secretion of estrogen from ovary increases significantly. Sparse hairs appear along the labia majora.

**Stage 3**
Breast enlarges with enlargement of areola. **Pubic hairs develop**, grow and become dark (**pubarche**). Hairs appear in axilla.

**Stage 4**
Breast further enlarges with areola and papillae projecting out of it. Pubic hair becomes adult type, but covers smaller area. **Menstrual cycle starts** (**menarche**), but irregular at the beginning.

**Stage 5**
Full adult pattern of breasts and pubic hairs develop. Menstrual cycle occurs regularly.

**Mechanism of Onset of Puberty**
The hypothalamic neurons gradually mature to **secrete more GnRH**. This maturational process is genetically preprogrammed.
1. Dehydroepiandrosterone secreted from adrenal gland plays some role in the maturation of hypothalamic neurons.
2. The adipose tissue via secretion of **leptin** also plays some role in the determination of the time of onset of puberty (see below).
3. Normally, the secretion of GnRH, LH and FSH is not pulsatile before the onset of puberty. It is clear that until puberty the release of GnRH is non-pulsatile, which prevents puberty to occur.
4. It is not known what mechanism inhibits the **GnRH pulse generator** till puberty. However, before puberty, the GnRH is secreted in a pulsatile pattern that stimulates pulsatile secretion of LH and FSH.
5. It is proposed that this pulsatile secretion of GnRH brings about the onset of puberty. This theory is supported by the fact that experimental pulsatile injection of GnRH in immature monkeys produces normal menstrual cycle and the cycles continue till the pulsatile injection continues.

**Role of Leptin**
It has been observed that **body weight increases to a critical level** before the onset of puberty, especially in females. It is also observed that the onset of puberty is **delayed in girls with lower body weight**.
1. Leptin, the hormone secreted from adipose tissue cell is believed to help in the **maturation of hypothalamic-gonadal axis**.
2. This is supported by the experimental evidence that injection of leptin in female mice results in precocious puberty.
3. But, the exact role of leptin in the control of puberty is not known.
Abnormalities of Puberty

Abnormalities of puberty can be broadly classified into precocious puberty and delayed puberty.

Precocious Puberty

Precocious puberty may be of two types: true precocious puberty and precocious pseudopuberty.

True Precocious Puberty

Early development of secondary sexual characteristics, may be associated with premature development of gonads is known as true precocious puberty. Precocious puberty can occur in both girls and boys. This occurs due to early pubertal pattern of secretion of gonadotropin from pituitary.

True precocious puberty occurs due to following causes:
1. **Hypothalamic precocity:** Usually occurs due to tumor or infection of hypothalamus that causes premature increased secretion of GnRH.
2. **Gonadotropin independent precocity:** Precocious gametogenesis without increase in gonadotropin secretion. Usually, it occurs due to increased sensitivity of LH receptors to gonadotropins.
3. **Constitutional precocity:** When the actual cause of precocity can not be ascertained.
4. **Tumor of pineal gland.**

Precocious Pseudopuberty

The development of secondary sexual characteristics without gametogenesis is called as precocious pseudopuberty. This occurs due to exposure of immature males to abnormal quantity of androgen, and in immature females the abnormal exposure to estrogen.

Precocious pseudopuberty occurs due to following causes:
1. **Adrenal causes:** Congenital virilizing adrenal hyperplasia can lead to precocious pseudopuberty. Androgen secreting or estrogen secreting tumors of adrenal gland resulting in precocious pseudopuberty are not uncommon.
2. **Gonadal causes:** Leydig cell tumor of testis in male or granulosa cell tumor of ovary in females can cause precocious pseudopuberty.

Delayed Puberty

When onset of puberty is delayed beyond the age of 17 in girls and 20 in boys, the condition is called delayed puberty.

1. It occurs usually due to panhypopituitarism that causes failure of maturation of gonads.
2. It is also associated with chromosomal abnormality of XO pattern or gonadal dysgenesis.
3. Puberty may be delayed in spite of presence of normal gonads, which is called eunuchoidism in males and primary amenorrhea in girls.

MENOPAUSE

With advancement of age, gonadal functions gradually decrease. In females, ovaries become unresponsive to the gonadotropins. The functions of gonads slowly decrease finally resulting in complete cessation of menstrual cycle. This is called menopause or climacteric.

Mechanism and Features

Mechanism of Menopause

The mechanism and purpose of menopause are not clear. The female gonads progressively become unresponsive to gonadotropins with advancing age. The mechanism by which ovarian responsiveness decreases is not known. Ovaries stop secreting progesterone and estrogen in appreciable amount. The **negative feedback effect** of ovarian hormones causes increased secretion of luteinizing hormone (LH) and FSH. The uterus and vagina become atrophic.

Age at Menopause

1. **In women,** onset of menopause occurs between the age of 45–55 years. In recent years, the age at menopause has gradually increased.
2. **In males,** though there is some decline in reproductive capacity from 5th decade of life, climacteric does not occur. Testicular functions and potency persist till 8th decade. Thus, in males, there is no andropause (male menopause).

Features of Menopause

Hot flushes (sensation of warmth spreading from trunk to the face) occur frequently. Night sweating, tachycardia, mental symptoms are also observed.

1. The mechanism of hot flushes is not exactly known but it coincides with the **surges of LH secretion.**
2. With the onset of menopause, LH secretion is increased, which occurs in episodes of 30–60 minutes. This is called circhoral secretion of LH.
3. Each hot flush coincides with an episode of LH surge. However, experimental evidences indicate that hot flushes are not due to episodic secretion of LH per se.
4. The decreased secretion of estrogen triggering some hypothalamic mechanism is proposed to cause both episodic secretion of LH and hot flushes.

Management of Menopause

The fear that the women will lose her womanhood may cause psychological depression.
1. It needs proper care, counseling and assurance of the spouse to make her understand and adjust to this physiological phenomenon of the nature.
2. In some cases, hot flushes and psychological symptoms become more problematic. In such women, hormonal supplementation of estrogen is usually helpful.
3. However, metabolic and other complications of estrogen should be kept in mind while continuing estrogen therapy for a longer period.

### CHAPTER SUMMARY

#### Key Concepts

1. Increased secretion of adrenal androgens (adrenarche) sensitizes hypothalamo-pituitary-gonadal axis for pubertal changes. Dehydroepiandrosterone secreted from adrenal gland plays some role in the maturation of hypothalamic neurons, and GnRH secretion becomes pulsatile. **Pulsatile secretion of GnRH** brings about the onset of puberty.
2. Reproducibility totally stops at menopause, whereas in males reproducibility continues. Therefore, the male menopause is not definitive.

#### Important to Know (Must Read)

1. In examination, **Long Questions** are usually not asked from this chapter.
2. Precocious puberty, Stages of puberty in boys and girls, Mechanism of onset of puberty, Mechanism, features and management of menopause may be asked as **Short Questions** in exam.
3. In **Viva**, examiner may ask… Define puberty, What is the age of onset of puberty in boys and girls, What are the stages of puberty in boys, What are the stages of puberty in girls, Explain the mechanism of onset of puberty, What is true precocious puberty and what are its causes, What is precocious pseudopuberty and what are its causes, What is delayed puberty, What is menopause, What is the mechanism of menopause, What is the age of menopause, What are the features of menopause, How menopause can be managed.
CHAPTER 67
Male Reproductive System

LEARNING OBJECTIVES
On completion of study of this chapter, the student MUST be able to:
1. Name the different parts of male reproductive system, and give the functions of each.
2. List the functions of Sertoli cells and Leydig cells.
3. Understand the importance of blood-testis barrier in testicular functions.
4. Name the steps of spermatogenesis and describe the mechanism and regulation of spermatogenesis.
5. Understand the importance of semen analysis.
6. List the testicular hormones and describe the functions of testosterone.
7. Name the secondary sex characteristics in males.
8. Understand the regulation of testicular functions.
9. Understand the physiological basis of testicular abnormalities.
The student MAY also be able to:
1. Describe the regulation of testicular functions and hypothalamo-pituitary-gonadal axis in males.
2. Describe the stages and mechanisms of spermatogenesis.
3. Explain the physiological basis of reproductive abnormalities in males.

The primary objective of the male reproductive system is to produce healthy sperms capable of fertilizing the ovum. The main specialty of male reproduction is that the male gametes are produced in millions and after puberty the process of production is a continuous phenomenon.

Scientist contributed
Enrico Sertoli (1842–1910) an Italian physiologist and histologist was a professor of anatomy and physiology at the Royal School of veterinary medicine in Milan, and after 1907, he worked only as a professor of physiology there. In Milan, he founded the laboratory of experimental physiology. He worked extensively on reproductive physiology. He is remembered for his 1865 discovery of the eponymous Sertoli cell that provide nourishment and support for developing sperm.

FUNCTIONAL ANATOMY
The male reproductive system consists of testes, epididymis, vas deferens, ejaculatory ducts, prostate, urethra, and penis. They have two important functions, spermatogenesis (formation of spermatozoa) and steroidogenesis (synthesis of testosterone). Spermatozoa produced by testes enter the epididymis from where they pass into the vas deferens (Fig. 67.1). Epididymis and proximal part of vas deferens store sperms. At the time of ejaculation, sperms enter into the urethra in the body of prostate through the ejaculatory duct and via urethra they come out of the genital tract.

The Testes
In human beings, testes are located in scrotum. During intrauterine life, testes are placed in the abdominal cavity beneath the posterior abdominal wall. Gradually they descend down to the inguinal canal during mid-pregnancy. During two months before term, they descend further through the inguinal canal into the scrotum (Application Box 67.1).

Application Box 67.1
Separate domicile for male gonad: Testes are the male gonads that are placed in separate sacs almost hanging away from the body. In female, the gonads (ovaries) are well preserved in the abdominal cavity. Then, why has the nature provided separate external compartments for male gonads? Scrotum is the sac, which keeps testis at about 2–3°C below the core body temperature and this cooler environment is highly favorable for spermatogenesis.
The scrotal temperature is cooler than core body temperature for the following reasons:

1. **Anatomical location:** Scrotum forms sacs that are like outpouching from the body, which has less direct transmission of the inner body temperature into it. Testes being placed in the scrotum avails scrotal temperature.

2. **Pampiniform plexus of the blood vessels:** Theseplexuses of blood vessels serve as counter-current exchanger between warm arterial blood entering the testes and cooler venous blood leaving the testes (Fig. 67.2).

3. **Role of cremasteric & darto muscles:** Cremaster muscle is a small band of skeletal muscle present in the spermatic cord that contracts or relaxes in response to change in environmental temperature.
   - It contracts on exposure to sever cold and elevates the testis and relaxes in warm environment and lowers the testis.
   - Also, a flap of smooth muscle is present in the fascial layer of scrotum, called darto muscle, which contracts on exposure to cold. This increases wrinkling of scrotal skin and facilitates lifting of the testis.
   - Thus, cremasteric and darto muscles on exposure to cold push testes close to the pelvic cavity where they can absorb body heat, and pull them away from the body in hot environment. Therefore, these muscles prevent temporary sterility in extreme weathers.

Weight of each testis is about 10–15 grams, length 5 cm and width 2.5 cm in adults. Testes receive blood supply from the spermatic arteries that originate directly from the aorta. Functional Histology of Testis

Testes are covered by thick connective tissue membrane called tunica albuginea. Each testis is made up of seminiferous tubules. Hundreds of tubules are tightly packed to from a mass of coiled loops (Fig. 67.3).

1. Each loop begins and ends in a single duct called tubulus rectus, which in turn drains into the epididymis.
Section 7: Reproductive System

2. Tubules are arranged in lobules separated by septa formed by extensions of tunica albuginea. Each tubule is about 50 cm long and 250 µm in diameter.

3. **Myoid cells** are present surrounding the basal lamina of the seminiferous tubules and **interstitial cells of Leydig** are present in the space between the seminiferous tubules (Fig. 67.4).

4. Thus, testis consists of seminiferous tubules and interstitium that mainly contains Leydig cells, connective tissues and capillaries, and few myoid cells and fibroblasts.

Seminiferous Tubule

Each seminiferous tubule has a basement membrane that separates it from the surrounding Leydig cells, the peritubular cells (myoid cells) and the connective tissue.

1. Spermatogonia and Sertoli cells are located in the wall of the tubule just beneath the basement membrane (Fig. 67.5).

2. There are **two principal cell types** in seminiferous tubules: somatic cells (**Sertoli cells** and **germ cells**) (Fig. 67.6).

Sertoli Cells

Sertoli cells are the sustentacular cells in seminiferous tubules, which form the major cell mass in them.

Structure of Sertoli cells

They are irregularly shaped cells that are extended from the basement membrane into the lumen of seminiferous tubule. Sperms are attached to the apical membrane of...
the Sertoli cells. At their bases, Sertoli cells are attached to each other by tight junctions. Tight junctions divide tubules into two compartments: basal compartment and adluminal compartment (Fig. 67.7).

**Basal Compartment**
The basal compartment is the outer compartment that mainly consists of spermatogonium. It is exposed to circulating substances as the capillaries are in close contact with it and substances from blood can easily be exchanged.

**Adluminal Compartment**
Adluminal compartment is the inner compartment that consists of primary and secondary spermatocytes and spermatids. It is separated from blood-borne agents by the tight junctions between the Sertoli cells close to basal lamina.

**Blood-Testis Barrier**
Because, the tight junctions between Sertoli cells are too tight (Fig. 67.7), they do not allow substances from interstitial space and blood to pass through them except steroids and few proteins. Thus, **tight junction between Sertoli cells near the basal lamina** forms the blood-testis barrier (BTB).

1. The BTB prevents the large molecules to be transported from interstitial tissue and basal compartment to the interior of the tubule (adluminal compartment).
2. However, maturing germ cells pass through BTB to enter into adluminal compartment. If maturing spermatocytes can pass through the BTB one could easily doubt the veracity of the barrier.
3. The proposed explanation is that when spermatocytes attempt to penetrate the barrier, the tight junction in front of them dislocate and give way for them, and immediately after the spermatocytes pass through the tight junctions the new tight junctions are concomitantly formed behind them.
4. Thus, physiologically, maturing germ cells pass through BTB without actually disrupting it.

**Functions of BTB:**
1. BTB protects germ cells in the seminiferous tubules from harmful elements in blood.
2. Antigenic elements are produced by germ cells during their growth and multiplication, which are capable of inducing immunological reactions in the body. BTB prevents these antigenic products to escape into circulation from tubule and thus prevents autoimmune reactions.
3. BTB maintains the composition of the fluid in the lumen of seminiferous tubules. The tubular luminal fluid contains less protein and glucose as they do not pass from blood through the BTB. However, it is rich in androgens, estrogens, K⁺, inositol, glutamic and aspartic acids.
4. BTB maintains higher osmolality of luminal content of the seminiferous tubules, which favors the osmotic movement of fluid into the tubular lumen.

**Functions of Sertoli Cells**
Sertoli cells have multiple functions. Important among them are:

1. **Germ cell development:** Sertoli cells are critical to germ cell development. They provide structural support and nutrition to germ cells. Sertoli cells are rich in glycoproteins that nourish the germ cells.
2. **Phagocytosis:** Sertoli cells phagocytose residual bodies and damaged germ cells from the seminiferous tubules. Residual bodies are cytoplasmic fragments formed by excess cytoplasm resulting from transformation of spermatids to spermatozoa.
3. **Nourishment and growth of spermatids:** They nourish the developing spermatids. About 10 to 12 spermatids are attached to each Sertoli cells. Sertoli cells synthesize transferrin, an iron-transport protein that helps in development of sperms.
4. **Formation of tubular fluid:** They secrete fluid into the lumen of seminiferous tubule. This fluid later forms the major components of seminal fluid.
5. **Support spermiation:** This is the process of detachment of mature sperms from Sertoli cells into the lumen. In this process, plasmin, the proteolytic enzyme assists in release of sperms from Sertoli cells. Sertoli cells produce plasminogen activator that causes formation of plasmin.

6. **FSH and testosterone sensitivity:** Sertoli cells have receptors for FSH and testosterone. FSH receptors are present on the cell membrane and testosterone receptors are present within the nucleus. During puberty, receptors for these hormones on Sertoli cell increase. FSH increases cAMP in Sertoli cells and induces production of androgen-binding protein (see below) and plasminogen activator in Sertoli cells. These chemicals help in sperm development.

7. **Endocrine functions of Sertoli cells:** Sertoli cells secrete many hormones. These are:
   i. **Inhibin:** Inhibin suppresses FSH release from pituitary.
   ii. **Activin:** Activin stimulates release of FSH.
   iii. **Follistatin:** It decreases FSH secretion stimulated by activin.
   iv. **Müllerian regression substance:** During 8th week of gestation MIS is secreted from fetal Sertoli cells. MIS causes regression of müllerian duct in fetuses destined to become males.
   v. **Estrogens:** Sertoli cells contain the enzyme aromatase that converts androgen into estrogen.

8. **Secretory functions:** Sertoli cells secrete androgen binding proteins (ABP) and H-Y antigen. ABP maintains concentration of androgen in Sertoli cells, which is essential for maturation of spermatozoa. H-Y antigen is secreted by Sertoli cells during fetal life that controls development of testis.

**Androgen binding proteins (ABP):** Sertoli cells secrete and synthesize ABP, a protein having molecular weight 90,000 into the luminal fluid. ABP has high affinity for binding dihydrotestosterone and testosterone. It is present in high concentration in luminal fluid. A high concentration of androgen in luminal fluid is essential for production and maturation of spermatozoa. ABP maintains this concentration of androgen in luminal fluid. It helps in storage of androgen in seminiferous tubule and facilitates transport of testosterone from testis to epididymis.

9. **Blood-testis barrier:** Sertoli cells provide the blood-testis barrier (BTB) for the seminiferous tubules. Thus, they protect the developing sperms from harmful effects of blood-borne toxins. Other functions of BTB are discussed above.

**Germ Cells**

Germ cells are germinal epithelial cells of seminiferous tubules. Each germ cell is a spermatogonium that forms spermatocytes and spermatozoa in the process of its development, i.e., spermatogenesis (see below).

**Leydig Cells**

Leydig cells are primary cells of steroidogenesis. They produce testosterone.

**Scientist contributed**

Franz von Leydig, also known as Franz Leydig (1821–1908), a German zoologist and comparative anatomist discovered Leydig cells in 1850. Leydig cells are named after him.

**Location**

Leydig cells are present near the capillaries in the interstitial space between seminiferous tubules.

**Structure**

They are rich in mitochondria and endoplasmic reticulum. The activity of Leydig cells is different in different phases of life.

**Functions**

Leydig cells mainly secrete testosterone. However, dehydroepiandrosterone and androstenedione are also secreted to some extent.

**Leydig Cells Activity in Different Phases of Life**

1. **During 8-15 weeks of intrauterine life,** Leydig cells are active and prominent as steroidogenesis is essential for differentiation of male genital ducts. During this period, as hypothalamo-pituitary gonadal axis is not fully formed, steroidogenesis is controlled by hCG, not by LH.
2. **Thereafter,** Leydig cell activity decreases. In male infants, during 3–5 months of postnatal life, Leydig cell activity increases significantly that results in increased testosterone secretion. The physiological significance of this infantile testosterone surge is not known.
3. Leydig cells then remain dormant till puberty. At the **onset of puberty,** activity of Leydig cells in males attains maximum.
4. After puberty, Leydig cell activity decreases, but maintains at a basal rate till senescence.

**Regulation of Leydig Cell Activity**

Leydig cells have receptors for LH.

1. **LH controls Leydig cell steroidogenesis by cAMP-dependent mechanism.**
2. Leydig cells do not have receptors for FSH. However, FSH indirectly controls Leydig cells activity. FSH stimulates Sertoli cells to produce growth factors, which in turn promote the growth of Leydig cells.
3. **Leydig cell activity is stimulated by androgen and inhibited by estrogen.**

**Interaction of Leydig cells with Sertoli cells**

Sertoli cells do not produce testosterone, but have receptors for it. **Testosterone secreted from Leydig cell enters**
**Chapter 67: Male Reproductive System**

**Sertoli cells** where it binds with the ABP. This testosterone is essential for three important functions:
1. **Spermatogenesis**
2. Functioning of Sertoli cells
3. Estrogen production in Sertoli cells. Estrogen produced in Sertoli cells diffuses back into the Leydig cells and regulates Leydig cell function (Fig. 67.8).

**Functions of Testis**
Testis serves three important functions.
1. **Spermatogenesis**, i.e., production of sperms (see below)
2. **Steroidogenesis**, i.e. synthesis of steroid hormones, mainly testosterone, which is later, converted to dihydrotestosterone and estradiol (see below).
3. Testis secretes other hormones like activin, inhibin and follistatin that influence many other reproductive functions.

**Epididymis**
Seminiferous tubules open into a network of tubules, called rete testis. Rete testis opens into epididymis via efferent ductules.

**Structure**
Epididymis is located on the posterior aspect of the testis. It contains a highly convoluted long duct, which is about 5 meter in length. Epididymis is divided into three parts: head (the part close to testis), body and tail (Fig. 67.9).

**Function**
The function of epididymis is the storage and maturation of spermatozoa (Application Box 67.2).
1. About 99% of testicular fluid is reabsorbed in the epididymis and rete testis. Spermatozoa from tubular fluid and rete testis are transferred to epididymis almost passively as they are essentially immotile.
2. In epididymis, they acquire the capacity for progressive forward movement and the ability to attach to zona pellucida of ovum and penetrate into it.
3. Thus, the sperms obtained directly from testis are functionally immature, whereas sperms obtained from body of the epididymis or further down in the male genital tract are fertile.

**Application Box 67.2**
Fate of stored spermatozoa: Spermatozoa are carried from epididymis via vas deferens and ejaculatory duct into the urethra in penis to be removed out of it at the time of ejaculation. The fate of sperms that are not voided through ejaculation is not clearly known. It has been suggested that these sperms are ultimately phagocytosed by macrophages in the epididymis or voided slowly in urine. However, in Indian spiritual scriptures, it has been noted that sperms in the body are converted into vital energy, which can be further transformed into spiritual energy if properly utilized with the help of higher spiritual forces. Therefore, in practice of yoga, it has been advised to conserve and properly utilize the energy of the semen.

**Vas Deferens**
Epididymis empties its content into the vas deferens (Fig. 67.9), which transfers sperms further down in the duct.
1. Proximal part of vas deferens like epididymis stores the sperms.
2. Vas deferens joins with the duct arising from seminal vesicle to from the ejaculatory duct.
3. The movement of sperm in vas deferens is active as they are capable of motility.
4. However, contraction of muscle in the wall of vas deferens facilitates the process of sperm movement.
Section 7: Reproductive System

Seminal Vesicle

There are two seminal vesicles located close to the prostate. They secrete a viscid and alkaline fluid called seminal vesicular fluid.
1. Seminal vesicular fluid contributes to 70% of the total volume of the semen.
2. Rest 20% of the volume is contributed by epididymal fluid and fluid secreted from accessory sex glands, and 10% is contributed by sperms.
3. The seminal vesicles secrete vitamin C and fructose. The fluid appears yellowish as it contains flavins.
4. Most of the prostaglandins found in semen are contributed by seminal vesicle.

Accessory Sex Glands

Accessory male sex glands are prostate gland and bulbourethral glands of Cowper.

The Prostate Gland

The ejaculatory duct enters the prostatic portion of the urethra after passing through the prostate.
1. Prostate gland consists of 30–50 branched tubuloalveolar glands whose secretions empty into prostatic urethra.
2. The prostatic fluid contains fibrinolysin, fibrinogenase and large quantity of acid phosphatase. Fibrinolysin prevents sperm heads to clump.
3. Prostate gland also releases a factor, which contains sugar, sulfate and vitamin E derivative that also prevents sperm head to cluster.

Bulbourethral Glands

They secrete mucus and alkaline fluid. They also secrete the enzyme hyaluronidase that facilitates penetrability of oocytes by sperms.

SPERMATOGENESIS

Definition and Course

The process of development of male germ cells into spermatzoa is known as spermatogenesis. The primordial germ cells migrate into the gonad during embryogenesis. These cells later become immature germ cells, called as spermatogonia. Spermatogonia are located attached to the basement membrane of the semiferous tubule. From puberty onwards, these cells divide mitotically to continuously supply spermatocytes that form spermatooza.

Course of Spermatogenesis in Life: Spermatogenesis begins at puberty. The germ cells remain inactive throughout childhood.
1. At puberty, under the influence of increasing level of gonadotropins and testosterone, the germ cells are activated and spermatogenesis is initiated.
2. From puberty onwards, spermatogenesis continues throughout life, though the process declines at old age.

Steps of Spermatogenesis

The process of spermatogenesis can be divided into three distinct phases: Mitosis, meiosis and spermiogenesis (Flowchart 67.1). Spermatogonium undergoes mitosis to produce primary spermatocytes that undergo two meiotic divisions to form spermatids. Spermatids, by the process of spermiogenesis become mature spermaatoza.

Mitosis

The primitive germ cells (spermatogonia) that are present in the basal lamina of seminferous tubules undergo mitotic divisions to from primary spermatocytes. This is called spermatocytogenesis (Fig. 67.10). In fact, the spermatogonia undergo many mitotic divisions to produce two types of spermatogonia: spermatogonia A and spermatogonia B.

Spermatogonia A: Spermatogonia A formed by mitotic divisions resemble the original spermatogonia and are the source of subsequent spermatogonia in the testis. Thus, they form the spermatogonia reserve pool in the testis.

Spermatogonia B: Spermatogonia B grow and enter adluminal compartment where they develop into primary spermatocytes.

Meiosis

The primary spermatocytes (diploid 4N DNA) undergo two meiotic divisions.
1. The first meiotic division forms secondary spermatocytes (haploid 2N DNA) and the second meiotic division forms spermatids (haploid 1N DNA).
2. Spermatids contain half of the number of chromosomes (23 chromosomes, i.e., 22 autosomes and 1 sex chromosome, which is either an X or a Y chromosome).
Chapter 67: Male Reproductive System

3. Of every four spermatids formed from primary spermatocytes, two of them contain X chromosome and two Y chromosomes.
4. Normally after undergoing several mitotic and two meiotic divisions in the process of spermatogenesis, each spermatogonium yields 512 spermatids.

Spermiogenesis

The process of development of spermatids into matured spermatozoa is called spermiogenesis. Spermatids are small, round and less characteristic cells. They undergo many structural changes to form spermatozoa (Fig. 67.10). The major changes are:

1. **Massive reduction in cytoplasm.** Cytoplasmic fragments are discarded as residual bodies.
2. **Elongation of the nucleus** to become head of spermatozoa.
3. Acquirement of an upper covering for the head called **acrosomal cap**.
4. Formation of a **middle piece and a tail piece** with the ability to move efficiently and swiftly.

All these changes occur in mature sperms to enable them to survive in a foreign and even hostile environment (**acidic vaginal pH**) in the female genital tract and to recognize and fertilize the ovum. These changes mainly help the sperm to move forward towards the ovum in the female genital tract, the movement known as **progressive motility** of the sperm.

Spermiation

Spermatozoa, after they are formed, remain in the lumen of the seminiferous tubule sticking to the apical membrane of the Sertoli cells. They **adhere tightly to the Sertoli cells.** The process of **detachment of head of spermatozoa and their free release** into the luminal fluid is called spermiation.

**Flowchart 67.1: Steps of spermatogenesis.** Note, till the stage of primary spermatocyte, each cell contains 46 chromosomes and from secondary spermatocyte to spermatozoa, each cell contains 23 chromosomes (number indicated against each category of cells as 46 chromosomes and 23 chromosomes in bracket).
Capacitation

When spermatozoa are ejaculated into the female genital tract, they undergo further maturation called capacitation. This includes increase in further motility of sperms and preparation for acrosomal reaction. However, capacitation is not so much essential for fertilization as fertilization can also occur in vitro.

Structure of Spermatozoa

A matured sperm is a motile cell rich in DNA, consisting of head, middle piece and tail (Fig. 67.11). A human sperm is about 65 µm long with average diameter of 2 µm.

Head

Head contains a prominent nucleus at the center, which is condensed with chromatin. The head is covered by a cap called acrosome, which is formed from Golgi apparatus. Acrosome is like a lysosome rich in proteolytic enzymes such as hyaluronidase, acrosin, neuraminidase and esterases that are activated during acrosomal reaction and help in sperm penetration of the ovum at the time of fertilization. The nucleus decondenses and becomes a pronucleus at the time of fertilization.

Middle Piece

The middle piece of sperm contains numerous mitochondria in the form of a spiral sheath surrounding a long axial filament made up of microtubules (9 + 2 arrangement; i.e., nine peripheral doublet surrounding a central pair) is typical that of cilia and flagella. Therefore, the tail portion is highly motile.

1. The tail of the sperm exhibits a twisting movement by which it propels the body of the sperm in forward direction. The twisting movement occurs due to the interaction between tubulin fibers and dynein side arms, which requires ATP.

2. The axoneme is surrounded by a fibrous sheath that provides strength to the tail. The membrane of the sheath contains germinal angiotensin converting enzyme. The exact function of this enzyme is not known but reduction of this enzyme concentration is suggested to be associated with decreased fertility.

Role of CatSper protein: The principal piece of tail contains a protein called CatSper protein, which is a calcium channel. This allows cAMP mediated calcium influx and facilitates sperm motility.

Duration of Spermatogenesis

In human beings, the process of formation of sperm from the spermatogonium takes 65–74 days. Sometimes, the stages of development of sperms are collectively called spermatogenic cycle. Each stage has a relatively constant duration:

1. Spermatogonia to primary spermatocytes is 16–20 days.
2. Primary spermatocytes to secondary spermatocytes is 23–25 days.
3. Secondary spermatocytes to spermatids is approximately 1 day.
4. Spermatids to spermatozoa is about 25 days.

Hormones like gonadotropins or androgen influence the number of spermatozoa produced, but not the duration of the cycle. Thus, the duration of spermatogenesis remains virtually constant. Normally, new cycles are initiated in every 2 to 4 weeks before the completion of old cycle. Therefore, in the tubules, cells of different stages are seen at any particular time. This ensures uninterrupted supply of spermatozoa throughout life.
Rate of Production of Sperms

A single spermatogonium forms 512 spermatids, if all of them remain alive.
1. Approximately, 200 millions of sperms are produced daily in an adult testis in humans. This is roughly same as the number of sperms in an ejaculate in a normal healthy adult. Expressed per unit weight of testicular tissue, about 6–7 million sperms are produced per gram per day.
2. The rate of production of sperms falls progressively in old age. After the age of 50, the rate of sperm production is 3.5–4 million per gram of tissue.
3. The decrease in production in elderly is due to degeneration of germ cells during meiotic prophase. However, appreciable spermatogenesis continues even at the age of 90.

Differences between Spermatogenesis and Oogenesis

There are few basic differences in the process of gametogenesis in females and males. These are:
1. In females, mitotic proliferation of germ cells completes before birth, whereas in males, spermatogonia grow only at the time of puberty and then continue to proliferate throughout life.
2. In female, the meiotic division of primary oocyte produces only one ovum, whereas in males one primary spermatocyte produces four spermatozoa.
3. In female, second meiotic division is completed only upon fertilization, whereas in males second meiotic division is completed during spermatogenesis.

Factors Controlling Spermatogenesis

Factors controlling spermatogenesis can be broadly divided into two categories: hormonal and environmental.

Hormonal Factors

Androgen, estrogen and gonadotropins mainly control spermatogenesis.
1. Androgen: Androgens stimulate spermatogenesis. LH creates an elevated local concentration of androgen in the testis by stimulating Leydig cells to secrete testosterone, and this high intertesticular testosterone is essential for spermatogenesis.
   - Testosterone secreted from Leydig cells diffuse into the seminiferous tubule. In tubule, only the Sertoli cells (not spermatogenic cells), have receptors for testosterone.
   - Testosterone binds with ABP in the Sertoli cells (Fig. 67.8), which maintains a high concentration of testosterone in the cell. However, it is not clearly known how testosterone promotes spermatogenesis.
   - It appears that, till the formation of spermatid does not depend on androgen, rather spermiogenesis (spermatids developing to spermatozoa) is androgen dependent.
2. Estrogen: Estrogen content of the fluid in the rete testis is high and there are estrogen receptors in the rete testis. Rete testis reabsorbs fluid and makes the spermatozoa concentrated, which is required for sperm maturation. The diluted volume of large fluid that enters rete testis and epididymis unless absorbed adequately results in infertility. Estrogen concentrates the fluid by facilitating fluid reabsorption.
3. LH and FSH: LH helps in spermatogenesis by producing a high local concentration of androgen. FSH maintains gametogenic functions of testis. It appears that FSH is required for initiation of spermatogenesis at the time of puberty, and then LH maintains it.

Environmental Factors

It is mainly the temperature that influences spermatogenesis. Lower environmental temperature facilitates spermatogenesis. Spermatogenesis best occurs at 30 to 35°C. However, very low temperature inhibits it. Conversely, increased temperature inhibits spermatogenesis. Therefore, in persons taking repeated hot bath or those who regularly use insulated athletic support for the scrotum, sperm count is invariably less. Generally, sperm count is more in comfortable winter and less in intense summer.

Semen Analysis

Semen analysis is one of the important tests for assessment of male fertility. It is performed to know if the sterility is related to sperm production. It is also performed after vasectomy, to check its completeness. It reflects the activity of the testes and accessory sex organs in males.

Analysis of freshly collected sample of semen gives the knowledge about the male fertility which is detected by examining the sample under microscope. Usually, the sample is collected after a period of sexual abstinence for 2 days.

Composition of Normal Semen

| Volume | 2 to 5 mL |
| Color | White, opalescent |
| Specific gravity | 1.028 |
| Motility | > 60% should be actively motile within 3 h of collection |
| Count | > 40 millions/mL is considered normal (usually, 100 millions/mL is seen normally) |
| Liquefaction | Should liquefy within half-an-hour |
| Morphology | > 80% should have normal morphology |
| pH | 7.3 to 7.5 |
| Fructose content | Fructose concentration is 2–7 mg/mL |
| Other biochemical constituents: | 1. Prostaglandins |
| | 2. Ascorbic acid |
| | 3. Flavins |
| | 4. Phosphorylcholine |
Section 7: Reproductive System

5. Ergothioneine
6. Fibrinolysin, fibrinogenase
7. Acid phosphatase
8. Zinc
9. Phospholipids
10. Cholesterol
11. Spermin
12. Citric acid
13. Phosphate
14. Bicarbonate
15. Hyaluronidase

Fructose and other biochemical compositions as noted above from serial No. 1 to 5 are synthesized and secreted from seminal vesicles. The secretion from seminal vesicle constitutes 60% of the semen volume. Other biochemical compositions from serial No. 6 to 11 are released from prostate. Secretion from prostate contributes to 20% of the total semen volume. Bicarbonate and phosphates are buffers in the seminal fluid. Normally, sperm motility is facilitated by prostate specific antigen (PSA) (Application Box 67.3).

Application Box 67.3

**PSA is a marker of prostate cancer:** Prostate specific antigen (PSA) is 30 kDa serine protease formed and secreted from the prostate into the seminal fluid. Semenogelin, the sperm motility inhibitor is hydrolyzed by PSA. Thus, PSA facilitates sperm motility. The PSA gene has two androgen response elements. Though PSA is elevated in BHP (benign hyperplasia of prostate) and prostatitis, it is markedly increased in malignancy of prostate. Hence, elevated plasma PSA is used as a screening test for detection of prostate cancer.

Abnormalities

**Volume**

A low volume might suggest an anatomical or functional defect or an inflammatory condition of the genital tract. Volume decreases with advancing age.

**Motility**

In a normal sample, at least 60% of the sperms should exhibit forward motility within the first 3 hours of collection of the specimen. Motility less than 40% is associated with sterility. The speed of normal human sperm in female genital tract is 3 mm/min. Within one hour of ejaculation in the vagina, the sperms reach fallopian tube where they fertilize the ovum.

**Count**

Sperm count below 20 millions/ml results in sterility. A count between 20 to 40 millions/ml indicates borderline infertility.

**Liquefaction**

Delayed liquefaction of more than 2 hours suggests inflammation of accessory glands or enzyme defects in the secretory products of the glands.

**Morphology**

Normally 70% of the sperms should have normal morphology. Abnormalities more than 30% indicate serious pathology. The abnormalities include abnormal shapes, and poorly formed head or tail. The abnormal sperms may have bifurcated tail, bifid head, spirally coiled tail, or absence of head (Figs. 67.12A to D).

**pH**

pH below 7.0 indicates semen content is mainly prostatic fluid, which may be due to congenital absence of seminal vesicle.

**Fructose Content**

The normal fructose content of semen is 2–7 mg/mL. Its absence indicates obstruction or absence of the ejaculatory ducts or seminal vesicle.

Figs. 67.12A to D: Abnormal sperms. (A) Bifid tail; (B) Bifid head; (C) No head; (D) Curved tail.
**Effects of Vasectomy**

Vasectomy is the bilateral ligation of vas deferens. This is the permanent contraceptive procedure for males. This is a safe and convenient contraceptive procedure.

1. About 50% of vasectomized males develop antibodies against sperms. However, the incidence is more following restoration of patency of the vas deferens in males those who wish to restore their fertility.

2. As such, restoration of patency of the vas (recanalization) is a difficult procedure. The anti-sperm antibodies further reduce the fertility.

---

**Testicular Hormones**

**Testosterone**

The principal steroid secreted from testis is testosterone. It is the essential hormone for male reproduction and its absence or decreased production leads to sterility. Primarily, it allows the development of male reproductive organs during fetal life, controls spermatogenesis, guides development of secondary sex characteristics and maintains male vigor.

**Source**

Testosterone is synthesized by the Leydig cells of testis. Testosterone is also secreted from adrenal cortex, ovaries and placenta. Thus, a small amount of testosterone is secreted in females.

**Structure, Synthesis and Secretion**

It is a C19 steroid hormone with an OH group at 17 position.

1. It is synthesized from cholesterol in Leydig cells of the testis. It is also formed from androstenedione secreted from adrenal cortex. Though, the biosynthetic pathways in the endocrine tissue that form steroid hormones are similar, minor differences exist among the enzymes that are involved in the process. For example, the 17α-hydroxylase is found in testis, whereas 11– and 21–β hydroxylases are found in adrenal cortex.

2. Therefore, in testis, pregnenolone is hydroxylated at 17 position.

3. Pregnenolone is converted to testosterone in two pathways: delta 5 and delta 4 pathways. Major steps of these pathways are summarized in Figure 67.13.

4. Pregnenolone also forms progesterone, which forms 17α-hydroxyprogesterone, which in turn forms androstenedione and testosterone by delta-4-pathway.

The normal secretion rate of testosterone from testes is 4–10 mg per day. The normal plasma concentration of testosterone is 300–1000 ng/dL in adult males and 30–70 ng/dL in females.

**Metabolism**

About 98% of testosterone binds with plasma proteins and only 2% is free in plasma. The free testosterone enters the target tissues in which it is converted to its active form dihydrotestosterone (DHT) by 5α-reductase and estradiol (17β-estradiol) by aromatase. Thus testosterone acts as prohormone and DHT is the biologically active hormone. DHT has 2–3 times more affinity than testosterone for binding with androgen receptors (Clinical Box 67.1). DHT causes hypertrophy of prostate (Clinical Box 67.2).

---

**Clinical Box 67.1**

**Penis-at-14 syndrome:** Normally, DHT which is formed from testosterone by the enzyme 5α-reductase is essential for the development of male genitalia during early embryonic life. Therefore, deficiency of 5α-reductase in males results in confusing genitalia containing internal male and external female characters. In the absence of DHT, female genitalia predominate in genetic male (male pseudohermaphroditism) at birth. Undescended testis is a common feature in this condition and they are born as female children. At the time of puberty, testosterone secretion increases and they develop male figure with enlargement of clitoris to become a penis like structure. At this point in their life, they become boys and change their name and sex. They may even develop full male libido and do intercourse with women. As it occurs around the age of 14, syndrome is called penis-at-14-syndrome. It is common in Dominican Republic.

**17-ketosteroids:** About 65% binding of testosterone in plasma occurs with gonadal steroid binding globulin (GBG) and 33% with sex steroid binding globulin (SBG). Most of the circulating testosterone is converted into 17-ketosteroids by the enzyme 17β-dehydrogenase and a small amount into estrogen. 17-ketosteroids possess about 20% of androgen activity. The principal ketosteroids are androstenedione and etiocholanolone. Ketosteroids are excreted in urine. However, two-thirds of urinary ketosteroid is of adrenal origin and one-third of testicular origin.
Clinical Box 67.2

Treatment for prostate hypertrophy: DHT induces hypertrophy of prostate. Therefore drugs that inhibit 5α-reductase are currently used in the treatment of benign hypertrophy of prostate (BHP). If it is androgen dependent BHP or malignant neoplasia, GnRH antagonists are used that inhibit LH secretion which in turn inhibits estrogen secretion from Leydig cells.

Testicular Estrogen

Circulating estrogens are estradiol and estrone. Estradiol is the major estrogen. In men, the plasma estradiol level is 20 – 50 pg/ml. The production of estrogen increases with advancement of age in males, whereas estrogen production decreases with age in female. In males, only 15% of circulating estradiol and 5% of circulating estrone comes from testes (Clinical Box 67.3). Rest is produced by aromatization of estrogen from testosterone outside the testes and secreted from adrenal cortex.

Clinical Box 67.3

Gynecomastia in males: In adipose tissues, skin, liver and brain, testosterone is aromatized to estrogen, which is then released into circulation. Therefore in men, circulating level of estrogen (estradiol and estrone) is almost close to the level of estrogen in follicular phase in females. However, men are protected from feminization due to high level of androgens and high responsiveness of tissues to androgens. Therefore, use of anabolic steroids or testosterone analogues (as athletes use), decreased testosterone secretion, estrogen producing testicular tumors, and tissue insensitivity to androgens result in gynecomastia.

Mechanism of Action

Testosterone like other steroid hormones acts by binding with the cytoplasmic nuclear receptors. In the cell, two pathways are activated: DHT pathway, and testosterone pathway (Fig. 67.14).

DHT pathway

This pathway is mainly active in prostate, scrotum, penis, skin and bones. The testosterone is converted to DHT by 5α-reductase. DHT then binds with androgen receptors in the nucleus and induces RNA transcription to form various proteins. This causes sexual maturation at puberty and external virilization. Thus, DHT is mainly responsible for development of facial hair, skin changes, recession of hair line, and enlargement of prostate, scrotum, penis and bone.

Testosterone Pathway

Testosterone directly binds with testosterone receptors in the nucleus that induces m RNA activity. This pathway mainly regulates gonadotropin secretion, causes muscle development, controls spermatogenesis, and influences male sex drive and libido.

Physiological Actions

Testosterone is an anabolic hormone. It promotes growth of male reproductive system and causes development of secondary sex characters. Among various androgens, the potency in order of sequence is as follows:

- DHT > testosterone > androstenedione > DHEA
- DHEA is dehydroepiandrosterone.

Development of Secondary Sex Characteristics

Testosterone is primarily responsible for changes in males that occur at puberty. It develops and maintains male secondary sex characteristics. These features mainly include changes in external and internal genitalia, distribution of body hair, skin changes, mental growth, voice change, change in body configuration and musculoskeletal changes.

1. Changes in external genitalia: Penis enlarges in length and width. The scrotum becomes more rugose and pigmented.
2. Changes in internal genitalia: Seminal vesicles increase in size and start secreting fructose. Prostate gland enlarges and secretion increases from prostate and bulbourethral gland.
3. Growth and distribution of body hairs: Hair growth is classified into three groups depending on their sensitivity to androgens: nonsexual, ambisexual and sexual. Nonsexual hairs are hairs of eyebrows and extremities.
Ambisexual hairs are the hairs in the axilla, and sexual hairs are the hairs in the face, chest and upper pubic triangle. Androgen stimulates growth of all types of hairs, though the effects are more on sexual and ambisexual hairs. It promotes hair growth in axilla, on the chest and pubic triangle, and around the anus. In the face, hairs grow in the form of moustache and beard. Pubic hairs grow with male pattern (in the shape of a triangle of which the apex is upward). The hair line on the scalp recedes in males. Therefore, it is believed that baldness is a sign of maleness.

4. Skin changes: In general, skin becomes tough. Secretion of sebaceous gland increases and becomes thick. This leads to acne formation. Sometimes acne vulgaris appears. Skin derived from urogenital sinus, i.e., the prepuce, clitoris, labia majora and scrotum becomes more sensitive. Skin in and around genitalia becomes more pigmented.

5. Mental changes: The individual becomes more active and aggressive. He takes more interest in opposite sex.

6. Voice change: Enlargement of larynx and thickening of vocal cord occur. Therefore, voice becomes thick and deep.

7. Body configuration: General increase in body height and girth occurs (growth spurt). Especially, Broadening of the shoulder occurs with general increase in size of skeletal muscles. These changes impart masculine phenotypic expression.

8. Musculoskeletal changes: Growth of long bones, pectoral girdle and vertebral bones occurs at puberty. Testosterone causes closure of epiphysis of long bone, ultimately limiting increase in height of the individual. It causes muscle hypertrophy, increases muscle protein synthesis and increases muscle mass.

Effects on Spermatogenesis
Testosterone stimulates spermatogenesis, the exact mechanism of which is not known. It is essential for sperm production and maturation.

Effects during Embryonic Life
In male fetus, between 8th and 18th week testosterone causes the differentiation of male genitalia.

1. The development of Wolffian duct into epididymis, vas deferens and seminal vesicles depends directly on the effects of androgen.
2. Also, the differentiation of urogenital sinus and genital tubercle into penis, scrotum and testis is mediated by testosterone and DHT.
3. Further, descent of testis into scrotum is promoted by testosterone.

Anabolic Effects
Testosterone increases the synthesis of proteins and decreases its catabolism. This results in increased growth and development of bones and muscles.

1. It causes sodium, potassium, calcium, phosphate, and water retention from kidney.
2. It is used as an anabolic drug in patients suffering from wasting diseases. Athletes use it as anabolic steroids.

Effects on Brain
Many areas in the brain have androgen receptors. However, the receptors are densely located in limbic areas, especially in amygdala and septum, and in hypothalamus, pituitary and preoptic area.

1. In these areas, testosterone is aromatized to estrogen (Flowchart 67.2).
2. Sexual dimorphism of neurons in the brain with respect to their distribution, size, number and activity has been reported in preoptic area and amygdala.

Other Effects
Testosterone, by its negative feedback effects, inhibits GnRH secretion from hypothalamus and LH and FSH secretion from anterior pituitary. It stimulates erythropoiesis.
Other Testicular Hormones

Other testicular hormones are androgens other than testosterone, inhibin, activin and follistatin. Estrogen is also produced in testis by aromatization of androgen in Sertoli cells.

Androgens

Testis secretes androgens. Testicular androgens are testosterone (see above), androstenedione and dihydrotestosterone. Among them, testosterone is the major androgen (Table 67.1).

Inhibin

Source

Inhibin is secreted from Sertoli cells of testes in males and granulosa cells of ovaries in females.

Types and Structure

There are two types of inhibins: inhibin A and inhibin B. Inhibins are made up of two subunits: α and β. The β subunit is of two types βA and βB. The inhibin A is made up of αβA and inhibin B is made up of αβB. The α and β subunits are made up of polypeptides. Inhibin B is the FSH regulating peptide.

The homodimers and heterodimers of β subunits are formed. This results in formation of βAβB, βBβB, and βAβA. These are called activins. Activins and inhibins are found in the gonads, brain, and many other tissues. In bone marrow, activins stimulate leucopoiesis.

Functions

The main function of inhibin is to provide feedback signal to inhibit FSH secretion from anterior pituitary. Inhibin B mainly inhibits FSH secretion.

Activin

It is a polypeptide hormone with molecular weight of 30,000. Activin is produced by Sertoli cells.

1. It stimulates secretion of FSH.
2. Activin results from various combinations of βA and βB subunits of inhibin that forms βAβB, βBβB, and βAβA.
3. They stimulate WBC development in the bone marrow, formation of mesoderm during embryonic life and also gonadal development.

Follistatin

Follistatin is a single chain protein having molecular weight of about 40,000. It has various isoforms that binds and inactivates activin.

1. When activins bind with follistatin they loose their functions.
2. Thus, FSH secretion is reduced from pituitary cells.
3. Follistatin influences developing spermatogenic cells by a paracrine mechanism.

Regulation of Testicular Functions

The major function of testes is to secrete testicular hormones, especially testosterone that controls gametogenesis, sexual development and anabolic effects. Testicular functions are controlled by hypothalamic and pituitary inputs.

Hypothalamic Control

Hypothalamus secretes GnRH. GnRH stimulates LH and FSH secretion from anterior pituitary that in turn influences testicular steroidogenesis.

Pituitary Control

Anterior pituitary controls testicular functions by secreting LH and FSH. FSH stimulates Sertoli cells to produce inhibin that maintains the gametogenic functions of the testis. FSH also stimulates secretion of androgen binding protein. LH stimulates Leydig cells to secrete testosterone, which controls gametogenesis.

Steroid Feedback

Testosterone provides negative feedback signal to hypothalamus to inhibit the secretion of GnRH, and to gonadotrophs of anterior pituitary to inhibit secretion of LH (Fig. 67.15). Inhibin provides negative feedback effect on anterior pituitary to inhibit the secretion of FSH.

| Testosterone | 6.5 |
| Androstenedione | 1.5 |
| Dihydrotestosterone | 0.5 |

Table 67.1: Average plasma concentration (µg/lit) of androgens in adult male.

Fig. 67.15: Feedback regulation of gonadal hormone secretion. Minus sign indicates inhibition.
TESTICULAR ABNORMALITIES

Cryptorchidism
The failure of migration of testis from abdominal cavity into the scrotum during fetal development is called **undescended testis** or cryptorchidism. The usual site of undescended testis is inguinal rings.
1. From posterior wall of the abdomen testis first descends into the inguinal region and then from there into the scrotum.
2. The descent from abdomen into the inguinal region depends on MIS.
3. The descent from inguinal region to scrotum depends on testosterone and other factors.
4. Descent of testis normally completes in few days before the birth.

Treatment
Treatment with **gonadotropin hormones** facilitates the descent of testis. Surgical correction is required when the hormonal treatment fails.

Complications
Undescended testis decreases sperm production, as temperature is high in the abdomen. The incidence of **malignant tumors** is significantly more in undescended testis.

Male Hypogonadism
There are mainly **two types**: Hypergonadotrophic hypogonadism and hypogonadotrophic hypogonadism.

**Hypergonadotrophic Hypogonadism**
If this occurs due to testicular dysfunctions, plasma level of gonadotropin is increased.

**Hypogonadotrophic Hypogonadism**
This occurs mainly due to tumor of hypothalamus or pituitary. Gonadotropin level in plasma is depressed.
1. If hypogonadism occurs after puberty, the secondary sex characteristics regress slowly as androgenic maintenance of these features is less essential. However, loss of libido is common.
2. If loss of Leydig cells occurs from childhood, **eunuchoidism** results.
   - Enuchoids are usually tall, with narrow shoulders and less muscular development.
   - The genitalia are small.
   - Though pubic hairs are present they are usually sparse and exhibit female pattern, i.e. triangle with base up.

**Androgen Secreting Tumors**
Hypersecretion of testis is usually due to a tumor in the testis. Leydig cell tumors secrete androgen and result in precocious puberty in prepubertal boys.

CHAPTER SUMMARY

**Key Concepts**
1. In males, gametogenesis is a continuous process. Gametes (sperms) are produced in millions every day, and the process continues throughout life starting from puberty, though the rate of production decreases in old age.
2. Sertoli cells provide support to the germ cells in the process of spermatogenesis. The tight junctions between Sertoli cells from the blood-testis barrier that provides protection to developing sperms from harmful blood born toxins.
3. Leydig cells secrete testosterone that provides hormonal stimulation for spermatogenesis.

**Important to Know (Must Read)**
1. In examination, ‘Describe the steps of spermatogenesis and factors controlling spermatogenesis, may be asked as a Long Question.
2. Spermatogenesis, Factors controlling spermatogenesis, Functions of Sertoli cells, Leydig cells, Blood-testis barrier, Spermiogenesis, Semen analysis, Physiological actions of testosterone, Testicular abnormalities, are usual Short Questions in exam.
3. In Viva, examiner may ask…. List the steps of spermatogenesis, List the factors controlling spermatogenesis, What is the duration of spermatogenesis, What is the rate of production of sperms, List the functions of testis, Why the scrotal temperature is lower than core body temperature, What is blood-testis barrier and what are its functions, What is the structure of a spermatozoa, What is the fate of stored spermatozoa, What is the composition of normal semen, How do you assess male infertility, What is the source of testosterone, List the physiological actions of testosterone, What are the secondary sex characteristics in male, List the functions of Sertoli cells, What are the functions of Leydig cells, What is the fate of testosterone secreted from Leydig cells, What is cryptorchidism and what is its treatment and complications, What is spermiogenesis and what are the changes that occur during this period, What is spermiation, What is capacitation, What is acrosomal reaction, What are the function of prostate glands, Why is the prostate specific antigen (PSA) a marker of prostate cancer, What is the use of 5α-reductase inhibitors in prostate hypertrophy, What is penis-at-14 syndrome, What is the source of estrogen in males, What are the causes of gynecomasia in males, What are the types and causes of male hypogonadism, What is eunuchoidism, What are the other testicular hormones and what are their functions, How is the testicular functions regulated, What is the mechanism of action of testosterone, What is CatSper protein and what is its function, List the differences between spermatogenesis and oogenesis, What is the structure and function of epididymis, How do the Leydig cells and Sertoli cells interact, What are the function of vas deferens, What are the function of bulbourethral glands, What is the effect of androgen secreting tumors.
CHAPTER 68
Female Reproductive System: Functional Anatomy, Oogenesis and Follicular Development

LEARNING OBJECTIVES

On completion of study of this chapter, the student MUST be able to:
1. Correlate the functional organization of female reproductive tract with their functions.
2. Give the different parts of uterus and ovary, and list their functions.
3. Give the steps and regulation of oogenesis.
4. Understand the mechanism and regulation of different phases of ovarian follicle.
5. Describe the structure and function of corpus luteum.

The student MAY also be able to:
1. Describe the process of oogenesis.
2. Describe the ovarian follicular development.

The important event in female reproductive functions is the cyclical release of gamete during the reproductive cycles. The ovarian changes are mainly growth, maturation and release of ovum and secretion of hormones, and uterine changes are mainly endometrial alterations to nourish the implanted fertilized gamete, or shedding of endometrium associated with uterine bleeding in the absence of fertilization. The follicular development during each cycle is a detailed and organized process controlled by hypothalamo-pituitary-ovarian endocrine axis.

**Scientist contributed**

Regnier de Graaf (1641–1673), was a Dutch physician, anatomist and physiologist who made key discoveries in reproductive biology during his only 32 years of short life span. He was the first scientist who pioneered in the study of physiology of reproductive system in males and females. He had demonstrated ovulation in mammals. The ovarian follicles are named after him as Graafian follicles in recognition of his outstanding contribution in the field of reproductive physiology. He had also studied the pancreatic secretion.

**FUNCTIONAL ANATOMY**

**External Genitalia**

Female external genitalia include labia majora, labia minora, clitoris, vestibule of vagina and vestibular glands (Fig. 68.1). These structures are collectively called as vulva.
Labia Majora

Labia majora are analogous to scrotum in males. These are two major skin folds that form the outer lips of vaginal vestibule, which include vaginal and urethral openings.

Labia Minora

Labia minora are two minor skin folds present between labia majora and form inner lips of vaginal and urethral openings.

Clitoris

Clitoris is located at the anterior pole of vaginal vestibule. This is the female analogue of penis. It consists of erectile tissue. The tip of the clitoris is the glans clitoris similar to glans penis.

Vaginal Vestibule

Vaginal vestibule contains two openings: vaginal and urethral openings. Vaginal opening lies below and posterior to urethral opening. In virgins, vaginal opening is partially closed by hymen, a thin fold of mucous membrane. Vestibular glands empty their secretion into the vaginal vestibule.

Internal Genitalia

The female internal reproductive organs are present in the pelvis and consist of vagina, uterus, fallopian tubes and ovaries (Fig. 68.2).

Vagina

This is a tubular canal which is present anterior to rectum and posterior to the urethra and bladder. It connects vaginal opening in the vestibule to the uterine cervix.

1. The length of vagina in adult is about 8 cm, but it is highly stretchable as its wall is folded normally. It can elongate to about double of its length during sexual act.
2. Under the action of relaxin, it widens and stretches further during parturition.
3. Vaginal wall contains muscle and contraction of vagina during sexual act facilitates the transportation of sperm into the uterus.
4. Vaginal epithelium changes during different phases of menstrual cycle.
   − In proliferative phase, under the influence of estrogen, cornification (keratinization) of vaginal epithelium occurs that secretes thin mucus.
   − In the luteal phase, under the influence of progesterone, cornification of epithelium is reduced; rather, polymorphonuclear leucocytes infiltrate and epithelium proliferates to secrete thick mucus.
5. After menopause, vaginal epithelium becomes thin and secretion is scanty. Therefore, post-menopausal vagina is dry and susceptible to infections.

Uterus

This is hollow organ having thick muscular wall. It is placed between bladder anteriorly and rectum posteriorly. It has two parts: the corpus (or the body) and the cervix (Fig. 68.3).

Body of Uterus

Uterus consists mainly of two layers (myometrium and endometrium) and uterine cavity.

Myometrium

The myometrium consists of multiple layers of smooth muscle.
Section 7: Reproductive System

Endometrium
The endometrium has two layers: a stromal layer close to myometrium and an epithelium.
1. The stroma is penetrated by spiral arteries and contains adequate connective tissue.
2. The epithelium contains uterine glands that are lined by columnar secretory cells. The glands also infiltrate into stroma. The arterial and glandular changes occur in different phases of menstrual cycle (see below).
3. Shedding of endometrial tissue at the end of luteal phase results in menstrual bleeding. Uterus enlarges during pregnancy to accommodate the growing fetus and expels the fetus at the time of parturition.

Uterine Cervix
The cervix is a narrow muscular tube that connects vagina with body of the uterus (Fig. 68.3). It has internal os, cervical canal and external os.
1. Cervical mucus changes from thick and viscous liquid to profuse, watery and highly elastic liquid, which forms the physiological basis of ‘spinnbarkeit test’ for ovulation (spinnbarkeit refers to a highly elastic substance).
2. Under the influence of estrogen, cervical mucus forms typical ‘fern pattern’, which disappears following ovulation.
3. Cervical dilation is done for uterine investigations (Clinical Box 68.1). Cervical dilation is the initial event in the initiation of parturition.

Clinical Box 68.1
D and C: Dilation of cervix is performed routinely in gynecological practice to obtain endometrial tissue from cervix or body of the uterus for diagnosis of various uterine pathologies. This is called dilatation and curettage (D and C). D and C are also performed therapeutically for treatment of few uterine diseases. Cervical dilation is done to evacuate the uterine content (conceptus) for abortion.

Fallopian Tubes
Two fallopian tubes (also called oviducts) arise from both sides of upper poles of uterus. Oviducts are 10–15 cm in length. They have three parts: isthmus, ampulla and infundibulum (Fig. 68.3).
1. Infundibulum opens into pelvic cavity close to ovaries. Infundibular openings have fimбриae (finger like projections lined by ciliated epithelium) that help in grasping ovum at the time of ovulation.
2. Normally, fertilization takes place in ampullary part of the oviduct and then fertilized ovum is transported to uterine cavity for implantation.
3. Thus, maldevelopment or diseases of fallopian tubes result in infertility (Clinical Box 68.2).

Clinical Box 68.2
BTL: Bilateral tubal ligation (BTL) is the commonest and permanent method of sterilization in parous women. Tubal ligation is preferred to tubectomy, when the parents keep the option for recanalization of the tubes if necessity arises in future.

Scientist contributed
Gabriele Falloppio (1523–1562) was Italian physician and anatomist of 15th century who pioneered in studying the structure and functions of the reproductive organs. He demonstrated the seminal vesicle, the uterine tubes and the details of the mammalian reproductive systems. For his immense contribution in the field of reproductive system during his life span of less than 40 years, the uterine tubes of female reproductive system are named after him as Fallopian tubes.

The Ovaries
There are two ovaries each weighing about 10 g in adults. Each one present on both sides of uterus and are attached by ovarian ligaments. Ovary consists of two zones: the cortex, and medulla.

Cortex of Ovary
The cortex is the outer and the major zone lined by the germinal epithelium. It is surrounded by a layer of fibrous tissue called tunica albuginea.
1. Cortex contains oocytes. Each oocyte is enclosed within a follicle, the ovarian follicle. Ovarian follicles are present in their various stages of development (Fig. 68.4).
2. The matured ovarian follicle is called Graafian follicle.
3. The stroma of the ovary is present in between the follicles, which consists of supporting connective tissue and interstitial cells.

Medulla of Ovary
The inner zone of the ovary forms the medulla that contains different types of interstitial and connective tissue cells. Blood vessels and lymphatics enter the ovary through its hilum.

Functions of Ovary:
Ovary like testis performs many functions:
1. Oogenesis during fetal life.
2. Maturation of oocyte.
Chapter 68: Female Reproductive System: Functional Anatomy, Oogenesis and Follicular Development

3. Ovulation

The primary function of ovary is to develop ovarian follicles and release ovum at the time of ovulation, and to secrete steroid hormones that control various reproductive and metabolic functions.

**Oogenesis**

Unlike spermatogenesis that starts at puberty and continues throughout life, the process of oogenesis starts in fetal life and ceases at menopause. Also, the process of development of each spermatocyte is completed in few days, whereas development of each oocyte that begins in intrauterine life is completed with ovulation that occurs during menstrual cycle.

Thus, many sperms are produced in few days whereas single ovum is produced during each cycle, the development of which occurs at different stages of life till ovulation. The stages of development of oocytes occur in three stages: Oogonium becoming primary oocyte, primary oocyte converted to secondary oocyte, and finally secondary oocyte developing to mature ovum.

**Oogonia Becoming Primary Oocyte**

**Oogonia**

The primordial germ cells (oogonia) migrate from the yolk sac of embryo to the genital ridge at about 6th week of gestation. The, oogonia undergo many mitotic divisions and the number of oogonia reaches to about 7 millions. When mitosis cease, the oogonia are called oocytes.

**Primary Oocytes**

The oocytes undergo two meiotic divisions (the meiotic cycle) at different stages of development to produce a haploid ovum. Oocytes in their preliminary stage of development are called primary oocytes.

**First Meiotic Division**

The first meiotic division starts in primary oocytes during fetal life, which occurs at about 8th week of pregnancy is arrested in prophase. The oocytes then grow in size.

1. However, the first meiotic division is not completed in fetal life, not even till puberty; in fact, it is completed just prior to ovulation.
2. Therefore, the life span of a primary oocyte can be up to 50 years, as ovulation can continue up to this age.
3. The suspension of oocyte division in prophase for such a long period depends on the internal hormonal environment provided by the surrounding supporting cells.

**Oocyte Degeneration**

The oocyte degeneration however, starts from the intrauterine life so that only about 1 million primary oocytes remain at the time of birth. By the time of puberty about 200,000 and by the age of 30 only about 26,000 oocytes remain in the ovary. At menopause, ovaries are virtually devoid of oocytes.

1. During a woman’s life, only about 400 oocytes are ovulated and the other oocytes degenerate. The process of degeneration of oocyte is called atresia.
2. A major difference in male and female gametogenesis is that the process of spermatogenesis is a continuous phenomenon and the production of sperm is unlimited, whereas primary oocytes degenerate with age (Application Box 68.1).
3. As new oogonia cannot be manufactured in ovary, the oocytes totally disappear at the time of menopause.

**Application Box 68.1**

*Age of oocyte contribute to health of children:* Because of the peculiar pattern of development of oocyte in females, the life span of an oocyte may be as old as 50 years. The oocyte that ovulates at about 40 years of age is about 25 years older than the oocyte that ovulates at the age of 15. This one of the important factors that contribute to the anomalies in children born to older woman as the aged-eggs oocyte have degenerative changes and therefore their fertilization may result in defective embryo.

**Primary Oocyte Converted to Secondary Oocyte**

In fetus, oogonia develop into primary oocyte, which undergo first meiotic division. However, the first meiotic division is not completed in fetus. This is called as meiotic arrest. Thus, all eggs present at birth are primary oocytes.
in meiotic arrest containing 46 chromosomes. This state continues until puberty.
1. The primary oocyte that is destined for ovulation completes the first meiotic division just before the ovulation.
2. This division results in production of two structures: one is the daughter cell, called secondary oocyte containing 23 chromosomes, and the other is the first polar body (Fig. 68.5).
3. However, the cytoplasmic division is grossly unequal in this process in which the secondary oocyte retains nearly all the cytoplasm with polar body containing very little of it. Thus, the polar body becomes completely nonfunctional.

Secondary Oocyte Forming Ovum
Second Meiotic Division
The second meiotic division occurs in the secondary oocyte after ovulation, and is arrested in metaphase.
1. The second meiotic division is completed when the egg is penetrated by a sperm. Thus, meiotic cycle is completed only on fertilization.
2. As a result of this meiotic division, the ovum containing 23 chromosomes and the second polar body are formed (Fig. 68.5). The polar body is extruded.
3. Thus, in the process of oogenesis, each primary oocyte produces only one ovum.

DEVELOPMENT OF OVARIAN FOLLICLE
The oocyte grows throughout their life in the ovarian follicle till ovulation when the ovum is released from the follicle (from the ovary). Along with development of oocyte in ovarian follicle, follicles also grow in different phases. This is called follicular growth or folliculogenesis.
1. It starts during intrauterine life and continues till ovulation that occurs during each menstrual cycle. Thus, a single ovarian follicle may develop from fetal life till menopause.
2. At the beginning of menstrual cycle, a number of follicles start growing. However, only the one dominant follicle finally matures and releases ovum, whereas rest others undergo degeneration (atresia).
3. About 99.9% of follicles present at birth undergo atresia during the reproductive life of a woman.

Stages of Follicular Development
Foliculogenesis occurs in four stages: Stages 1–4 (Figs. 68.6A to D).

Stage 1 (Primordial Follicular Stage)
The ovarian follicle, also called Graafian follicle begins as a primordial follicle (Fig. 68.6A).
1. The primordial follicle consists of a primary oocyte at the center surrounded by a layer of spindle cells (flattened pregranulosa cells) that form granulosa cells later. A basal lamina is formed outside the spindle cells. The size of oocyte in primordial follicle is about 25 μm.
2. Primordial follicles form the resting pool of follicles in the ovary.
3. However, they degenerate progressively from fetal life to menopause.
4. The oocyte enters into **first meiotic division** and the division is **arrested in prophase**. This prophase of oocyte is maintained till just prior to ovulation.

**Stage 2 (Primary Follicular Stage)**

The primordial follicles grow into the **primary follicles**.

1. During this process the flattened pregranulosa cells (spindle cells) become **cuboidal granulosa cells** that further proliferate to form a continuous cell layer surrounding the oocyte (Fig. 68.6B). The size of oocyte increases to about 80-140 µm.
2. A type of **glassy material** consisting of mucopolysaccharide is secreted from granulosa cells, which forms a thick layer between the oocyte and the granulosa cell layer, called as **zona pelucida**.
3. The primordial follicle becomes primary follicle at about 28th weeks of gestation.
4. The oocyte is maintained in prophase of its first meiotic division.

**Stage 3 (Secondary Follicular Stage)**

The primary follicle becomes **secondary follicle** in this stage during which the granulosa cells divide and form several layers of cells around the oocyte. Thus, the size of follicle increases enormously in this stage to about 500 µm.

1. At this stage, follicle is called **preantral follicle**. However, small antrum may develop (Fig. 68.6C).
2. A layer of spindle cells (**pre or early theca cells**) is formed at the periphery of the basal lamina, which forms the theca cell layer in the next stage.
3. All these development occur slowly in the prepubertal ovary.

**Stage 4 (Tertiary Follicular Stage)**

This is the final stage of follicular development. It occurs in two sub-stages: the early tertiary stage and the Graafian follicular stage.

**Early Tertiary or Antral Follicular Stage**

In this stage, the spindle cell layer surrounding the basement membrane proliferates and differentiates into inner **theca interna** and outer **theca externa**.

1. **Theca interna cells** multiply to form multiple cell layers and become steroidogenic.
2. **Theca externa cell** lie in a single layer and provide mechanical support to the follicle from outside.
3. Thca cells receive blood, lymphatic and nerve supply whereas **granulosa cells remain avascular** as blood vessel cannot penetrate the basement membrane.
4. Along with the expansion of theca cell layer, a fluid-filled space is created in the midst of granulosa cells, called as **antrum** (Fig. 68.6C). Therefore, the follicle in this stage is also called **early antral follicle** and the stage also as **early antral follicular stage**.
5. The granulosa cells increase in number and **acquire receptors for FSH** and start secreting estrogen. In fact, the progression of early tertiary stage to the next stage of follicular development is FSH dependent.

**Late Tertiary or Graafian Follicular Stage**

This is the most rapid stage of development. It occurs only in the post-pubertal ovary.
1. After 5–7 days of onset of menses, a single follicle becomes dominant follicle for that cycle. The follicle in this stage is called Graafian follicle (Fig. 68.6D) and the stage is called Graafian follicular stage. It occurs in one ovary during each cycle.

2. The size of the antrum and the amount of antral fluid are increased significantly. This pushes the oocyte to the periphery of the follicle.

3. The mucopolysaccharide, which is present in the antral fluid, is depolymerized to increase the osmotic pressure of the fluid. However, the total intrafollicular pressure remains within 20 mm Hg.

4. The antral fluid contains many hormones such as estrogen, progesterone, FSH, LH, prolactin, androsterone and growth factors, inhibin, activin, GnRH, CRH, opioid peptides and oxytocin.

5. It also contains plasminogen activator, mucopolysaccharide, proteins, electrolytes, glycosaminoglycans and proteoglycans.

6. The vascularity of theca increases.

7. The granulosa cells in this stage are anatomically divided into three compartments: antral, cumulus and mural granulosa cells (Fig. 68.7).

   - **Antral granulosa cells**: Granulosa cells lining the antral cavity are called antral granulosa cells (Discus proliferous). Antral granulosa cells are highly steroidogenic.

   - **Cumulus granulosa cells**: Granulosa cells surrounding the oocyte are cumulus granulosa cells (cumulus oophorius). Therefore, the granulosa cells that project into the antrum like a mound are collectively called as cumulus oophorus.

   - **Mural granulosa cells**: Granulosa cells that are attached to the basement membrane are called mural granulosa cells (Membrana granulosa). Mural granulosa cells are highly steroidogenic.

8. The diameter of the follicle in this stage is about 2.5 cm. The follicle is called pre-ovulatory follicle as it is ready for ovulation at this stage. The basement membrane close to the surface of the ovary undergoes proteolysis that slowly leads to rupture of the follicle resulting in release of oocyte from the follicle, the process called ovulation.

9. Just prior to ovulation, the first meiotic division is completed.

10. The oocyte is taken up by the fallopian tube.

11. If fertilization occurs, the penetration of ovum by the sperm completes the second meiotic division, which results in functional ovum (fertilized egg).

12. If fertilization does not occur, the oocyte begins to degenerate in 24 to 48 hours.

### Corpus Luteum Formation

#### Luteinization

After ovulation, the ruptured follicle is quickly filled with blood, and at this time, the follicle is called corpus hemorrhagicum. However, the cells lining the follicle rapidly proliferate to replace blood with luteal cells that are rich in lipid. Now, the follicle is called corpus luteum and its appearance heralds the beginning of luteal phase of the cycle.

1. The corpus luteum is a yellow body made up of endocrine tissue that consists of granulosa luteal cells, theca luteal cells and fibroblasts (Fig. 68.8). The number of mitochondria, lipid droplets and the endoplasmic reticulum increase in the granulosa cells of corpus luteum. These morphological changes are collectively known as luteinization, which is essential for synthesis of more steroid hormones.
2. The granulosa and theca cells of matured corpus luteum are respectively called as **granulosa lutein cells** and **theca lutein cells**.

3. Luteal granulosa cells are vascular unlike the follicular granulosa cells that are nonvascular.

4. Vascularity of luteal cells **facilitates the synthesis of steroid hormones** by promoting the supply of cholesterol from plasma to these cells.

### Regulation of Luteinization

Progesterone, estrogen and androgen are formed in corpus luteum.

1. **Progesterone secretion** reaches its peak in menstrual cycle at about 7 days after ovulation, which correlates with the full maturity of corpus luteum. These hormones (Progesterone, estrogen and androgen) may be playing some role in luteinization.

2. However, **LH is the major stimulator of luteinization.** LH maintains the functions of corpus luteum by promoting luteinization of its cells, and therefore, LH is referred to as luteinizing hormone.

3. **FSH** increases the number of LH receptors on the cells.

### Luteal Regression

If **fertilization does not occur**, corpus luteum degenerates in about 13 days after ovulation.

1. The endocrine cells of corpus luteum become necrotic, and are invaded by leucocytes and fibroblasts. This process is called **luteolysis** or luteal regression.

2. The exact mechanism of luteolysis is not known. However, it is proposed to be due to the action of **luteolysins** that are produced locally in the ovary. The proposed luteolysins are **oxytocin, prostaglandins and GnRH**.

3. **Luteolysins** promote luteal regression by preventing the action of LH on corpus luteum.

4. The degenerated corpus luteum is replaced by avascular and nonfunctional fibrous tissue, known as **corpus albicans**.

   If **fertilization occurs**, the implanted fertilized ovum secretes hCG from its embryonic trophoblast, which has LH-like activity. Therefore, **hCG maintains luteinization** and promotes the functions of the **corpus luteum of pregnancy**.

### Functions of Corpus Luteum:

1. The corpus luteum **secretes hormones**. During luteal phase, increased secretion of progesterone, estrogen and inhibin A occurs from corpus luteum. It also secretes androgen.

2. It provides endocrinial **environment for implantation of fertilized ovum**.

3. **It maintains the early part of pregnancy** by secreting progesterone in adequate concentration till the placenta becomes functional.

   Infertility occurs due to luteal deficiency (Clinical Box 68.3)

#### Clinical Box 68.3

**Luteal deficiency:** One of the common causes of infertility is the luteal deficiency, also called **luteal insufficiency**, in which either luteinization of granulosa cells of corpus luteum is deficient due to less number LH receptors on luteal cells, or due to ovulation of prematurely developed follicle that contains less number of luteinized granulosa cells. FSH also promotes expression of LH receptors in the follicular cells. Therefore, FSH deficiency can also cause luteal insufficiency. Due to **inadequate secretion of progesterone** from malfunctioning corpus luteum, pregnancy is terminated very early. Luteal insufficiency is diagnosed by demonstrating a **low progesterone level in the midluteal phase in successive cycles**. The condition is treated by administration of progesterone that maintain follicular phase and early part of pregnancy, or clomiphene citrate that induces follicular development, or hCG that facilitates luteinization of granulosa cells of corpus luteum.

### Atresia of Follicle

During the entire reproductive period of a woman, about 400 oocytes grow to culminate in ovulation. The follicles that do not become dominant undergo a **process of degeneration** called atresia. Atresia starts in fetal ovary soon after the appearance of primordial follicles. It occurs due to **apoptosis**, a process of programmed cell death.

### Regulation of Follicular Development

Factors affecting development of follicles are different in different phases of follicular growth.

#### Primordial Follicular Stage

The growth of primordial follicle is not affected by gonadotropins. It is purely a local phenomenon.

#### Primary Follicular Stage

The **chemical substances secreted by oocyte** stimulate the transformation of pregranulosa cells to granulosa cells. The **products of granulosa cells** stimulate the formation of spindle (pre-theca) cells. **FSH and LH** stimulate the development of follicle toward the later part of gestation. During early childhood, though LH and FSH are secreted in low concentration, they are essential to maintain follicular growth. Follicular growth is impaired without gonadotropins.

#### Secondary Follicular Stage

At the time of puberty, secondary follicles start developing. The granulosa cells of secondary follicles **acquire FSH receptors** and secrete estrogen in less concentration. This **follicular estrogen** promotes further follicular development.
**Early Tertiary Stage**

Immediately after menarche (the first menstrual bleeding), in the early luteal phase of the same first cycle, usually the secondary follicles enter the tertiary follicular stage of development. The granulosa cells respond to FSH in the follicular phase of the next cycle.

1. **The FSH stimulates the granulosa cell** and increases the aromatase activity, which increases the synthesis of estrogen from androgen. The follicular concentration of estrogen increases.

2. **Estrogen** along with FSH induces expression of LH receptors on granulosa cells. Estrogen also conditions the hypothalamo-anterior pituitary axis that maintains LH activity in the plasma.

3. LH synthesis is increased by estrogen at this point of time, which is essential for pre-ovulatory surge of LH.

4. Estrogen also increases the number and sensitivity of LH receptors in the theca cells. Therefore, LH stimulates androgen synthesis in the theca cells that becomes substrate for estrogen production in the granulosa cells (Fig. 68.9).

5. LH also stimulates granulosa cells to produce progesterone. Therefore, progesterone concentration also increases.

**Late Tertiary Stage**

Between 5th to 7th days of follicular phase, only one follicle grows sufficiently to become the dominant follicle.

1. The aromatase activity and number of FSH receptors increase in the granulosa cells of dominant follicle. This increases the synthesis of estrogen, and more concentration of estrogen allows the dominant follicles to prime the hypothalamo-pituitary axis to generate LH surge just prior to ovulation. Under normal conditions, estrogen inhibits LH secretion.

2. But, when the plasma concentration of estrogen reaches about 200 pg/ml and maintains that high concentration for about 36 hours, estrogen stimulates LH secretion. Thus, the positive feedback effect on LH increases secretion of LH. This leads to LH surge, which causes ovulation (see below). This positive feedback on LH secretion is due to the effect of estrogen both at the levels of hypothalamus and pituitary.

3. LH increases progesterone secretion, which increases the proteolytic enzyme activity and causes the distention of follicle due to rapid increase in follicular fluid volume.

4. LH also stimulates the activity of endoperoxide synthase that increases synthesis of prostaglandins and leukotrienes.

5. Prostaglandins cause lysis of follicular wall leading to rupture of follicle.

6. Breaking down of follicular wall is facilitated by the proteolytic enzyme plasmin. FSH, by stimulating the activity of plasminogen activator facilitates the formation of plasmin.

7. Oxytocin causes contraction of follicular wall and extrudes the oocyte. This is called ovulation. Immediately after LH surge, the number of LH receptors decreases. This desensitizes granulosa and theca cells to LH.
### Chapter Summary

#### Key Concepts

1. In females, the period of gametogenesis is restricted from puberty to menopause, which is less than 40 years. Gametes (sperms).
2. The process of oogenesis starts in fetal life. The development of each oocyte that begins in intrauterine life is completed with ovulation that occurs during menstrual cycle.
3. If fertilization occurs, corpus luteum provides hormonal support for implantation of fertilized egg and maintenance of early part of pregnancy.

#### Important to Know (Must Read)

1. In examination, Long questions are usually not asked from this chapter. However, ‘Describe the stages and regulation of ovarian follicle’ may come as a Long Question.
2. Oogenesis, Corpus luteum, Graafian follicle, Stages of follicular development, Regulation of follicular development, may be asked as Short Questions in exam.
3. In Viva, examiner may ask…… How the corpus luteum is formed, What are the functions of corpus luteum, How is the lutenization regulated, What is luteal regression, What is luteal deficiency and what are its features, What is D and C, What are the functions of ovary, What are the stages of oogenesis, How the age of oocyte contributes to the health of children, List the stages of follicular development, How the early tertiary stage is regulated, How is the late tertiary stage regulated, What are the changes that occur in primordial follicular stage, What are the changes that occur in primary follicular stage, What are the changes that occur in secondary follicular stage, What are the changes that occur in tertiary follicular stage.
The fundamental difference in female and male reproductive functions is the cyclical release of gametes in females during their reproductive life. The structural and functional changes of female reproductive system during each cycle are synchronized with the changes in hypothalamo-pituitary-ovarian axis. The ovarian changes are mainly growth, maturation and release of gamete and secretion of hormones, and uterine changes are mainly endometrial alterations to nourish the implanted fertilized gamete, or shedding of endometrium associated with uterine bleeding in the absence of fertilization. These cyclical changes in human beings are called menstrual cycles and the uterine bleeding is called menstruation.

Menstrual cycles start at puberty, temporarily stop during pregnancy and lactation, and finally cease at menopause. During different stages of menstrual cycle, ovarian hormones, especially estrogen and progesterone provide feedback effects on hypothalamo-pituitary secretions generating typical cyclic release of gonadotropins from anterior pituitary. As hypothalamo-pituitary axis is subjected to various influences, menstrual cycle can easily be affected by stress and psychosocial and environmental factors.

**MENSTRUAL CYCLE**

The reproductive functions in women exhibit cyclical changes that occur regularly over a period of about one month. This is called menstrual cycle, which is the periodic preparation of the reproductive system for fertilization and implantation of the fertilized ovum. In human beings and primates, the reproductive cycle externally manifests by periodic vaginal bleeding, called as menstruation. Therefore, the cycle is called menstrual cycle. The first menstrual cycle is called menarche. The usual age for menarche is 12–14 years.

**Duration and Phases of Menstrual Cycle**

**Duration of Menstrual Cycle**

The length of menstrual cycle usually averages at about 28 days. However, the duration of cycles is never fixed in all women. Also, the duration of all cycles is not same in one woman. This is because menstrual cycle is frequently influenced by psychological, environmental, nutritional, and social factors.
1. Normally, it ranges from 21 to 35 days.
2. The cycle is described by number of days, the first day being the day of beginning of menstrual bleeding.
3. The cycle becomes irregular toward menopause.
4. Nevertheless, irregularity in cycle length or in duration and quantity of bleeding in an apparently normal woman indicates dysfunctions of reproductive system, especially in the uterus or in the ovary.
5. Physiologically, menstrual cycle temporarily ceases during pregnancy and lactation.

**Phases of Menstrual Cycle**

Characteristically, the menstrual cycle is divided into two phases: follicular phase and luteal phase, separated by ovulation that occurs between these two phases.

**Follicular Phase**

This is the period from the onset of bleeding to the day of ovulation. This is called follicular phase as the dominant follicle in ovary matures in this phase to terminate in ovulation at the end of the phase.
1. This phase has two parts: the menstrual phase (the phase of menstrual bleeding), and the proliferative phase (phase of proliferation of the uterine endometrium).
2. Follicular phase is also called preovulatory phase.

**Luteal Phase**

This is the part of menstrual cycle between ovulation and the onset of the next menstrual bleeding.
1. This is called luteal phase as corpus luteum is formed in the ovary, which mainly controls activities of this phase.
2. This is also called the secretory phase as uterine endometrium is highly secretory during this phase.
3. Luteal phase is also called postovulatory phase.

**Length of Each Phase of Cycle**

In a 28 days cycle, the follicular phase is of 14 days (1–14 days) and the luteal phase is of 14 days (15–28 days).
1. However, alteration of the length of menstrual cycle occurs due to alteration in the duration of follicular phase. Once ovulation occurs, menstrual bleeding starts after 14 days of ovulation.
2. Thus, the length of the luteal phase remains constant irrespective of the cycle length.

Menstrual bleeding occurs in the early part of follicular phase, and usually, ovulation occurs in the mid-cycle or more appropriately, at the end of the proliferative phase and just prior to the beginning of the luteal phase. Therefore, menstrual cycle is sometimes loosely divided into four phases: bleeding phase, follicular phase, ovulatory phase, and luteal phase. However, it should be remembered that bleeding phase is part of the follicular phase and ovulation is not a separate phase, but an event that occurs at the junction between proliferative and secretory phases of the cycle.

**Changes in Reproductive Organs in Menstrual Cycle**

**Changes in the Follicular Phase (Menstrual and Proliferative Phase)**

**Ovarian Changes**

In the follicular phase, one follicle is selected to become the dominant follicle by 4th day. The mechanism of selection of a follicle to grow is not known.
1. The dominant follicle develops into mature follicle (for details of follicular development, see above).
2. The granulosa and theca interna cells proliferate and secrete estrogen.
3. The antrum increases in size and stromal fluid increases in volume.
4. The distended follicle ruptures at about 14th day resulting in ovulation.

**Uterine Changes**

In the early part of the follicular phase, along with the menstrual bleeding, layers of the uterine endometrium are sloughed. Under the influence of estrogen secreted from the developing follicle, thickness of endometrium rapidly increases from 5th to 14th day of the cycle. During this process, following uterine changes occur (Fig. 69.1C):
1. The uterine endometrium undergoes hyperplasia and hypertrophy and increases in size and thickness.
2. The endometrial glands lengthen and glands are drawn out. The glands are lined with columnar epithelium.
3. The endometrium is vascularized with formation of more number of spiral arteries that increase blood supply to the deeper layers. Increased blood supply further promotes growth of uterine mucosa.
4. Endometrial veins also grow in size.
5. Myometrial excitability increases due to the effect of estrogen.

As proliferation of endometrium is the major feature in this phase of the cycle, this is called proliferative phase. This is also called preovulatory phase as the changes occur before ovulation.

**Change in Uterine Cervix**

Under the effects of estrogen, volume of cervical mucous increases.
1. The alkalinity and elasticity of cervical mucous also increase.
2. This forms the physiological basis for spinnbarkeit.
3. The cervical epithelium becomes more secretory.

Sperm easily passes through the estrogen-dependent cervical mucous.
Section 7: Reproductive System

Figs. 69.1A to D: Changes in reproductive organs and secretion of hormones in menstrual cycle. (A) Changes in LH and FSH level; (B) Changes in estrogen and progesterone level; (C) Endometrial changes; (D) Follicular changes.
**Vaginal Changes**
During this phase, under the influence of estrogen, vaginal epithelial cells become cornified (keratinized). The cornification index increases from almost zero on day 1 to about 100 on 14th day.

**Changes in the Luteal Phase**  
**SECRETORY PHASE**

**Ovarian Changes**
Luteal phase starts after ovulation. Following ovulation, follicle is rapidly filled with blood. Therefore, the follicle is called corpus hemorrhagicum. The blood clot inside the follicle is replaced by proliferation of granulosa cells. The granulosa and theca cells of the follicle undergo luteinization to become granulosa lutein cells and theca lutein cells. Thus, the follicle develops into corpus luteum (Fig. 69.1D). The luteal cells secrete progesterone and estrogen. If pregnancy occurs, corpus luteum persists; otherwise it degenerates between 26th to 28th days, and forms corpus albicans.

**Uterine Changes**
During the luteal phase, progesterone secretion increases significantly. Estrogen secretion also increases to some extent. Therefore, following uterine changes occur under the combined effects of estrogen and progesterone. However, major changes are due to the effects of progesterone.
1. The uterine glands become coiled and tortuous.
2. The glandular cells store glycogen and secrete large quantity of carbohydrate-rich mucus and fluid. Therefore, this phase is called secretory phase.
3. The vascularity of endometrium increases further due to combined effects of estrogen and progesterone secreted from corpus luteum. Spiral arteries become tortuous (Fig. 69.1C).
4. Due to increased blood supply and increased secretion, the endometrium becomes edematous and thick.
5. Endometrial veins form venous lakes and anastomoses (Fig. 69.2).
6. Myometrial excitability decreases due to the effects of progesterone.
7. Toward later part, due to regression of corpus luteum, progesterone and estrogen secretions decrease. Coiled arteries constrict that reduces blood supply to endometrium. The foci of necrosis appear in the endometrium at many places.
8. Necrotic areas coalesce and endometrium starts sloughing at the end of secretory phase that heralds the onset of bleeding.

**Change in Cervical Mucous**
Under the effects of progesterone, the cervical mucus becomes thick and its elasticity decreases. Sperm cannot easily enter through the progesterone-dominated cervical mucus.

**Vaginal Changes**
Under the influence of progesterone, vaginal epithelium proliferates and secretes a thick mucus. The epithelium is infiltrated with leucocytes and cornification decreases.

**Mechanism of Menstrual Bleeding**
When corpus luteum degenerates, hormonal support of endometrium is withdrawn. This causes the endometrium to become necrotic.
1. The coiled arteries constrict and reduce blood supply to endometrium.
2. The foci of necrosis coalesce leading to confluent hemorrhage, which occurs along with sloughing of endometrium.
3. This results in menstrual bleeding.

**Mechanism**
The mechanism is initiated by decreased secretion of steroid hormones.
1. Reduction in steroids causes destabilization of lysosomal membranes in the endometrial cells, which leads to release of proteolytic enzymes and production of prostaglandins, especially PGF2α.
2. The proteolytic enzymes cause lysis of the endometrial tissue and PGF2α causes vasospasm producing endometrial ischemia (Application Box 69.1). The ischemic changes result in areas of local necrosis, which is facilitated by proteolytic damage.
3. The foci of necrosis join with each other that result in sloughing of the uterine endometrium.

**Application Box 69.1**
Prostaglandins cause menstrual cramps: Vasoconstriction and uterine contractions are mediated by prostaglandins formed in the endometrium in response to the decrease in plasma estrogen and progesterone. The main mechanism of dysmenorrhea (menstrual cramps) is overproduction of prostaglandins causing excessive uterine contractions. Prostaglandins also cause smooth muscle contraction in other parts of body that accounts for nausea, vomiting, and headache associated with dysmenorrhea.
Amount of Loss
During a normal menstruation, about 30–130 mL of blood is lost. The menstrual blood contains tissue debris, prostaglandins, and fibrinolysin. Increased menstrual loss is known as menorrhagia and decreased loss as hypomenorrhea.

Hormonal Changes in Menstrual Cycle

Estrogen
Estrogen has two peaks in the menstrual cycle.
1. The fist peak, which is the major peak, occurs about 48 hours before ovulation and the second peak, which the minor peak, occurs in the post-midluteal phase (Fig. 69.1B).
2. With the growth of ovarian follicle, estrogen concentration slowly increases in the early part of follicular phase. The concentration rises rapidly from 8th day of cycle to reach the peak about one or two days before ovulation. The concentration decreases thereafter and decreases further after ovulation.
3. About two days after ovulation (after the formation of corpus luteum), again estrogen concentration increases slowly to reach a smaller peak that occurs just after the midsecretory phase.

Progesterone
Progesterone concentration is minimal in the proliferative phase.
1. It starts rising following ovulation and reaches peak in 4 to 5 days after ovulation.
2. The peak is maintained till corpus luteum is active.
3. With regression of corpus luteum, progesterone concentration decreases toward the end of luteal phase.

LH
The concentration of Luteiuing hormone (LH) remains low almost throughout the proliferative phase. However, about a day before ovulation, the secretion of LH increases sharply to reach the peak about 8–10 hours before ovulation. This is called LH surge (see below). Then, it declines fast in 24–48 hours and remains low in rest of the secretory phase (Fig. 69.1A).

FSH
Follicle-stimulating hormone (FSH) secretion increases in the early part of the follicular phase (during menstrual bleeding), and then declines slowly. Synchronous with the rise in LH, secretion of FSH rises toward ovulation and thereafter the pattern of change in FSH is similar with LH pattern.

Inhibins
The pattern of change in concentration of inhibin B coincides with the change in concentration of FSH, whereas the concentration of inhibin A coincides with the pattern of progesterone.

OVULATION
Ovulation is the process of release of ovum (oocyte) from the ovary that results from rupture of Graafian follicle at the end of the follicular phase of the menstrual cycle. Usually, ovulation occurs on 14th day in a 28 days cycle. However, if the cycle length is altered, ovulation occurs 14 days before the onset of menstrual bleeding as the duration of luteal phase (which is 14 days) always remains constant.

Mechanism of Ovulation
Ovulation occurs due to midcycle LH surge.
1. LH surge occurs due to high rise in estrogen concentration toward the later part of follicular phase that provides a positive feedback effects on LH secretion from pituitary.
2. Normally, a mild to moderate increase in estrogen for a brief period is inhibitory on LH secretion.
3. Two-days prior to ovulation, estrogen concentration increases to a higher level and when this high concentration is maintained for about 36 hours, the process of ovulation is initiated.
4. A series of biochemical and morphological changes occur in ovarian follicle that culminates in follicular rupture.
5. Three chemical substances are involved in rupture of ovarian follicle: prostaglandins, cyclin D2 (a protein that regulates cell cycle), and C-EBP (CCAAT-enhancer binding protein). Decreased formation of these chemicals in ovary has been demonstrated to prevent ovulation in mice.

Steps of Follicular Rupture
1. LH surge increases release of prostaglandins and bradykinin that increase the ovarian blood flow. Thus, follicular blood flow increases.
2. The dominant follicle becomes highly vascularized and edematous. This increases the size of the follicle to about 25 mm.
3. Follicular blood flow also increases antral fluid volume, which in turn exerts pressure on the surrounding granulosa cells. The cumulus-oophorus complex gets detached from the follicular wall.
4. The basement membrane that separates granulosa cells and theca cells disintegrates due to intrafollicular pressure and the effects of proteolytic enzymes.
5. LH promotes synthesis of plasminogen activator by granulosa and theca cells, which causes conversion of plasminogen to plasmin. Plasmin causes proteolysis of follicular wall. Plasmin also activates the synthesis of collagenase that causes destruction of connective tissue matrix of the follicular wall and adjacent ovarian capsule.

6. Increased intrafollicular pressure and degeneration of the follicular wall facilitate the rupture of the follicle, which results in expulsion of oocyte from the follicle and the ovary.

7. FSH surge is not essential for ovulation (Application Box 69.2)

**Application Box 69.2**

FSH surge occurs simultaneously: It should be noted that though midcycle FSH surge also occurs almost simultaneously along with LH surge, FSH surge is not essential for ovulation. However, FSH primes the follicular cells to express adequate number of LH receptors.

---

**Indicators of Ovulation**

It is important to know the day of ovulation for its physiological and clinical significance. The indicators of ovulation are as follows:

1. **Rise in of basal body temperature:** The basal body temperature (BBT) increases during ovulation by about 0.5°C. Accurate charting of this temperature can exactly detect the day of ovulation.
   a. It is recorded orally, early in the morning before getting up of the bed, and before taking any drink or washing the mouth.
   b. The increase in body temperature is due to the influence of progesterone that starts increasing with the beginning of secretory phase. Progesterone is thermogenic.

2. **Fleeting lower abdominal pain (mittelschmerz):** With ovulation, bleeding occurs into the antrum of the follicle.
   a. Small amount of blood also escapes into the abdominal cavity, which causes peritoneal irritation and produces fleeting (short-lived) lower abdominal pain.
   b. This is called as mittelschmerz.

3. **Vaginal discharge (spotting):** There may be transitory increase in vaginal discharge during ovulation.
   a. When rise in BBT is associated with mittelschmerz and spotting, they are collectively called as ovulation cascade.
   b. If all the three features are present, occurrence of ovulation is almost confirmed.

4. **Spinnbarkeit:** In the proliferative phase, estrogen makes the cervical mucous thin and alkaline.
   a. With the beginning of secretory phase, progesterone secreted from corpus luteum makes the cervical mucous thick and tenacious. Thus, uterine mucous is thinnest at the time of ovulation and its elasticity is maximal.
   b. Therefore, a drop of cervical mucous collected at the time of ovulation can be stretched to as long as 10 cm or more like a thread. This elastic nature of the mucous is called spinnbarkeit.
   c. Decreased elasticity indicates ovulation has already taken place.

5. **Fern test:** Under the effect of estrogen, the cervical mucous before ovulation forms an arborizing fern like pattern, when the mucous is spread on a slide.
   a. This is confirmed by microscopic examination of the mucous smear.
   b. Following ovulation, due to progesterone effect, the mucous become thick and fern pattern is not observed in smear of the mucous.

6. **Laparoscopic observation:** Demonstrating ovum in the abdominal cavity by laparoscopy confirms ovulation.

7. **Demonstration of LH peak:** LH surge occurs just prior to ovulation. Therefore, daily estimation of plasma LH in the periovulatory period will accurately detect the day of ovulation.

---

**Physiological Importance**

Determination of day of ovulation helps in family planning.

1. The life span of ovum is about 72 hours.
2. Therefore, those who are desirous of a child, should have regular sexual act in the periovulatory period (day of ovulation, and two days before and after the ovulation).
3. Those who want to avoid pregnancy, should not have unprotected sexual act during the unsafe period (day of ovulation, four days before and after ovulation) of the cycle (Fig. 69.3).
4. Thus, it helps in planning both conception and contraception (for details, see “Female Contraceptives”).
Amenorrhea
Absence of menstrual cycle is referred to as amenorrhea. Amenorrhea is broadly classified into two categories: primary and secondary; each category subdivided into physiological and pathological.

Primary Amenorrhea
When menstruation has never occurred, the condition is called primary amenorrhea. There are physiological and pathological causes of primary amenorrhea.

Physiological Primary Amenorrhea
Amenorrhea occurs in many physiological conditions. Physiological amenorrhea is more common than pathological amenorrhea. The causes of physiological amenorrhea are:
1. Before puberty: Amenorrhea is normal in childhood and prepubertal age. Usually, menstruation starts at the age of 12–14 years.
2. Constitutional amenorrhea: Though menstrual cycle starts normally by the age of 16 years, sometimes it may not occur even at the age of 18 years or more, without there being any abnormality. This is called constitutional amenorrhea.

Pathological Primary Amenorrhea
When menstrual cycle does not start till the age of 18 years due to some prevailing disease, the condition is called pathological primary amenorrhea.
1. It usually occurs due to congenital and genetic defects. Examples are Turner syndrome, Kallman syndrome, etc.
2. Congenital malformations of reproductive tract like absence of uterus can also cause primary amenorrhea.

Secondary Amenorrhea
When menstrual cycle stops in a woman who had normal cycles before, the condition is called secondary amenorrhea. There are physiological and secondary causes.

Physiological Secondary Amenorrhea
Physiological causes of secondary amenorrhea are more common than pathological causes.
1. Peri-pubertal amenorrhea: In first one to two years of onset of menarche, menstrual cycles are often anovulatory and therefore irregular. Menstruation does not occur even for 2–4 consecutive cycles. This is called peripubertal amenorrhea. This very common till the age of 12–14 years.
2. Pregnancy: Pregnancy is the commonest cause of secondary amenorrhea. It is so common amongst all forms of amenorrhea that before investigating for the causes of amenorrhea, first, pregnancy should be ruled out.

Pathological Secondary Amenorrhea
Pathological secondary amenorrhea occurs due to a defect in hypothalamus, pituitary, ovary and uterus or due to a systemic disease or chronic use of some drugs.
1. Hypothalamic disorders: Hypothalamic diseases resulting in decreased secretion of GnRH leads to amenorrhea. The reduction in frequency of GnRH pulses rather than the absolute decrease in concentration of GnRH is the cause of hypothalamic amenorrhea. Recently, it has been observed that this occurs due to increased opioid activity and treatment with opioid blockers like naltrexone cures hypothalamic amenorrhea.
2. Pituitary disorders: Tumors and other diseases of pituitary (hypopituitarism) resulting in decreased secretion of gonadotropins leads to amenorrhea. Examples are Sheehan’s syndrome (post-partum ischemic necrosis of anterior pituitary due to severe hemorrhage during childbirth) and Simmond’s syndrome (complete destruction of anterior pituitary) etc.
3. Ovarian diseases: Diseases that decrease the production of estrogen and progesterone, frequently lead to amenorrhea. In Stein-Leventhal syndrome (polycystic ovarian disease), amenorrhea occurs due to abnormal production of hormone leading to high LH-FSH ratio and high androgen level.
4. Uterine pathology: Congenital absence of uterus, underdeveloped uterus and severe infective or non-infective endometritis produce amenorrhea.
5. Systemic illness: Amenorrhea occurs in chronic illnesses like chronic hypothyroidism, chronic renal failure and cirrhosis of liver. Any systemic illness that leads to cachexia may also cause amenorrhea.
6. Drugs: Phenothiazine derivatives, reserpine, ganglion blocking agents and estrogen-progesterone preparations (pill contraceptives) are common drugs that prevent menstrual cycles. They mainly act by inhibiting hypothalamic release of GnRH.
**Anovulation**

Absence of ovulation during a menstrual cycle is called anovulatory cycle.

1. **Following menarche**, menstrual cycles may be anovulatory for first 1 to 2 years.
2. Few cycles may also be anovulatory in lactating woman, and about six months before menopause.
3. Anovulation also occurs in severe strenuous exercise or severer job related stress.
4. Except these physiological situations, anovulation is abnormal and occurs mainly due to hormonal deficiencies.

**Treatment of Amenorrhea and Anovulation**

If amenorrhea is due to hypothalamo-pituitary defects, pulsatile administration of GnRH gives successful result. In hypopituitarism, sequential administration of FSH and hCG is useful. If amenorrhea is due to pituitary tumor, their surgical removal should be considered. Clomiphene, that binds with estrogen receptors and blocks estrogen action, induces ovulation. Clomiphene increases LH and FSH secretion by reducing the negative effects of estrogen. For uterine pathologies, corrective surgeries should be performed.

**Hypomenorrhea and Oligomenorrhea**

Decreased menstrual bleeding in duration or amount or both is called hypomenorrhea. It may be constitutional, or due to uterine pathology or due to hormonal disorders.

Decreased frequency (cycle more than 35 days) of menstrual cycle is called oligomenorrhea. Usually, oligomenorrhea occurs in ovarian diseases in which menstruation is irregular and infrequent.

**Dysmenorrhea**

Dysmenorrhea means painful menstrual bleeding. It is classified into two categories:

1. **Primary dysmenorrhea** in which there is no visible pelvic pathology, and
2. **Secondary dysmenorrhea** in which a uterine or pelvic pathology is associated with it. Usually, it occurs due to passage of clots in flow.

Dysmenorrhea occurs due to accumulation of prostaglandins in the uterine fluid. Therefore, use of prostaglandin inhibitors usually gives relief from dysmenorrhea.

**Menorrhagia, Metrorrhagia, and Polymenorrhea**

**Menorrhagia**

*Increased menstrual bleeding* in amount, duration or both is called menorrhagia.

1. It is generally caused by conditions that affect uterus and its vascular apparatus rather than any ovarian dysfunction.
2. Or, sometimes it may be a manifestation of coagulation disorder.

**Metrorrhagia**

Bleeding occurring between the periods (acyclical and irregular) is called metrorrhagia. It usually indicates a surface lesion in the genital tract, which may be benign or malignant.

**Polymenorrhea**

When menstrual cycle occurs frequently (less than 21 days), it is called polymenorrhea. Usually, the amount and duration of bleeding remain normal.

**Premenstrual Syndrome**

Few women develop some nonspecific features about a week before the onset of menstrual bleeding that are combinely called as premenstrual syndrome (PMS) or premenstrual dysphoric disorder (PMDD).

**Features:** The usual features are edema, painful or swollen breasts, depression, loss of concentration, irritability, headache, behavioral changes, and emotional disturbances. These features disappear within 1–3 days after the start of menstruation.

**Etiology:** Though the salt and water retention has mainly been attributed to PMS, the exact cause of it is not known. Recently, it has been proposed that PMS occurs due to an excess and complex interplay between the sex steroids and brain neurotransmitters.

**Treatment:** Treatment with drugs that prematurely terminate luteal phase of the cycle does not give any substantial relieve, which indicates that the PMS is not due to hormonal imbalance. Also, the plasma concentrations of hormones usually found to be normal in these patients. However, treatment with alprazolam (minor tranquilizer), prozac (serotonin uptake inhibitor) and GnRH agonist give some relief. This proves the hypothesis that PMS is due to the complex interplay between the gonadal steroids and neurotransmitters in the brain.

**Anorexia Nervosa**

It is a complex behavioral disorder in women which manifests as severe anorexia (loss of food intake) associated with functional abnormalities.

1. **Amenorrhea** is seen in 30–40% of cases.
2. Patient is grossly emaciated.
3. Emaciation (low body fat) and stress inhibit LH secretion through endorphins.
4. Pubic hair development and breast development usually remain unaffected.
CHAPTER SUMMARY

**Key Concepts**

1. The duration of menstrual cycle is not constant even in a healthy woman, as it affected by many psychosocial factors that alter hormones related to hypothalamo-pituitary-gonadal axis. The luteal phase remains constant and alteration in cycle occurs due to change in proliferative phase.
2. BBT is a good sign of ovulation. But BBT should be recorded properly to note the exact change in temperature.
3. LH surge is an example of positive feedback mechanism.

**Important to Know (Must Read)**

1. In examination, "With the help of a suitable diagram, describe the uterine and ovarian changes during different phases of menstrual cycle" is usually asked as a Long Question.
2. Indicators of ovulation, Uterine changes during different phases of menstrual cycle, Ovarian changes during different phases of menstrual cycle, Amenorrhea, Premenstrual syndrome (PMS), Mechanism of ovulation, Mechanism of menstrual bleeding, are asked as Short Questions in exam.
3. In Viva, examiner may ask… List the indicators of ovulation, What is mittelschmerz, What is spinnbarkeit, What is spotting, What is ovulation cascade, What is fern test, What are the phases of menstrual cycle, What are the uterine changes during different phases of menstrual cycle, What are the ovarian changes during different phases of menstrual cycle, What are the hormonal changes during different phases of menstrual cycle, What are the vaginal changes during different phases of menstrual cycle, What is the duration of menstrual cycle, How do you calculate the day of ovulation, How does the determination of the day of ovulation help in family planning, List the steps of follicular rupture, What is the mechanism of menstrual bleeding, What is the role of prostaglandins in menstruation, What is amenorrhea and what are its types, What is primary amenorrhea and what are its types, What is physiological primary amenorrhea and what are its causes, What is pathological primary amenorrhea and what are its causes, What is secondary amenorrhea and what are its types, What is physiological secondary amenorrhea and what are its causes, What is pathological secondary amenorrhea and what are its causes, What is the treatment of amenorrhea, What is anovulation and what is its treatment, What is hypomenorrhea and what are its causes, What is oligomenorrhea and what are its causes, What is dysmenorrhea and what are its causes, What is menorrhagia and what are its causes, What is metrorrhagia and what are its causes, What is polymenorrhea and what are its causes, What is premenstrual syndrome (PMS), What are the causes, features and treatment of PMS, What is anorexia nervosa and what are its features.
Ovarian Hormones and Control of Ovarian Functions

CHAPTER 70

Learning Objectives
On completion of study of this chapter, the student MUST be able to:
1. List the ovarian hormones.
2. Describe the functions of ovarian hormones.
3. List the secondary sexual characteristics in females.
4. Understand the mechanisms of control of ovarian functions.
5. Apply the knowledge of ovarian functions to understand the abnormalities of female reproduction.
The student MAY also be able to:
1. Describe the control of ovarian functions.

Ovarian Hormones

Ovary secretes estrogens, progesterone, Inhibins and relaxin.

Estrogens

The naturally synthesized estrogens are 17β-estradiol, estrone, and estriol (Fig. 70.1). Estradiol is 15 and 80 times more potent than estrone and estriol respectively.

Source

Estrogen is secreted from granulosa cells of ovarian follicles, corpus luteum, and placenta. Estrogen is not directly secreted from adrenal gland, but adrenal androgen is converted to estrogen by the enzyme aromatase.

Synthesis

Estrogen is a steroid hormone, synthesized from cholesterol (Flowchart 70.1). LH, acting on LH receptors located on theca interna cells converts cholesterol to androstenedione.

1. In theca cells, some androstenedione is converted into estradiol, but most of it is supplied to granulosa cells to be converted into estrogen in those cells.
2. FSH acting on the FSH receptors on the granulosa cells facilitates the conversion of androgen to estrogen by activating the activity of the enzyme aromatase.

Secretion

Estrogen secretion occurs in two peaks during the menstrual cycle. A larger peak occurs during proliferative phase just before ovulation and a smaller peak in the mid-secretory phase. The rate of secretion of estradiol is about 35 µg per day in the early follicular phase, 400 µg per day
just before ovulation and 250 µg per day in the midluteal phase. Secretion of estrone is similar to the secretion of estradiol. The secretion is very low after menopause.

**Metabolism**

Like other steroid hormones, about 98% of circulating estrogen is bound to proteins. 60% of the estrogen is bound to albumin and 38% to steroid-binding globulin. In liver, estrogens are metabolized through oxidation or are converted to their glucuronide and sulfate derivatives that are excreted in urine.

**Mechanism of Action**

Like other steroid hormones, estrogen binds with the receptor in the nucleus and increases the formation of mRNA. There are two types of estrogen receptors: ERα and ERβ. ERα are present mainly on uterus, liver, kidney and heart, and ERβ are present in ovaries, brain, GI tract, hemopoietic tissues, lungs and prostate. Estrogens have both genomic and nongenomic actions. Most of the actions are genomic that are mediated via production of mRNA. However, some of the effects are nongenomic that occur rapidly and are mediated via intracellular second messengers.

**Physiological Actions**

**Effects on Female Reproductive System**

Estrogen promotes growth of all components of female reproductive system. In general, it causes growth of smooth muscle and proliferation of epithelial lining of reproductive tract.

**On ovary**

Estrogen stimulates growth of ovary and ovarian follicles. Role of estrogen on follicular growth has been described in Chapter 70 ‘Follicular development’.

**On Fallopian Tubes**

Estrogen stimulates smooth muscle contraction of fallopian tubes and therefore increases fallopian tube motility. It also increases ciliary activity of the tubes.

**On Uterus**

Estrogen has wide ranging effects on uterus.

1. It increases uterine size. Therefore, in prepubertal girls or castrated females the uterus is small with thin myometrium.
2. During the follicular phase of menstrual cycle, estrogen causes proliferation of uterine endometrium.
3. During luteal phase, along with progesterone, it increases uterine fluid secretion. It also increases progesterone receptor on uterine endometrium. Thus estrogen prepares endometrium for progesterone action.
4. It increases uterine blood flow. Therefore, it increases myometrial size (Application Box 70.1).
5. It increases the content of contractile proteins in uterine smooth muscles. It increases the activity and excitability of uterine muscle. It also increases the sensitivity of uterus to oxytocin. Estrogen secretion increases towards term and all these uterine changes prepare the uterus for parturition.

**Effects on Cervical Mucus**

Under the influence of estrogen, cervical mucus becomes abundant, clear, and watery. These characteristics become more pronounced at the time of ovulation to allow sperm to easily pass through the cervical mucus barrier on their way to the uterus and fallopian tubes.

**Effects on Breast**

Estrogen causes breast enlargement during puberty. Therefore, it is known as “growth hormone of the breast”. It causes growth of ducts of the mammary gland. It also causes pigmentation of the areola.

**Effects on Secondary Sexual Characteristics**

At the time of puberty, secondary sexual characteristics develop in girls due to the effects of estrogen. Following are the secondary sexual characteristics in females:

1. Female body configuration: Narrow shoulders and broad hips.
2. Wide carrying angle: Thighs that converge and arms that diverge.
3. Female distribution of fat: Fat deposition in the hips and breast (breast enlargement).
4. Voice remains high pitched, as no change in larynx occurs.
5. Less hair on the body and more hair on the scalp.
6. **Pubic Hair:** Female escutcheon of pubic hair. Pubic hair distribution in females forms a triangle with **base upward and apex downward.**
7. **Internal Genitalia:** Vagina, uterus, ovary, fallopian tube grow in size and functions (as described above). It is believed that growth of pubic and axillary hairs occurs due to androgen in females rather than estrogen.

**Effects on Endocrine Organs**
Estrogen has wide ranging endocrine effects.
1. Estrogen **inhibits LH secretion** by its negative feedback effects directly on pituitary and by indirectly inhibiting GnRH secretion from hypothalamus. However, before ovulation, the feedback becomes positive that results in LH surge.
2. Estrogen **inhibits FSH secretion.**
3. It **stimulates prolactin secretion.** However, it inhibits the milk producing action of prolactin on breast.
4. It **promotes the synthesis of angiotensinogen** from liver. Thus, it **activates renin-angiotensin system.** By increasing the formation of angiotensin II, it **increases blood pressure,** especially when estrogen is taken for a longer period; for example as contraceptive pill.
5. Estrogen **increases the formation of thyroxine-binding globulin.** Therefore, the free thyroxine concentration decreases in estrogen therapy and also in later part of pregnancy when estrogen concentration is high.
6. It **stimulates androgen secretion** from adrenal cortex (Application Box 70.2).

**Application Box 70.2**

**Estrogen stimulates growth of animals:** In farm animals, commercially available estrogen injections are given to increase the body weight of the animal. This occurs due to the **protein anabolic effect** of estrogen, which is ** induced by increased androgen secretion** from adrenal cortex. Estrogen injection is known to promote growth of chickens and cattle.

**Effects on CNS**
By activating neurons in the limbic system, estrogen stimulates **libido.** Especially, acting on the suprachiasmatic area of hypothalamus, it produces **sexual behaviors.** Conversely, estrogen implantation into arcuate nucleus-ventral hypothalamus complex in experimental animals has been observed to produce ovarian atrophy.

**Effects on Musculoskeletal System**
Estrogen **stimulates bone growth.**
1. It **prevents osteoclastic activity.** Therefore, estrogen **prevents osteoporotic activity.**
2. Estrogen causes **epiphyseal closure.** Hence, it causes cessation of longitudinal growth of bone and therefore, **determines the height** of the female.
3. Estrogen has no direct effect on growth of skeletal muscle. However, by stimulating androgen secretion, it facilitates skeletal muscle development.

**Effects on Water and Electrolyte Metabolisms**
Estrogen promotes **salt and water retention** to some extent by directly acting on kidney tubules. This contributes to **ECF expansion and hypertension** in chronic estrogen therapy, in addition to its activation of renin-angiotensin system.

**Effects on Lipid Profile**
Estrogen is a strong **cholesterol lowering agent,** and therefore, it **prevents atherosclerosis.** Hence, coronary artery disease, especially myocardial infarction is less common in females during their reproductive life. Possibly, estrogen also increases HDL concentration in plasma.

**Effects on Sebaceous Secretion & Skin**
From sebaceous gland, estrogen promotes more fluid secretions. This antagonizes the thick sebaceous secretion of androgen. Thus, estrogen **inhibits the formation of acne.** Chronic high estrogen levels may produce cutaneous angiomas (Clinical Box 70.1)

**Clinical Box 70.1**

**Hyperestrogenemia in liver diseases:** Androstenedione is metabolized in liver. Therefore, in advanced liver diseases, circulating androstenedione concentration increases, that facilitates their conversion into estrogen. Hence, spider angiomas and breast enlargement are features of advanced stage of liver diseases.

**Estrogen Preparations**
Naturally occurring estrogens as extracted from plants have adverse effects when injected into farm animals. They may promote uterine and breast cancer. Therefore, **synthetic estrogens** that have no effects on uterine and breast tissue but have bone preserving and anabolic effects are used in humans and animals. This becomes possible due to the activation of selective estrogen receptor modulators in specific tissues. Examples of such estrogens are tamoxifen and raloxifene.

**Progesterone**

**Source, Synthesis and Metabolism**
Progesterone is secreted from **corpus luteum, placenta and ovarian follicle.** It is also an intermediate product in many steroid biosynthesis.
1. It is formed from pregnenolone. The plasma concentration of progesterone in follicular phase is about 0.9 ng/mL, and in luteal phase at its peak is 18 ng/mL.
2. Like other steroid hormones, progesterone is mainly bound to plasma proteins. Only 2% circulates freely in plasma, whereas 80% is bound to albumin and 18% is bound to corticosteroid-binding globulin.
3. In the liver, it is converted to **pregnanediol,** which forms **glucuronide conjugates** and excreted in urine (Flowchart 70.2).
Mechanism of Action
Like other steroid hormones, progesterone acts on the receptors located in the nucleus, and the biochemical mechanism of action is through increased gene transcription.

Physiological Actions

Effects on Reproductive Organs
Progesterone inhibits uterine myometrial contractions, by following mechanisms:
1. It opposes the stimulatory actions of estrogen and locally generated prostaglandins. This is very important for implantation of fertilized egg and continuation of pregnancy.
2. It increases the rate of conversion of 17β-estradiol to less active estrogens.
3. Progesterone also directly causes relaxation of uterine smooth muscles.
4. It also decreases excitability of myometrium and the sensitivity of myometrium to oxytocin. Progesterone increases the membrane potential and decreases the spontaneous electrical activity of myometrial cells.

Uterine quiescence is maintained throughout pregnancy by progesterone, which is crucial to prevent premature expulsion of the fetus (abortion).

Progesterone also has important effects on the secretion of mucus from the cervix. It causes the cervical mucus to become thick and sticky; in essence, this acts as a plug that prevents infective organisms from vagina to enter the uterus. This antibacterial blockage protects the growing embryo if conception has occurred.

Progesterone acts on estrogen-primed endometrium and increases secretions from endometrial glands. It inhibits proliferation of the cells lining the vagina.

Effects on Breast
It promotes growth of the breast, especially the growth of the glandular tissue (lobules and alveoli). It supports the differentiation of estrogen-prime ductal tissue. It also supports the secretory functions of breast during lactation.

Effects on Body Temperature
Immediately after ovulation, there is a small increase (approximately 0.5°C) in body temperature that occurs due to an action of progesterone on temperature regulatory centers in the brain. Progesterone is thermogenic.

Effects on Hypothalamo-Pituitary Axis
Progesterone has negative feedback effects on hypothalamo-pituitary axis. It decreases LH secretion. In large doses, it also potentiates the inhibitory effects of estrogen. Therefore, it prevents ovulation. Hence, it is used as a contraceptive agent.

Effects on Respiration
Progesterone stimulates respiration and produces tachypnea. Therefore, the PCO₂ decreases in pregnancy.

Effects on Blood Pressure
Progesterone causes vasodilation (relaxation of vascular smooth muscle). Therefore, diastolic pressure decreases in pregnancy. Thus, hypertension is never a feature of normal pregnancy. This also contributes to wide pulse pressure in pregnancy as systolic pressure increases due to ECF expansion.

On Electrolyte and Water Metabolisms
In large doses, progesterone produces natriuresis and diuresis by blocking the effects of aldosterone on kidney tubules.

Other Ovarian Hormones

Relaxin
Relaxin is a polypeptide hormone. Structurally it is similar to insulin and insulin like growth factors. The gene for relaxin is located on chromosome 9.

Source
Relaxin is secreted from corpus luteum, placenta, uterus and breast tissue in females, and prostate glands in males. The secretion of relaxin increases towards later part of pregnancy reaching a peak just before term.

Functions
1. It relaxes pubic symphysis and pelvic joints and ligaments.
2. It causes softening and dilation of uterine cervix. Thus it facilitates parturition.
3. It inhibits uterine contraction.
4. It promotes development of mammary gland.
5. In nonpregnant woman, it is secreted from corpus luteum in the secretory phase of menstrual cycle. However, its physiological significance is not known.
6. In males, it is secreted from prostate. It facilitates sperm motility and penetration of ovum by sperm.
Inhibins
Inhibins are secreted from granulosa cells of ovary. Inhibin inhibits the secretion of FSH from anterior pituitary (for details, refer ‘Male Reproductive System’).

Androgens
Androgens are secreted in women from adrenal glands and ovaries.
1. These androgens play some role in the female reproductive functions.
2. They stimulate the growth of pubic and axillary hairs and possibly they also promote growth of skeletal muscle.
3. They also help maintain sexual desire (libido).
4. However, excess production leads to male body hair distribution, abnormal skeletal muscle growth, enlargement of clitoris and reduction in breast size.

CONTROL OF OVARIAN FUNCTIONS
Ovaries have the following major functions:
2. Release of oocyte (ovulation) at the end of proliferative phase of the menstrual cycle.
3. Nourishment and development of resident oocytes.
4. Preparation of fallopian tube to facilitate fertilization.
5. Preparation of uterus for implantation of fertilized ovum.
6. Providing hormonal support to the embryo till placenta starts functioning.

The ovarian functions are controlled by hormones secreted from hypothalamus, anterior pituitary and ovary. They are GnRH, FSH and LH, and gonadal sex hormones. The major factor determining ovarian function is the pulsatile secretion of GnRH from hypothalamic neuroendocrine cells. The pattern of frequency and amplitude of GnRH pulses during a 24-hour period is different over the course of the menstrual cycle. Also, responsiveness of the pituitary to GnRH and of the ovaries to gonadotropins varies in different phases of the cycle.

Hypothalamic Control
Hypothalamus plays an important role in regulating ovarian functions by controlling the secretion of gonadotropins from anterior pituitary.
1. Hypothalamus secretes GnRH, which is released in episodic bursts. This episodic secretion of GnRH determines circannual peaks of LH secretion. It has been experimentally observed that maintaining a constant and steady release of GnRH inhibits (Clinical Box 70.2), whereas episodic and pulsatile injection of GnRH stimulates LH secretion.
2. Episodic secretion of GnRH not only stimulates LH secretion, but also regulates secretion of other hormones that control menstrual cycle.
3. The frequency of GnRH burst is important in bringing the LH surge.
4. Also, the sensitivity of gonadotrophs of anterior pituitary to the GnRH burst is important in bringing LH surge, which increases towards ovulation.
5. The higher concentration of estrogen stimulates this frequency towards the later part of follicular phase that finally culminates in LH surge.
6. However, the exact site of GnRH pulse generator in the hypothalamus is not known.
7. Progesterone, androgen, catecholamines, enkephalins and endorphins inhibit frequency of GnRH pulses.

Clinical Box 70.2
Long-acting GnRH analogs: As described above, a constantly elevated GnRH level in plasma inhibits LH secretion by down-regulating receptors on gonadotrophs. Therefore, long-acting GnRH analogs are used in treatment of precocious puberty as it inhibits LH secretion by chronically maintaining a GnRH level. It is also used in therapy of prostate cancer.

Pituitary Control
The anterior pituitary secretes LH and FSH. The major target organs of these hormones are gonads. Therefore they are called gonadotropins. Primarily, they control ovarian functions in both the phases of menstrual cycle. Ovarian control by gonadotropins has a similar analogy with testicular control (Clinical Box 70.3).

Clinical Box 70.3
Analogy with testis: The granulosa and theca cells of ovarian follicle are similar to the Sertoli and Leydig cells of testis. Sertoli cells provide microenvironment in testis in which the germ cells develop and mature, and Sertoli are stimulated by FSH. Granulosa cells resemble Sertoli cells in their function by providing environment for development of oocyte, and for their control by FSH. Like Sertoli cells granulosa cells also secrete inhibin-B that controls FSH secretion from pituitary. The theca cells are similar to the Leydig cells in that they produce androgens and are stimulated mainly by LH.

The Pattern of Secretion of Gonadotropins
The FSH level in plasma slowly increases in the early part of the follicular phase and then steadily decreases in the remainder of the phase and then increases rapidly towards the end of the phase to attain a mid-cycle peak (refer to Fig. 69.1, Chapter 69).
1. The LH in level plasma is low in most part of the cycle except in the periovulatory period. It starts increasing rapidly about a day before ovulation to reach a very large mid-cycle peak, called LH surge.
2. This is followed by a rapid decline of LH in the luteal phase.

Regulation by FSH
A number of primary and early antral follicles are always present in the ovary between puberty and menopause. Further development of these follicles beyond these stages requires stimulation by FSH.
1. **Before puberty**, the concentration of FSH in the plasma is too low to bring such development.

2. **After puberty**, during first half of each menstrual cycle, increase in FSH secretion stimulates follicular growth. FSH stimulates proliferation of granulosa cells to produce estrogen, and stimulates enlargement of the antrum.

3. FSH also primes the granulosa and theca cells to the effect of LH.

### Regulation by LH

LH acts on the theca and granulosa cells. These cells are converted to luteal cells as follicle becomes corpus luteum after ovulation. LH causes luteinization of these cells. LH surge is responsible for ovulation to occur (for details, refer “Mechanism of Ovulation” in previous chapter).

### The Ovarian Control

Ovary controls its own functions by secreting hormones that directly influence granulosa cell function or indirectly influence hypothalamic-pituitary-ovarian axis (feedback control).

### The Pattern of Secretion of Gonadal Hormones

#### Estrogen

After remaining low in the first week, estrogen first increases slowly and then rapidly in the second week as the dominant ovarian follicle grows and secretes more estrogen.

1. **Estrogen peak occurs about two days before ovulation** and then decreases rapidly in next two days.
2. The second but **slow and small peak** of estrogen occurs in luteal phase due to its secretion from corpus luteum.

#### Progesterone

Progesterone release is low during the follicular phase.

1. But, soon after ovulation, progesterone concentration **increases rapidly in luteal phase** due to its release in large amount from corpus luteum.
2. Inhibin-B secretion resembles the secretory pattern of FSH.

### Direct Regulation

Theca cells secrete androgen, which facilitates secretion of estrogen by the granulosa cells.

### Feedback Regulation

The dominant follicle secretes estrogen that inhibits gonadotropins (the **negative feedback effect**) from pituitary and GnRH secretion from hypothalamus (Fig. 70.2).

1. When plasma concentration of estrogen is very high the secretion of gonadotropin increases (the **positive feedback effect**).

### APPLIED ASPECTS

Reproductive abnormalities that either lead to or occur due to ovarian dysfunctions can broadly be classified into two categories: genetic and hormonal abnormalities.

### Genetic and Hormonal Abnormalities

Following genetic abnormalities are common in women, and are associated with hormonal dysfunctions:

#### GnRH Resistance

This occurs due to **decreased number and sensitivity of GnRH receptors** on gonadotrophs of pituitary.
FSH Resistance
This occurs due to decreased number and sensitivity of FSH receptors on granulosa cells of pituitary.

LH Resistance
This occurs due to decreased number and sensitivity of LH receptors on granulosa and theca cells of ovarian follicles.

Aromatase Deficiency
The enzyme aromatase is required for synthesis of gonadal hormones. Aromatase (CYP 19) converts testosterone to estradiol and androstenedione to estrone. Therefore, its deficiency leads to estrogen deficiency and amenorrhea.

McCune-Albright Syndrome
This is an example of receptor protein (G protein) abnormality in which $G_{sa}$ is active in some cells and defective in others. It causes endocrine dysfunctions associated with precocious puberty, amenorrhea and galactorrhea. Lina Medina of Peru was the commonly quoted example of Albright syndrome.

Kallmann’s Syndrome
This is a hypogonadal form of deficiency of LH and FSH neurons that occurs due to failure of migration of these neurons from the olfactory bulb. The GnRH secretion from hypothalamus is less and therefore deficiency occurs in secretion of LH and FSH. Pubertal maturation of testes in males and ovaries in females fail to occur (hypogonadotropic hypogonadism).

**CHAPTER SUMMARY**

**Key Concepts**

1. The major function of estrogen is development secondary sexual characters in women including the development of breast and reproductive structures. It causes proliferation of endometrium and follicular development in preovulatory phase of menstrual cycle. It protects from atherosclerosis and cardiovascular risks.

2. The major function of progesterone is relaxation of uterine smooth muscle and decreases excitability of the myometrium in early part of pregnancy. This favors implantation and prevents abortion. It causes uterine changes in the secretory phase of the cycle. It decreases BP.

3. Ovarian functions are controlled mainly by feedback regulation of hypothalamo-pituitary-gonadal axis driven by the circulating ovarian hormones.

**Important to Know (Must Read)**

1. In examination, ‘Describe the physiological actions and regulation of secretion of estrogen and progesterone’ may be asked as a Long Question.

2. Physiological actions of estrogen on female reproductive system, Secondary sexual characteristics in females, Physiological actions of progesterone, Hypothalamic control of ovarian function, Pituitary control of ovarian function, Ovarian control of ovarian function may be asked as Short Questions in exam.

3. In Viva, examiner may ask… Name the hormones secreted from ovary, What are the functions of estrogen, Name the secondary sexual characteristics in women, What are the physiological actions of estrogen on female reproductive system, on breast, on secondary sexual characteristics, on endocrine organs, on CNS on musculoskeletal system, on water and electrolyte metabolism, on lipid profile, Why is estrogen used in animal farms, Why does hyperestrogenemia occur in liver diseases, What are the estrogen preparations, List the functions of progesterone, What is the mechanism of action of estrogen and progesterone, What are the functions of relaxin, What is the function of inhibin released from ovary, What are the functions of androgens in women, List the functions of ovaries, How does the hypothalamus control the ovarian function, What is the use of long-acting GnRH analogs, How does the pituitary control the ovarian function, How does the ovary regulate its own function, List the genetic and hormonal abnormalities in women, What is McCune-Albright syndrome, What is Kallmann’s syndrome.
CHAPTER 71

Physiology of Copulation

LEARNING OBJECTIVES
On completion of study of this chapter, the student MUST be able to:
1. Understand the blood supply and innervation of the erectile tissues of the penis.
2. Learn the mechanism of erection of penis.
3. Understand the process of emission and ejaculation.
4. Describe the sexual responses in females.
5. Appreciate the mechanism of orgasm.
6. Define impotence and give its physiological basis.

The student MAY also be able to:
1. Describe the processes and mechanisms involved in male and female sexual act.

Copulation is the process of mating that occurs in human being by coitus, or the sexual act. Though the physiology of mating is similar in primates, the sexual responses of male and female are different in human being. It is important to understand the physiology of copulation to learn the pathophysiology of impotency, which is quite common in the present society.

MALE SEXUAL ACT
In sexual intercourse, male is the active partner. The major events of male sexual act include:

- Erection of penis,
- Penetration of penis into the vagina, and
- Ejaculation.

These are the series of reflexes that are integrated in the spinal cord and mediated via autonomic and somatic nerves.

1. Male genital tract receives both sympathetic and parasympathetic innervation, and in addition, penis receives the somatic innervation.
2. Though the sexual act per se is mainly a neural process, its overall integration is a behavioral phenomenon that includes hormonal, biochemical and psychological interactions.

Erection
Blood supply: Penis is supplied by internal pudendal arteries that enter the organ as dorsal artery of penis from its dorsal surface. Dorsal artery penetrates deeply into the erectile tissues of penis as deep artery (Fig. 71.1). Venous drainage from penis occurs by dorsal vein.

Mechanism
Erection occurs due to dilatation of the penile arterioles filling the erectile tissues of the penis by blood. The erectile tissues of penis are three in numbers: two corpora cavernosa and a corpus spongiosum (Fig. 71.2).

1. In normal state, penis is flaccid due to paucity of blood in the spaces of these erectile tissues.
2. Upon arousal, mainly the spaces in cavernous erectile tissue fill with blood and penis becomes turgid (Fig. 71.3).
3. Relaxation of the smooth muscles of corpora allows increased flow of blood into corporal interstices (cavernous spaces) that increases the volume and rigidity of the penis.
4. As veins are compressed by the erectile tissues filled with blood, engorgement of penis inhibits venous return and keeps the interstices filled with blood, which maintains erection.
3. **NO activates guanylyl cyclase that increases the production of cGMP,** which is a potent vasodilator. The drugs that inhibit the breakdown of cGMP such as tadalafil, vardenafil and sildenafil are very useful in the treatment of erectile dysfunctions.

**Impotency**

Impotency is the erectile dysfunction in males. It is the inability to keep the penis adequately erected to be penetrated into the female genital tract.

1. **Erectile dysfunction** (ED) or impotence is sexual dysfunction characterized by the inability to develop or maintain an erection of the penis during sexual activity in humans.
2. It can temporarily happen due to psychosocial disturbances or acute illness.
3. But it can regularly happen due to physical problems and neural deficits that causes deficit in sexual reflexes.
4. Now-a-days it can be treated by use of Viagra (Clinical Box 71.1)

Clinical Box 71.1

Use of Viagra: Spinal cord diseases, peripheral neuropathies, spinal cord injuries, psychological trauma, chronic physical stress and aging cause erectile dysfunction. Sildenafil (Viagra) is used for the treatment of erectile dysfunction. It prevents the breakdown of cGMP by inhibiting phosphodiesterase. Thus, it potentiates the action of NO. It is used worldwide for the treatment of impotence. It produces side effects like visual problems by inhibiting cGMP specific phosphodiesterase V1 (PDE V1) in the retina, transient inability to differentiate blue and green color, and hypotension (by aggravating vasodilation). Viagra should be taken one hour before planned intercourse. However, it should not be used regularly for its known side effects.

Ejaculation

Ejaculation is the emission of semen from the male genital tract and its propulsion out of the urethra at the time of orgasm. Thus, it is a two-part reflex response: the emission and the ejaculation per se.

Emission

Normally, sperms are stored in epididymis and proximal part of vas deferens.
1. Emission is the process in which sperms move into the urethra.
2. It is a sympathetic response that occurs due to contraction of smooth muscle of vas deferens and seminal vesicles.
3. The fibers travel in hypogastric nerve.

Ejaculation

This is the propulsion of semen out of urethra at the time of orgasm.
1. This occurs due to contraction of bulbocavernosus muscle, a skeletal muscle.
2. This is a spinal reflex integrated at lower lumbar and upper sacral segments of spinal cord (L5, S1-3). The efferent fibers traverse in pudendal nerve.
3. It is proposed that the carbon monoxide (CO) is the transmitter in the neural circuit of ejaculation as evidenced from the fact that the ejaculatory performance is diminished when the gene responsible for the enzyme HO2 (heme oxygenase) is knocked out. HO2 normally catalyzes the formation of CO. Retrograde ejaculation occurs in diabetes (Application Box 71.1).

Application Box 71.1

Retrograde ejaculation: The internal urethral sphincter constricts at the time of emission. When this sphincter fails to constrict, the sperms instead of passing down the urethra enter the urinary bladder. The quantity of ejaculate decreases and sperms appear in urine (more than 15 sperms per high power field). Usually it occurs in diabetic neuropathy, multiple sclerosis and use of sympatholytic drugs.

Premature Ejaculation

Premature ejaculation (PE) occurs when a man ejaculates sooner during sexual intercourse. Though the prevalence of PE vary, as many as 1 out of 3 men say they experience this problem at some time. As long as it happens infrequently, it is of no much concern. But if it occurs often, investigations should be done to detect its cause.

The diagnostic criteria for premature ejaculation are:
1. Always or nearly always ejaculate within one minute of penetration.
2. Are unable to delay ejaculation during intercourse all or nearly all of the time.
3. Feel distressed and frustrated, and tend to avoid sexual intimacy as a result.

Causes and Treatment

Both psychological and biological factors can play a role in premature ejaculation. Although many men feel embarrassed to talk about it, premature ejaculation is a common and treatable condition.
1. Regular counseling, learning the proper sexual techniques and few medications can delay ejaculation.
2. Physical, mental and psychosocial stress must be removed.
3. As penile erection is a parasympathetic and ejaculation is a sympathetic mechanism, the male partner has to learn to delay the sympathetic activation during sex to avoid early ejaculation.
4. Therefore, practice of Yoga helps a lot to improve sex life.

FEMALE SEXUAL ACT

Normally, during sexual intercourse, female is the passive partner. However, the responses to intercourse in females are not passive.
1. The female responses are characterized by marked increase in blood flow and muscular activities in many parts of the body.
2. Increased sexual excitement is accompanied by engorgement of the breasts and erection of the nipples, increased diameter and length of clitoris due to increased blood flow into these structures.
3. Nipple and clitoris have rich sensory innervation. Therefore, clitoral and nipple stimulations during sexual act add to sexual excitement.
4. Blood flow also increases to vagina due to release of VIP from vaginal nerves and increased fluid secretion from vagina lubricates vaginal epithelium.
5. Mucous secretion is also increased from vestibular glands.

Sexual desire in women is possibly dependent on androgens, because sex drive is maintained long after the menopause, when estrogen level in plasma is very low. Therefore, it is believed that androgens secreted by the adrenal glands maintain sexual appetite in females.
Chapter 71: Physiology of Copulation

**Vaginal Changes**

Vaginal secretion increases during sexual excitement and intercourse.

1. This occurs mostly due to release of VIP from vaginal nerves.
2. **Vestibular glands** secrete mucus that also helps in lubrication.
